Abstract

The success of the urban regeneration of an entire district, where the total or partial replacement of the building is planned because it is obsolete in terms of energy, seismic and social aspects, involves the balance between different requests. The process involves the demolition of old buildings still occupied and their replacement with a new sustainable building in turn supported by the construction of new equipped public spaces. The cost of these interventions should be covered by private capital. It is therefore essential the initiative of entrepreneurs who find economic convenience in the operation. Revenues are those expected from the sale of tradable surfaces (residences or other uses) obtained as volume premiums compared to the existing or as residual with respect to the amount returned to the old residents. In fact, the latter will have to accept a new equivalent residential surface lower than the existing property. The relationship between these two surfaces for each resident owner, the new one and the old one, should at least reflect the ratio of the corresponding market values. Another actor who can play a fundamental role in the success of the regeneration intervention is the public administration. The latter in view of the collective benefits deriving from urban regeneration on the entire district and on those adjacent to it (in which no intervention is planned), should implement a series of actions aimed at favoring the process. These include the aforementioned volumetric premiums, incentives for investors and residents in terms of tax exemption. This work aims, also through an application example, to implement a model able to define the balance between the different instances in order to manage the fundamental parameters that characterize the regeneration intervention and guarantee its success.

Keywords: Urban Regeneration, Sustainability, Housing Market, Cost Effectiveness, Social Benefit.

1 INTRODUCTION

In Italy, the construction industry market has long been in a heavy crisis partly produced by external contingencies and partly also generated by the inefficiency of the administration. In particular, the absence or lack of urban planning requirements suitable for rational development has played an important role in limiting investments. This theme is combined with that of the poor condition of the building heritage of many cities, built in the post-war period and often today characterized by a high socioeconomic degradation. In turn, this condition of degradation discourages investments, thus making the spontaneous renewal of these areas much more difficult and thus contributing to strengthening social exclusion [1].

It is known, both in Italy and in Europe, the existence of a considerable percentage of residential buildings that has now exceeded the performance efficiency limit, both due to the widespread obsolescence and the lack of maintenance interventions. It is therefore necessary to identify new intervention strategies that give concrete possibilities for re-launching the sector. Sustainable urban regeneration, due to the depletion of energy resources and the poor condition of the building stock, is the priority issue in the development policies of the coming years.

The new approaches to sustainable development should favor actions aimed at limiting urban sprawl, reducing environmental impacts, curbing the consumption of new territory, by concentrating volumes in some areas against clearing out of other urbanized areas, to be transformed into services and places of aggregation, thus also relaunching a socio-economic redevelopment [2].

On the one hand, the demand from users who are now aware of the environmental problems linked to energy waste, oriented towards buildings characterized by higher quality and new technological energy standards, located in areas with adequate services, shops, meeting places, green areas and parking lots ; on the other hand, the need to limit the consumption of soil leads to thinking of regenerating already urbanized but degraded areas.

The redevelopment of real estate assets is a forced choice to guarantee citizens the quality and safety of living and to improve the social and environmental quality of degraded suburbs. It is also a great opportunity to promote local entrepreneurship employment. We therefore need policies that involve the legislative, institutional and financial framework capable of activating private capital more than the volumetric incentives done so far [3].

We need to put in place solutions capable of identifying, supporting and developing sustainability policies that balance social, environmental and economic interests.

Social sustainability, on the other hand, can be fostered through social inclusion, the coexistence of social classes with different economic capacities, through a mix of housing that has been ceded in ownership and leased with economic contributions to families.

Environmental sustainability must be pursued by means of strategies capable of acting on the transformation of urban spaces, reducing the consumption of new soil, increasing the resilience of the existing area or reducing their vulnerability to possible natural events or environmental changes.

Finally, economic sustainability can be achieved through the planning and execution of urban regeneration based on concerted and partnership forms [4]. The dissemination of negotiation practices involving private investors in the construction of social housing and in the renewal / redevelopment of the existing real estate and the use of specific financial and fiscal instruments can guarantee the success of urban regeneration processes.

This work focuses on the development of a model capable of defining a fair compromise between the different needs of the actors of an urban redevelopment program. It therefore constitutes a useful tool for defining urban planning and economic parameters capable of guaranteeing the success of the operation within a given regulatory and territorial constraints.

2 LITERATURE REVIEW AND MODEL BASES

Urban regeneration policies must address the issue taking care of the multiple dimensions involved. The definition of urban regeneration provided by Roberts and Sykes [5] emphasizes this interaction of the physical, economic and social dimensions of urban problems: "*Comprehensive and integrated vision and action which leads to the resolution of urban problems and which seeks to bring about a lasting improvement in the economic, physical , social and environmental condition of an area that has been subject to change*."

Urban regeneration interventions must go beyond physical regeneration and, although the latter is an important component, the main objectives are economic growth, the reduction of social inequalities and the increase in community cohesion [6,7,8] and environmental sustainability, through infrastructure provision and building specifications, and indirectly through making possible and incentivizing more sustainable lifestyles [9].

A process of urban regeneration also involves many subjects, existing residents and those arriving, investors and the public administration. The most important challenge in the practice of urban regeneration is to avoid imbalances in the distribution of benefits, i.e. to avoid that at the end of it there are winners and losers, to avoid that the benefits are captured by the strongest groups (external investors) and that the disadvantages instead fall on existing residents [10,11].

A response to this issue can be given by public-private partnership (PPP) and other participation mechanisms, and by the definition of long-term monitoring policies [12]. PPP attempt to build mutually beneficial cooperation between public and private partners. They facilitate the urban regeneration process because they lighten the public financial burden determined by infrastructure costs, thus transferring risks from the public to the private sector. The intervention of the latter is fundamental because it makes the process more efficient, in turn the risk that the private investor assumes is compensated by an expectation of economic return. Negotiating and organizing how risks and benefits are distributed is crucial to the success of the process.

Urban regeneration involves financial and market risks for external investors who spend time and resources on the expectation of a profit. Dedicated financing mechanisms, direct public investments, fiscal mechanisms are the possible actions of the public administration which, for this reason, assumes financial and political risks with the aim of maximizing collective well-being (social integration, economic development, environmental sustainability). Finally there are the residents who have to face difficult and risky choices.

In fact, many of them are not aware of living in buildings that are vulnerable to the earthquake [13]. It will therefore be necessary first of all to make them aware of the benefit resulting from the replacement of their old home with a new one. Although in the trade-off they will lose in quantitative terms they will gain in terms of quality, sustainability and security, while indirectly they will get the benefit of a changed and better social condition.

The challenge of this work is to try to combine the interests of public and private partners in a fair compromise.

3 THE MODEL

The hypothesis underlying the model is that the three actors, the public, the private investor and the residents are involved in a process of urban regeneration of an entire dormitory area (lack of services) in a seismic risk area. A neighborhood characterized by poor quality construction, inadequate both with regard to earthquake regulations, and those on containing energy

consumption [14,15], as well as by a consequent condition of social degradation also due to the lack of suitable infrastructures both in terms of quantity and quality.

Each of them has different needs and interests. Regeneration involves the demolition of existing residential volumes and their replacement with new buildings that are environmentally sustainable and seismically safe. The transformation process requires the private sector to take on the burden of upgrading the infrastructures and services in the neighborhood and to integrate the existing ones with new facilities and services (parking, green areas, etc.). The process involves an increase in the existing volumes as a reward to be attributed to the private investor and tax incentives for reaching the condition of convenience.

The parameters and variables involved are:

- Current Value (*start*) of the residential units (*Vs*);
- Future Value (*arrival*) that is predictable at the end of the regeneration. It corresponds to the difference in terms of cost between the two buildings (the old and the new) plus a differential to be commensurate with the increase in urban income resulting from the regeneration process (*Va*);
- Current surfaces (*start*) (*Ss*);
- Final surfaces (*arrival*) (*Sa*);

The difference *Sa*-*Ss* constitutes the premium (Δ) guaranteed by the public administration. 30% is the upper limit of Δ, considering the national and local regulations;

- New surfaces replacing the old ones assigned to residents (trade-off) (Sra);
- Demolition costs for old buildings (*Cd*);
- Total Cost of building transformation (new residences, infrastructures and services) (*Ct*);
- Tax incentives commensurate with a percentage of the cost (*Ti*).

The model involves the construction of utility functions to be maximized for each actor involved. The independent variables are subject to constraints. The aggregation of the individual functions takes place through the assignment of weights that express the contractual capacity of the different subjects in participatory programming.

All utility functions are assumed to be linear and are normalized in the range 0-1.

$$\frac{Vs}{Va} = i \quad \text{with } i < 1 \tag{1}$$

$$\text{constrain} \quad Ss \cdot i \leq Sra \leq Ss \tag{2}$$

$$Sa = Ss + \Delta \cdot Ss \tag{3}$$

$$\text{constrain} \quad 0 \leq \Delta \leq 0.30 \tag{4}$$

Amount of real estate (surface) sold by the private investor:

$$Sa - Sra = Si \tag{5}$$

Possible income of the private investor:

$$Si \cdot Va \tag{6}$$

Additional revenues (or tax deductions):

$$Ti \cdot (Cd + Ct) \ \ constrain \ 0 \leq Ti \leq Timax \tag{7}$$

3.1 Utility function of the residents (*Ur*)

Figure 1 shows the utility function of the residents, then formalized in equation (8).

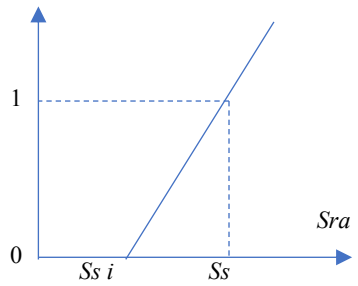

Figure 1: Utility function of the residents.

$$Ur = \frac{Sra - Ss \cdot i}{Ss \cdot (1 - i)} \tag{8}$$

The redevelopment of public spaces, affecting the quality of life of the inhabitants and their sense of belonging to places can, in fact, be a decisive factor in reducing disparities between rich and poor neighborhoods, helping to promote greater social cohesion.

However, the quantification in the utility functions of improving social welfare is excluded from this outline. The benefit is partly directed to residents and partly to the entire community (public sector).

3.2 Utility function of the public sector (*Upb*)

This utility function is associated only with the reduction of land consumption. Figure 2 shows the utility function of the public sector, then formalized in equation (9).

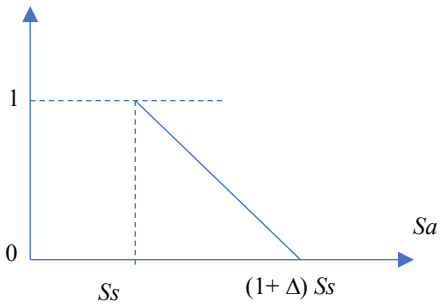

Figure 2: Utility function of the public sector.

$$Upb = \frac{Ss - Sa}{\Delta \cdot Ss} + 1 \tag{9}$$

3.3 Utility function of the private investor (*Upv*)

The investor has the goal of obtaining the maximum profit. In this scheme we assume to neglect the time dimension. Therefore, the calculation of the net present value (NPV) of urban regeneration operated only with private capital can be simplified with the expression (10), with *r* equal to the minimum expected rate of return, and *n* the time required for regeneration

$$\text{NPV}= \left[\frac{Si \cdot Va-(Cd+Ct)\cdot(1-Ti)}{(1+r)^n}\right] \tag{10}$$

The utility function, which must be normalized in the range 0-1, is constructed by calculating the maximum value of the NPV (*NPVmax*). The latter is obtained by setting the Delta and Ti equal to the maximum values (see the constraints) and the surface assigned to the residents (*Sra*) in the trade off equal to the minimum threshold (*Ss i*).

Calculating in this way the *NPVmax*, the utility function, as shown in Figure 3 and Equation (11), depends on the variables already described.

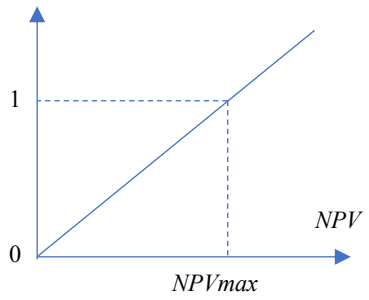

Figure 3: Utility function of the private investor.

$$Upv = \frac{NPV}{NPVmax} \tag{11}$$

3.4 Function aggregation and solution

At this point it is necessary to attribute the weights to the utility functions (ρ). Since the objective function and the constraints of the optimization problem are linear functions, then the mathematical programming problem is a linear programming problem.

$$Max\ f(Sra, \Delta, Ti) = \sum_i U_i.\rho_i \tag{11}$$

4 CONCLUSIONS

The "urban regeneration" project already contains within itself the economic resources that, with adequate financial instruments and public incentives, volumetric bonuses and European funds, can generate income and make this challenge realizable.

Through a new urban conception and, therefore, through an adequate tool, it is possible to trigger a virtuous economic flow able to recover those parts of the city, where the lack of services and the deterioration of public spaces have produced forms of tension and exclusion social. We need to implement programs that, in addition to urban and building redevelopment with the use of sustainable materials and the use of alternative energies, also favor the elimination of social problems. Because the first recipient of Sustainable Urban Regeneration must be the citizen. Also, for this reason his contribution is fundamental. It is necessary for him to become aware of the state of security of living and the patrimonial conditions of his property so that he

accepts the choice of replacing his old real estate unit in a tradeoff that would see him lose in quantitative terms but gain in qualitative terms.

To achieve this, however, the contribution of private capital is fundamental, i.e. the intervention of investors who see in these initiatives the possibility of a profit. The model presented in this research represents a tool capable of facilitating negotiation among the stakeholders, trying to outline a condition of sustainable balance between the different interests and expectations.

SEISMIC RISK MAP FOR THE ITALIAN RESIDENTIAL BUILDING STOCK

M. A. Zanini[1*], L. Hofer[1], F. Faleschini[1], K. Toska[1] and C. Pellegrino[1]

[1] University of Padova
Via Marzolo 9, 35131 Padova
e-mail: marianoangelo.zanini@dicea.unipd.it

Abstract

The paper illustrates the seismic risk maps derived for the residential building stock of Italy by using a general framework specifically set up by the authors for mapping seismic risk for a generic asset of interest. Seismic risk maps are computed taking into account a seismogenic model of the analyzed area, and properly characterizing vulnerability and exposure of an asset of interest. A risk-targeted indicator named Municipal Expected Annual Loss (MEAL) is introduced and used as suitable metric for the development of the maps, and for the subsequent seismic risk rating.

Keywords: Seismic risk map, Italy, Expected Annual Loss, Risk Reduction, Structural retrofit

1 INTRODUCTION

In the last decade, the number of significant losses following natural disasters worldwide, has been rapidly growing [1]. This is mainly due to the growing of urbanization, world population and Gross Domestic Product (GDP). This main three factors, imply a concentration of people, thus increasing the exposure of our society to natural hazards more than in the past [2]. In addition, the vulnerability of many structures and infrastructures is still high, since retrofitting and re-building are time and money consuming processes. Furthermore, in many cases the vulnerability of old structure is increased by degradation phenomena [3]. Earthquake represent one of the most destructive natural events that can significantly affect the economy of a region and lead to long-term restoration processes [4]. In particular, in Italy, several significant losses occurred in the last decades: in 2009 a moment magnitude M_w = 6.1 stroke the Abruzzo Region, in 2012 a M_w = 6.0 and M_w = 6.1 earthquake occurred in Emilia Romagna, while within the summer of 2016 and the winter of 2017 several significant seismic events with M_w = 6.0-6.5 occurred in the Central Italy area [5-6]. The rapid succession of these seismic events unavoidably ended up to weight on public financial funds. For this reason, the Italian government has recently approved specific incentives for householders interested in seismically retrofitting their properties [7]. In this way, a private citizen can take advantage of a tax relief when reducing the seismic vulnerability of his private home with structural retrofit and improvement. The reduction of structural vulnerability is the most immediate way for addressing the problem of the seismic risk mitigation. Nowadays seismic risk evaluation is a well-known and established procedure, mostly applied for the risk assessment of punctual structures or spatially distributed portfolio of structures [8-9]. The use of this procedures is then commonly extended for a quantitative assessment of seismic risk at regional level. In this case, a multidisciplinary approach is needed for fully describing the seismic activity of the region of interest, its vulnerability distributions, and the associated exposure. In particular, the development of seismic risk maps is the key point when dealing with the seismic risk assessment at territorial level, since they provide a quantitative representation of the current risk and are a fundamental tool for computing the benefit associated to the structural retrofit. Their use is thus needed when dealing with the design of possible sustainable risk reduction programs at regional and national scale. In scientific literature, several authors investigated issues related to the computation of seismic risk maps. In 2000, Musson [10] proposed a framework the seismic risk assessment at regional level adopting as reference measure the EMS-98 scale [11], and highlighting the significant difference between hazard and risk curves. In Germany, Tyagunov et al. [12] developed a risk map based on the EMS-98 macroseismic intensity, in which they computed the mean damage ratio and losses for the German residential building stock. Worldwide, Zhongchun et al. [13] computed the seismic risk mortality map for the Chinese state, Huttenlau and Stotter analyzed the seismic risk of the Austrian Province of Tyrol [14], and Frolova et al. showed different approaches for the seismic risk computation in Russia, basing on the different extension of the considered area [15]. Regarding Italy, some first works adopting the MCS intensity scale for representing the seismic hazard and damage probability matrices can be found in [16-17-18]. Recently, researcher focused their attention on the development of more detailed fragility functions [19] and seismic risk maps, adopting quantitative intensity measures for the ground shaking, as the Peak Ground Acceleration (PGA). In 2011, Rota et al. [20] developed typological seismic risk maps for Italy, by simply convolving hazard, in terms of PGA, and vulnerability expressed by empirical typological fragility curves derived from data collected during post-earthquake survey after the main Italian events of the past 30 years. In [20], authors did not included exposure, due mainly to the lack of data. The

contribute of exposure has been considered by Asprone et al. 2013 [21], who computed a possible seismic insurance premium for five different types of building categories within all the Italian territory, starting from the Italian seismic hazard map. In the last few years, the OpenQuake engine [22] has been adopted for developing maps of losses conditioned on ground motion with a specific return period, for Portugal [23], Nepal [24] and Turkey [25]. In these latter cases, the OpenQuake engine has been used with the s-called PSHA-approach, consisting in the calculation of the loss exceedance curve starting from the output of the hazard analysis, coupled with vulnerability and exposure. Literature review, showed as the computation of seismic risk maps is mainly subdivide into two main steps, the hazard computation, and then the risk estimation starting from hazard outputs. For this reason, this work proposes a novel-approach for computing the Italian seismic risk map for the residential building stock, directly starting from simulation of earthquake scenario consistent with the national seismogenic source model. This paper adopts as seismic synthetic risk indicator the Expected Annual Loss (EAL) that represents the potential economic loss to be yearly sustained to repair the seismic damage to the residential building asset of each Italian municipality. EAL is computed at three different levels of granularity, i.e. the most detailed municipal level (Municipal Expected Annual Loss, MEAL), the intermediate provincial level (Provincial Expected Annual Loss, PEAL), and the less refined regional level (Regional Expected Annual Loss, REAL), accordingly with the cogent administrative subdivision of Italy.

2 SEISMIC RISK COMPUTATION FRAMEWORK

The computation of the seismic risk in each municipality, and concretely the EAL estimation, requires a set of suitable models able to represent the spatial distribution of the hazard and the exposure, and the all the possible structural classes of the considered buildings assets.

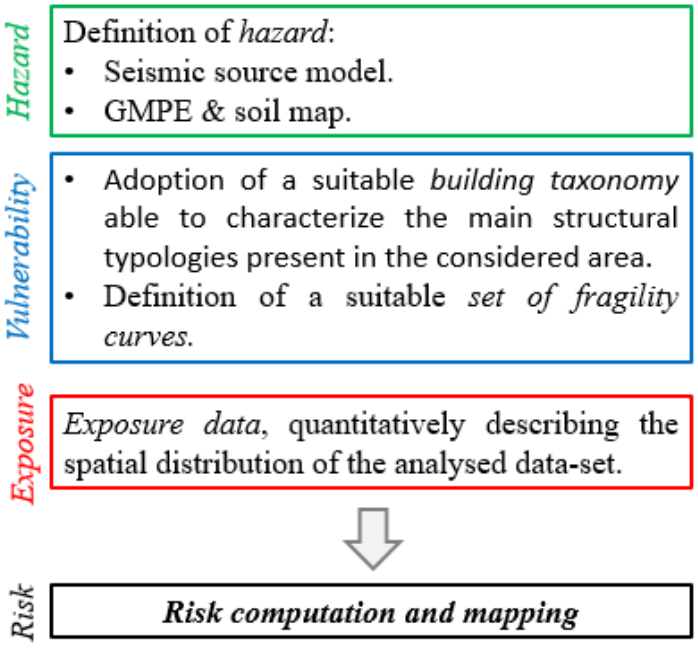

Figure 1: Main steps of the proposed framework

Figure 1 shows the main steps for the *MEAL* computation, whose input data are:

- Seismic source model represented by a set of *s* seismogenic zones (ZSs). Each ZS is characterized by a specific spatial shape, and by a Gutenberg–Richter law representing the seismogenic potential of the considered ZS. Furthermore, a suitable Ground

Motion Prediction Equation (GMPE) has to be adopted for the computation of the shaking field, jointly with a soil map representing the shear wave velocity in the first 30 m soil-depth ($v_{s,30}$);

- A building taxonomy able to represent all the structural typologies that are present in the considered area. Each of the *p* taxonomy classes (TCs) is characterized by common seismic vulnerability features. Formally, each TC is characterized by a set of fragility curves able to express the exceedance probabilities of a set of *q* mutually-exclusive and collectively-exhaustive damage states (DSs). Commonly, fragilities are derived analytically via the use of structural models [26], or empirically, starting from evidences of structural damage due to occurred earthquakes [27].
- Exposure data: they have to provide the spatial distribution of the analysed asset. In particular, exposure data provides the built area of each *p* taxonomy class, for every municipality.

The first passage consists in the creation of a grid of *e* epicenter, and in the definition of a set of *m* magnitude values between $M_{w,min}$ and $M_{w,max}$ for each i^{th} SZ, with $t=1\ldots s$. Earthquakes scenario analysis have thus to be run in every x^{th} municipality centroid ($x = 1 \ldots n$), for every j^{th} epicenter ($j = 1\ldots e$) and for every k^{th} ($k = 1 \ldots m$) magnitude, belonging to each i^{th} SZ ($i = 1 \ldots s$). By using the GMPE it is possible to compute the correspondent value of the adopted intensity measure *IM*, in each x^{th} municipality, namely $IM_{x,k,j,i}$, and consequently the associated total losses $L_{x,k,j,i}$ as sum of direct losses over the *p* TCs

$$L_{x,k,j,i} = \sum_{y=1}^{p} L_{x,k,j,i,y} \tag{1}$$

where $L_{x,k,j,i,y}$ can be computed as

$$L_{x,k,j,i,y} = RCR_{Tot,y,x,k,j,i} \cdot A_{y,x} \cdot URC_y \tag{2}$$

In Equation (2), $A_{y,x}$ represents the built area of the y^{th} TC in the x^{th} municipality, URC_y is the unit repair cost for the y^{th} TC (in €/m^2), and $RCR_{Tot,y,x,k,j,i}$ is the total repair cost ratio of the y^{th} TC, that can be computed as

$$RCR_{Tot,y,x,k,j,i} = \sum_{z=0}^{q} P\left[DS_{z,y} \mid IM_{x,k,j,i}\right] \cdot RCR_{z,y} \tag{3}$$

where $RCR_{z,y}$ are a set of repair cost ratios (i.e., ratio between unit cost to repair a building in a specific damage state and the unit replacement cost), assumed deterministic and homogeneous for each y^{th} TC. In Equation (3), $P\left[DS_{z,y} \mid IM_{x,k,j,i}\right]$ is computed as

$$P\left[DS_{z,y} \mid IM_{x,k,j,i}\right] = P\left[DS_{z,y} \mid \geq ds_{z,y} \mid IM_{x,k,j,i}\right] - P\left[DS_{z+1,y} \mid \geq ds_{z+1,y} \mid IM_{x,k,j,i}\right] \tag{4}$$

and assuming $P[DS_{0,y} \geq ds_{0,y} \mid IM_{x,k,j,i}] = 1$ and $P[DS_{5,y} \geq ds_{5,y} \mid IM_{x,k,j,i}] = 0$.

The damage state exceedance probability of the z^{th} DS for the y^{th} TC, in each x^{th} municipality centroid, in computed via fragility curves as

$$P\left[DS_{z,y} \geq ds_{z,y} \mid IM_{x,k,j,i}\right] = \Phi\left[\frac{1}{\sigma_{DS_{z,y}}} \ln\left(\frac{IM_{x,k,j,i}}{\mu_{DS_{z,y}}}\right)\right] \quad (5)$$

At this stage, for each x^{th} municipality a set of e losses caused by each k^{th} magnitude, generated by the i^{th} SZ is available. This vector of data represents the probability density function (*pdf*) of direct losses conditioned on the specific magnitude value k^{th}. From this samples, is thus straightforward to compute *ad hoc* statistics, as the sample mean, representing the distribution expected value, and other percentile of interest (25th, 50th, 75th ecc). In the following the paper assumes the mean value as relevant statistic, namely $L_{x,k,mean,i}$. The final step of the proposed procedure consists in the computation of the $MEAL_{x,mean,i}$ in each x^{th} municipality due to losses cause by the i^{th} SZ. This calculation can be performed according to Figure 2 by associating to each $L_{x,k,mean,i}$ the corresponding mean annual rate $\nu_{k,i}$ of exceeding a certain moment magnitude $M_{k,i}$ in the i^{th} SZ, and applying the total probability theorem. $\nu_{k,i}$ can be easily computed from the Gutenberg-Richter (GR) recurrence law, given by the following expression

$$\log\left(\nu_{k,i}\right) = a_i - b_i \cdot M_{k,i} \quad (6)$$

where a_i is the total seismicity rate and b_i is the negative slope of the GR law for the i^{th} SZ. The expected annual loss, in the x^{th} municipality, due to seismicity arising from the i^{th} SZ is thus given by

$$MEAL_{x,mean,i} = \int_0^{\nu_{M_{\min,i}}} L_{x,mean,i}\left(M\right)\left|d\nu_{M,i}\right| \quad (7)$$

As Figure 2 shows, two additional points are introduced for the computation of Eq. (7), consistently with the following assumption:

- A minimum magnitude value $M_{min,i}$ is assumed for each zone, aiming to remove small events characterized by negligible impacts in terms of structural damage and thus losses. For this reason, earthquakes with magnitudes lower than $M_{min,i}$ are associated to zero loss;
- Since every zone, basing on its seismological characteristics, is characterized by a maximum magnitude $M_{max,i}$, the loss exceedance curve is truncated in correspondence of $M_{max,i}$, excluding in this way from the computation higher impossible losses.

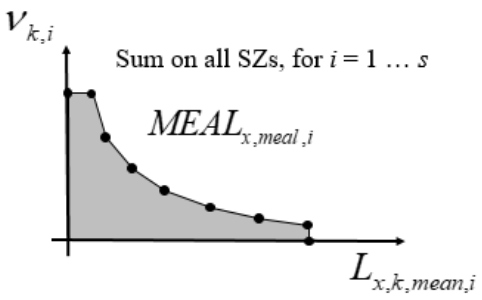

Figure 2: MEAL computation.

The MEAL considering the contribution of every SZ determining the seismicity of the considered x^{th} municipality, can be computed by simply adding each contribution as:

$$MEAL_{x,mean} = \sum_{i=1}^{s} MEAL_{x,mean,i} \tag{8}$$

Once the $MEAL_{x,mean}$ is computed for each n municipalities, results can be mapped thus obtaining the seismic risk map. Since $MEAL_{x,mean}$ is strongly influenced by the exposure, it is possible to refer the $MEAL_{x,mean}$ to the build surface in each municipality, i.e. the $MEAL_{x,mean}$ for 1 m^2 of built area in each x^{th} municipality, obtaining in this way the $UMEAL_{x,mean}$ as:

$$UMEAL_{x,mean} = \frac{MEAL_{x,mean}}{\sum_{y=1}^{p} A_{y,x}} \tag{9}$$

Finally, a dimensionless indicator is introduced to easily rank seismic risk throughout a country, i.e. the Municipality Seismic Risk Class (*MSRC*, in % of replacement cost), estimated as:

$$MSRC_{x,mean} = \frac{UMEAL_{x,mean}}{URC_y} \tag{10}$$

The same three risk indicators can be easily computed also for different granularity levels, as the provincial and regional level. The development of a seismic risk map is therefore a key-starting point for the definition of a rational seismic mitigation program for a country, since it allows government to understand needs and priorities, and compare resulting benefits with costs associated to the implementation of specific seismic retrofitting schemes [28].

3 APPLICATION TO ITALY

The proposed framework is applied to compute the seismic risk map for the residential building stock of Italy, considering as target losses the reconstruction cost of damaged structural elements (i.e. the so-called *direct losses*). However, the framework is general and flexible and can be applied to different target losses, as losses due to business interruption [29], losses due to failure of spatially distributed networks [30-31], or losses arising from different natural hazards [32], for which the same conceptual scheme can be applied.

3.1 Hazard model

The ZS9 model [33] has been adopted for describing the Italian seismicity; parameters of the GR law for each i^{th} SZ are taken from [34] and the values showed in Figure 3. In particular, a 5-km mesh grid of epicenters is adopted, for a total of 7237 points. Sardinia has not been considered in the computation, since the ZS9 model does not provide SZs for this region.

Regarding the GMPE model, the formulation proposed by Bindi et al. [35] is adopted, jointly with the $v_{s,30}$ soil map provided by the United States Geological Survey (USGS) [36]. Finally, for each i^{th} SZ a total of m = 6 magnitudes between $M_{min,i}$ and $M_{max,i}$ have been adopted.

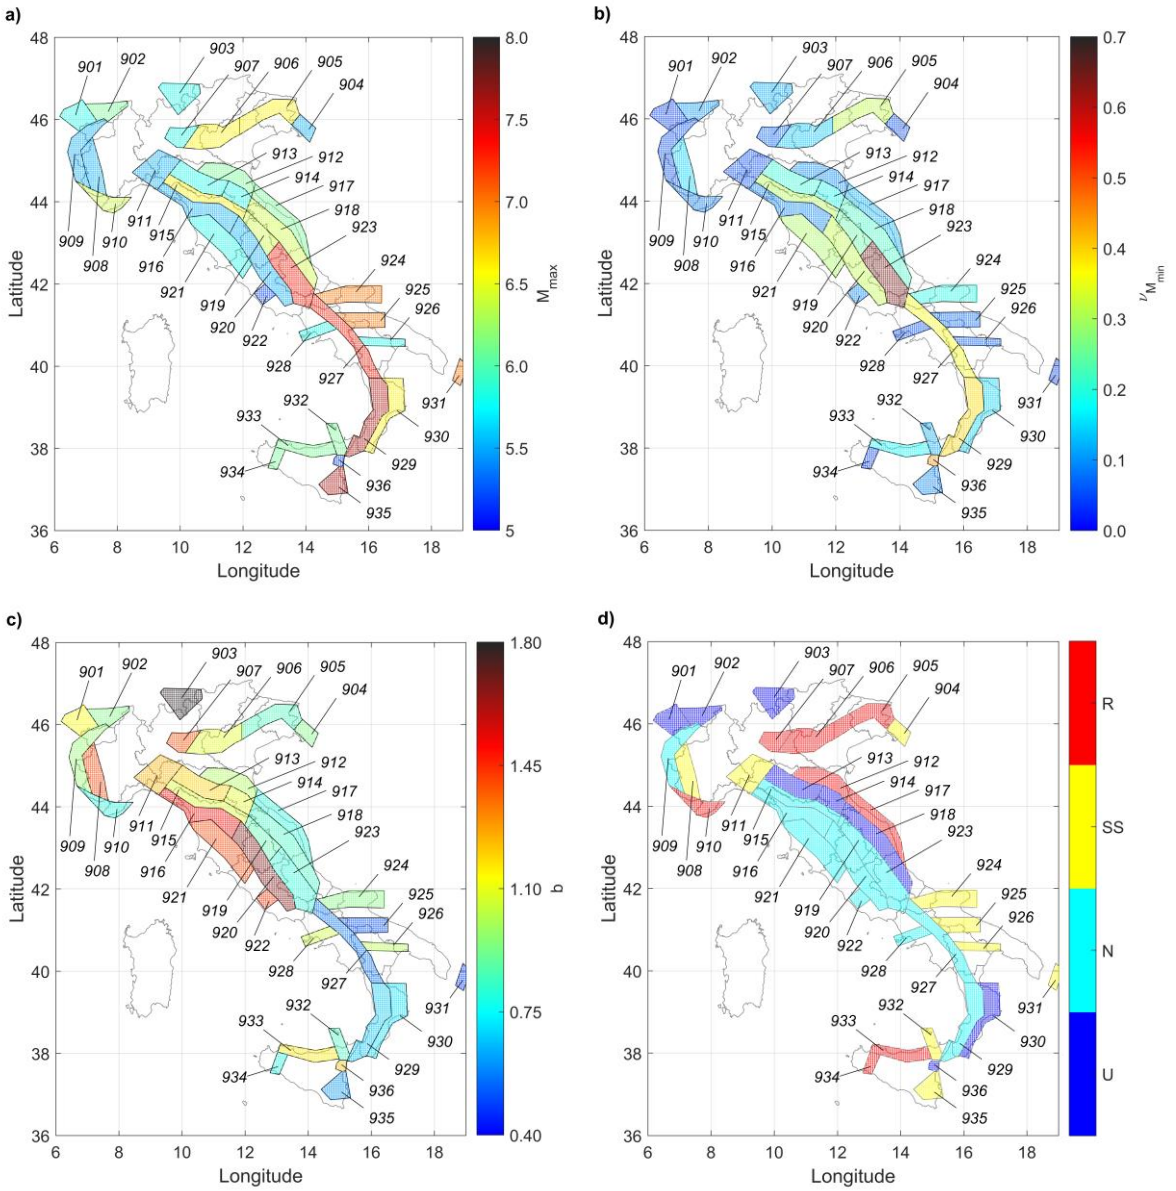

Figure 3: Seismogenic source model: M_{max} (a) and $\nu_{M_{min}}$ (b) values, G-R *b* coefficients, and d) prevailing mechanism of faulting for each SZ (U = undetermined, N = normal, SS = strike-slip, R = reverse).

3.2 Vulnerability Model

For characterizing the seismic vulnerability of the analyzed building stock, a suitable building taxonomy has been adopted. In particular, 8 TC classes have been adopted for representing the residential building stock of Italy, each one characterized by a set of fragility curves related to four mutually exclusive and collectively exhaustive damage states (i.e. DS_1, DS_2, DS_3, DS_4 respectively related to slight, moderate, extensive and complete damage), according to [37]. Two masonry classes have been adopted for characterize masonry buildings, according to Kostov et al. [38]: masonry building built before 1919, and after 1919. As regards reinforced concrete (RC) structures, the first important distinction is between gravity load designed and seismic load designed. The subdivision for each municipality between the two classes, have been performed by using the ECS-IT software which provide the temporal

evolution of the Italian seismic code in each municipality [39]. Moreover, since the census data is classified per decade (i.e. in 1971, 1981, and 2001), a linear variation with time was assumed in order to bridge the gap between the milestone years marking the code evolution and the census ten-year classification. A further subdivision has also been performed both for RC-gravity and RC-seismic buildings, considering the number of stories and thus defining two additional subclasses (1-2 story, 3 or more stories). Fragility parameters for the four reinforced concrete TCs have been taken from Ahmad et al. [40]. Finally, two TCs have been considered representative of "other" mixed structural types, particularly combined RC-masonry, again subdivided in gravity-load and seismic-load designed, with the same approach adopted for RC classes [35]. All main parameters of the adopted fragilities are listed in Table 1.

Taxonomy Class	Damage State	$\mu_{DS_{z,y}}$ [g]	$\sigma_{DS_{z,y}}$
Masonry – pre 1919	DS_1	0.10	0.79
	DS_2	0.14	0.80
	DS_3	0.17	0.81
	DS_4	0.24	0.80
Masonry – post 1919	DS_1	0.12	0.79
	DS_2	0.17	0.81
	DS_3	0.19	0.79
	DS_4	0.33	0.79
RC - Gravity | 1-2	DS_1	0.09	0.33
	DS_2	0.12	0.44
	DS_3	0.25	0.37
	DS_4	0.33	0.36
RC - Gravity | 3+	DS_1	0.08	0.32
	DS_2	0.11	0.43
	DS_3	0.17	0.40
	DS_4	0.22	0.38
RC - Seismic | 1-2	DS_1	0.09	0.33
	DS_2	0.12	0.44
	DS_3	0.24	0.37
	DS_4	0.48	0.36
RC - Seismic | 3+	DS_1	0.08	0.32
	DS_2	0.11	0.41
	DS_3	0.17	0.39
	DS_4	0.31	0.36
Other - Gravity	DS_1	0.11	0.79
	DS_2	0.16	0.78
	DS_3	0.27	0.78
	DS_4	0.35	0.79
Other - Seismic	DS_1	0.12	0.79
	DS_2	0.19	0.79
	DS_3	0.30	0.79
	DS_4	0.41	0.79

Table 1: Main parameters of fragility curves for each TC and DS.

3.3 Exposure Model

The exposure of the national residential building is based on the 15th census database of the National Institute of Statistics [41], from which the built area of each TC has been computed, as in [34]. The unit repair cost has been assumed constant among the eight TCs and equal to 1200 €/m^2. Figure 3a shows the total build area in each municipality, while Figure 3b shows the exposed value. Regarding, the percentage disaggregation of the TCs, Figure 3c shows that masonry structures are the most diffused structural typology within all the Italian municipalities. Regarding the $RCR_{z,y}$, they have been assumed constant among the TCs and equal to [0.15, 0.40, 0.65, 1], respectively for DS_1, DS_2, DS_3 and DS_4, resulting from statistical post-processing of rough data [42].

3.4 Seismic Risk computation

For the *MEAL* computation the expected value of the loss distribution *f(L|M)* has been assumed as reference statistic. *EAL* is computed first at municipality level (*MEAL*), and then aggregated for obtaining the *EAL* at provincial level (*PEAL*), and the EAL at regional level (*REAL*), according to the administrative subdivision of Italy.

Figure 4 shows results for the three adopted granularity levels. In particular, it is worth to note as in this case the risk maps in terms of absolute EAL are highly influenced by the spatial distribution of the exposure. The contribution of each SZ to the *EAL* of each municipality can be found in Zanini et al. [43].

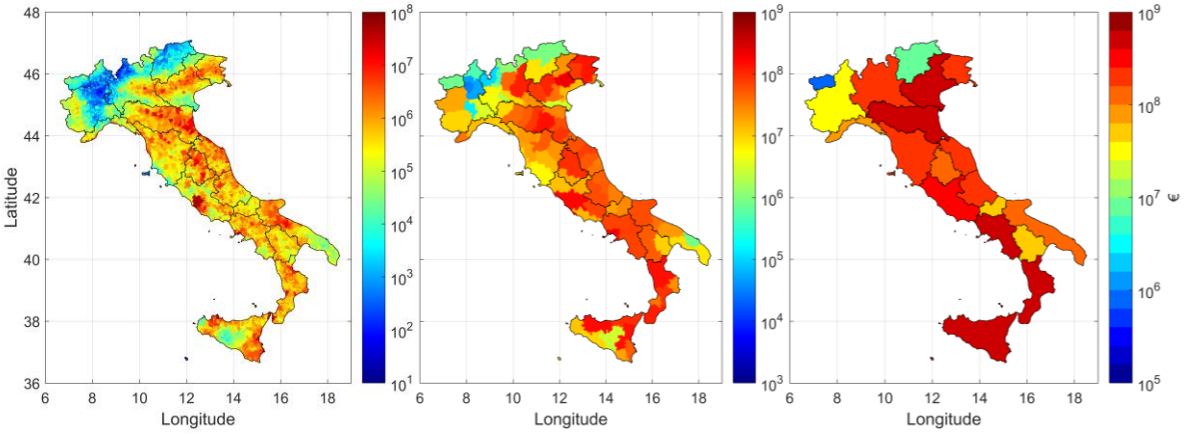

Figure 4: The seismic risk map of Italy in terms of MEAL (left), PEAL (center), REAL (right).

The same maps can therefore be expressed in relative terms using the following unitary metric, the *UMEAL* (i.e. the *MEAL* for 1 m^2 built area in each municipality, in €/m^2), the *UPEAL* (i.e. the *PEAL* for 1 m^2 built area in each province, in €/m^2), and the *UREAL* (i.e. the *REAL* for 1 m^2 built area in each region, in €/m^2). *UMEAL*, *UPEAL* and *UREAL* map, showed in Figure 5, allows to better detail the effective spatial distribution of seismic risk, since they represent risk in relative terms, and can be used as a basic metric when dealing with defining insurance coverage schemes.

In particular, Figure 5 shows the beneficial effect of computing seismic risk at higher granularity levels than respect to the more refined municipal level. Indeed, the maximum amount of *UMEAL* of 17-18 €/m^2 drops to 5-6 17-18 €/m^2 for *UPEAL* and *UREAL*. Previous risk maps reported in Figure 4 and Figure 5, detail seismic risk of Italy quantifying in economic terms its impact: such risk maps are therefore relevant for stakeholders (e.g. government, research institutes, insurance, industry, banks).

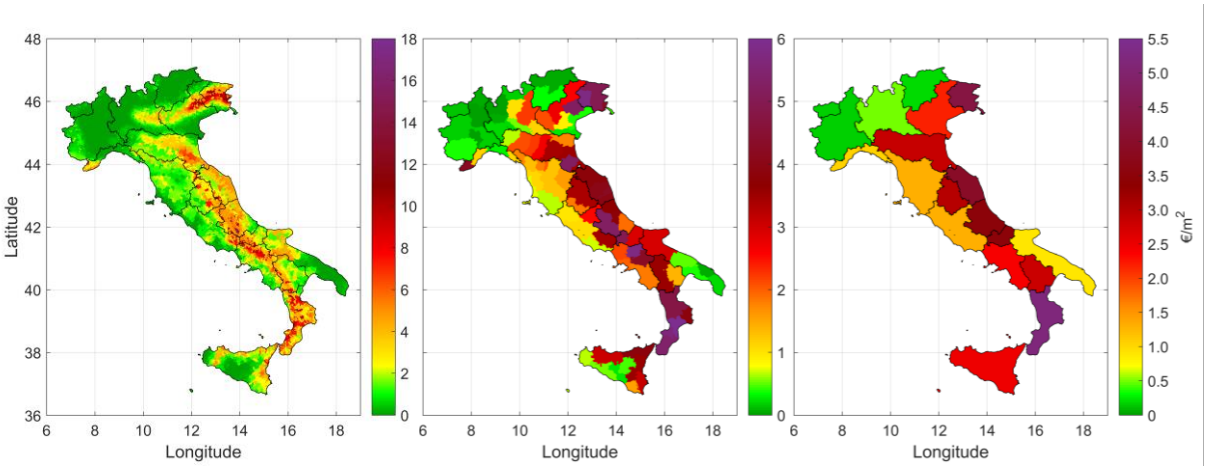

Figure 5: The seismic risk map of Italy in terms of *UMEAL* (left), *UPEAL* (center), *UREAL* (right).

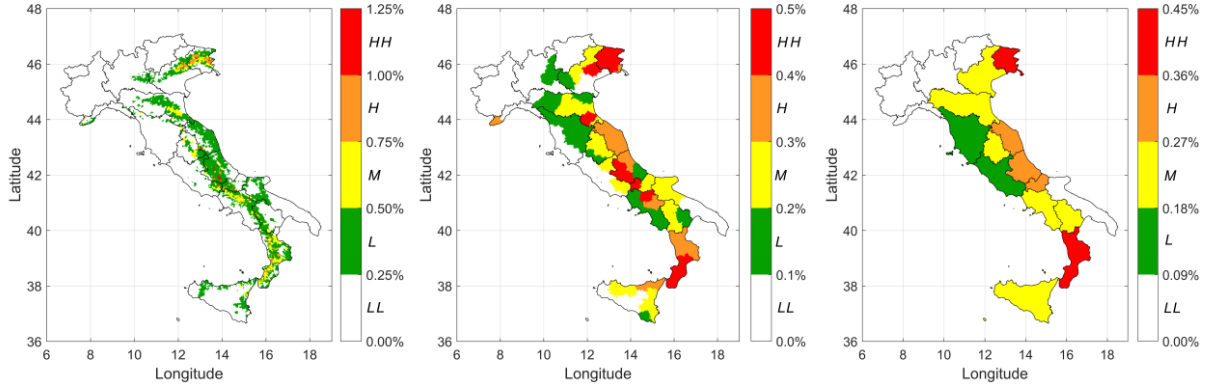

Figure 6: The seismic risk map of Italy in terms of *MSRC* (left), *PSRC* (center), *RSRC* (right).

A qualitative and dimensionless seismic risk indicator can be obtained from the ratio between *UMEAL* and the *URC* value, namely the Municipality Seismic Risk Class (*MSRC*). The same calculation can be performed also at provincial level, obtaining the Provincial Seismic Risk Class (*PSRC*), and at regional level (*RSRC*, Regional Seismic Risk Class).

For all three different granularity levels the range between 0 and the correspondent maximum value, has been subdivided in 5 classes, finding five different risk levels: Very Low Seismic Risk (*LL*), Low Seismic Risk (*L*), Medium Seismic Risk (*M*), High Seismic Risk (*H*), and Very High Seismic Risk (*HH*). Table 2 shows the range on each class for the three granularity levels, while Figure 5 show the *MSRC*, *PSRC* and *RSRC* map.

	LL	*L*	*M*	*HH*	*HH*
MSRC [%]	0.00 - 0.25	0.25 - 0.50	0.50 - 0.75	0.75 - 1.00	1.00 - 1.25
PSRC [%]	0.00 - 0.10	0.10 - 0.20	0.20 - 0.30	0.30 - 0.40	0.40 - 0.50
RSRC [%]	0.00 - 0.09	0.09 - 0.18	0.18 - 0.27	0.27 - 0.36	0.36 - 0.45

Table 2: *MSRC*, *PSRC* and *RSRC* range values for the adopted seismic risk ratings.

4 CONCLUSION

Seismic risk maps are a key tool for public authorities of countries prone to significant losses due to earthquakes, for developing suitable seismic risk transferring solutions. The described formulation deals with this specific topic, proposing an overall framework for computing the seismic risk and introducing some useful risk indicators. In particular, an application to the Italian residential building stock is reported and seismic risk maps for Italy are computed. For this scope, a detailed hazard, vulnerability and exposure models are assumed. Seismogenic zones are used for representing the seismicity of Italy, while eight taxonomy classes are assumed for describing the different vulnerability of the residential Italian buildings. The Expected Annual Loss is used as suitable risk indicator, representing the yearly amount that has to be save for facing possible significant future losses. In the application, *EAL* computation is performed at three granularity levels, municipal (*MEAL*), provincial (*PEAL*), and regional level (*REAL*). Results showed as this first risk indicator, in the Italian case, is strictly related to the exposure. Seismic risk maps have been computed also in terms of *UMEAL*, *UPEAL* and *UREAR*, that represent each municipal, provincial and regional *EAL* referred to the corresponding built area of each municipality, province and region. Results show as considering less refined granularity has an averaging effect on the risk computation. Finally, adimensional seismic risk maps have been computed and used for providing qualitative and immediate risk maps of Italy. Resulting maps depict national seismic risk spatial distribution, thus providing reliable information to government agencies, which can promote specific mitigation intervention at the territorial scale to reduce the impact of future earthquakes in the areas mostly. Risk maps are a fundamental tool for knowing the current exposure to seismic risk of a wide territory, and provide a quantitative tool for evaluating the benefit associated to a possible national retrofit scheme, and for designing possible sustainable financial risk reduction programs.

Abstract

This paper gives the methodology to get the floor response spectra of the buildings on the base of the results of the probabilistic assessment. On the base of the geophysical and seismo-logical monitoring of locality the peak ground acceleration and the uniform hazard spectrum of the acceleration was defined for the return period 10 000 years. The algorithms to generate a synthetic ground motion accelerogram compatible with a response spectrum are described. The methodology of the seismic resistance of the cable support structures are presented. The experimental and numerical analysis of the seismic resistance of the technology structures are discussed.

Keywords: Structural Dynamics, Earthquake Engineering, Safety, Technology, NPP, ANSYS.

1 INTRODUCTION

The earthquake resistance analysis of NPP (Nuclear Power Plant) buildings in Mochovce were based on the recommends of IAEA (International Agency of Energy Atomic) in Vienna to get international safety level of nuclear power plants [1]. Three logical possibilities of the source zones were defined for Mochovce site – contact of Eastern Alps and Western Carpathians, Dobra Voda and alternative fault. The seismic load was defined by PGA (Peak Ground Acceleration) and local seismic spectrum in dependence on magnitude and distance from source zone of earthquake [2, 3]. Two principal methods are appropriate for assessing the seismic safety of facilities, the SMA (Seismic Margin Assessment) method and the SPSA (Seismic Probabilistic Safety Assessment) method [3, 4]. The RLE (Review Level Earthquake) is very effective method to reevaluation of NPP safety then the new seismic hazard is defined. The SMA methodology is based on the RLE determination. The first seismic reevaluation of the seismic hazard of the Mochovce site was established on the deterministic method and seismic-tectonical consideration of the Mochovce site was analyzed on the base of probabilistic method. The design response spectra were prepared based on results of the PSHA (Probabilistic Seismic Hazard Analysis) study for the NPP Mochovce site developed by GFÚ SAV [4].

Basic parameters of the design GRS (Ground Response Spectrum) are as follows [2]:

- Spectral shape MDE (SL-2) (Maximum Design Earthquake) corresponds to 84% NEP (Non Exceedence Probability) (i.e. median + 1 sigma);
- Seismic event with annual recurrent frequency 10^{-4};
- PGA for horizontal direction $PGA_H = 0.150$ g;
- PGA for vertical direction $PGA_V = 0{,}100$ g;
- Vertical response spectra

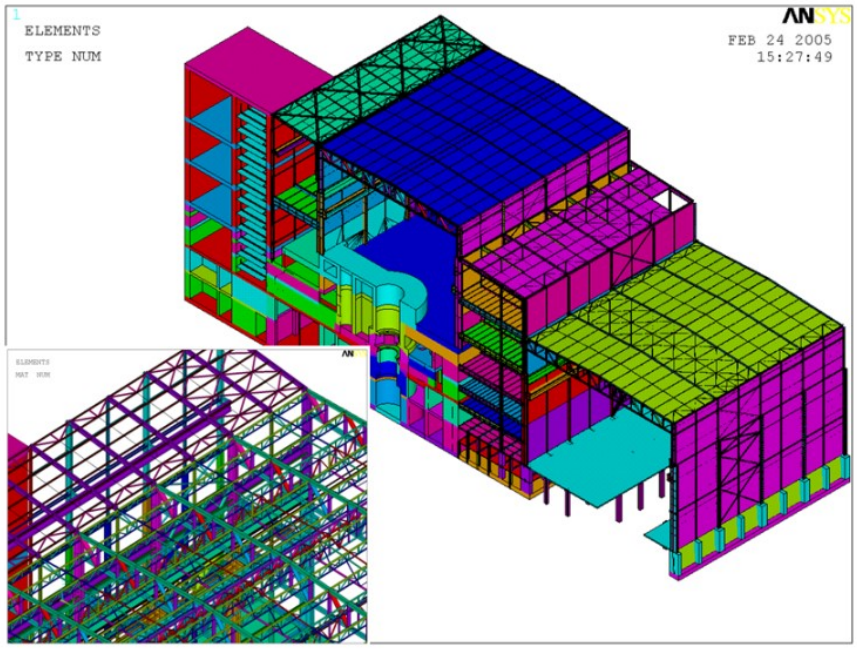

Figure 1: Calculation model of NPP V2.

Firstly the value of PGA was defined at 1994 (PGA_{RLE}=0,1g) follow in accordance of the results of seismological monitoring this locality at 2003 (PGA_{UHS}=0.142g and

PGA_{HS}=0.143g). The last PGA for horizontal direction was defined as PGA_{HS} = 0.150 g on base of the seismic-tectonic investigation of Mochovce NPP site.

The Mochovce NPP structures are typically the same as the NPP structures for reactor VVER 440. Around of the reinforced concrete structures of the box SG and bubbler tower are the steel structures of the reactor hall, longitudal and transversal electrical buildings are built. The calculation model of NPP structures (Fig.1) created by VUT Brno [5] and modified by STU Bratislava has 161 856 elements and 135 629 nodes [2]. The foundation of the reactor building is embedded into the rock subsoil.

2 SEISMIC EVALUATION METHODOLOGY

To provide input excitations to structural models for sites with no strong ground motion data, it is necessary to generate synthetic accelerogram. It has long been established that due to parameters such as geological conditions of the site, distance from the source, fault mechanism, etc. different earthquake records show different characteristics [6 - 9].

The program COMPACEL was created by J. Králik [2] to generate synthetic accelerograms. The methodology of structure resistance verification is elaborately described in [1 - 4]. There are illustrated the procedures, requirements and criterion of calculation models and methods for design of structure reliability. There are two principal methodology available for seismic design of NPP structures - deterministic (SMA- seismic margin assessment) and probabilistic (SPRA – seismic probabilistic risk assessments). The CDFM method is very similar to the design procedure followed in the industry, except that the parameter values have been liberalized. The objective of seismic margin assessment (SMA) is to determine for a nuclear power plant the high-confidence-of-a-low-probability-of-failure (HCLPF) capacity for a pre-selected seismic margin earthquake (SME), which is always chosen higher than the design basis input. In probabilistic terms, the HCLPF is expressed as approximately a 95% confidence of about a 5% or less probability of failure.

Based on Kanai's investigation regarding the frequency content of different earthquake records [7], Tajimi proposed the following relation for the spectral density function of the strong ground motion with a distinct dominant frequency

$$S(\omega) = \frac{\left[1 + 4\xi_g^2 \left(\omega/\omega_g\right)^2\right]}{\left[1 - \left(\omega/\omega_g\right)^2\right] + 4\xi_g^2 \left(\omega/\omega_g\right)^2} S_0 \tag{1}$$

Here ξ_g and ω_g are the site dominant damping coefficient and frequency, and S_0 is the constant power spectral intensity of the bedrock excitation. The Kanai-Tajimi power spectral density function may be interpreted as corresponding to an "ideal white noise" excitation at the bedrock level filtered through the over-laying soil deposit at site [7].

3 ACCEPTABLE EVALUATION METHODS

For seismic analyses of structures and technological equipment, following methods are acceptable [2, 7 - 9]:

- Response Spectrum Modal Analysis Method – RSMAM,
- Methods of direct time integration of the motion equations system (Linear Time History Method – LTH and Non-linear Time History Method – NTH are discerned),
- Equivalent Static Method – ESM (or also “approximate equivalent static seismic loads method”).

The equivalent static seismic loading method is used in cases when a structure or an equipment component is, in the viewpoint of the mechanics, a simple single-degree of free-

dom (SDOF) or 2-degree-of-freedom (2-DOF) system and when the intention of the analysis is to determine only the seismic forces and moments in the point of anchorage to the civil structure or to perform the stress analysis in some critical cross-section (when such a simple substitution is obviously sufficient).

The spectral analysis is based on linear behavior of the structures, while damping takes into account the plastic deformations and the over thrust of friction-type connections. The response spectrum will be obtained by a combination of a response magnitudes for the individual shapes by the CQC method (considering the proximity) as follows [7]:

$$R_{CQC} = \left\{ \left| \sum_{i=1}^{N} \sum_{j=1}^{N} k.\varepsilon_{ij}.R_i.R_j \right| \right\}^2, \qquad k = \begin{cases} 1 \; ak \; i = j \\ 2 \; ak \; i \neq j \end{cases}, \qquad r = \omega_j/\omega_i, \tag{2}$$

where $\varepsilon_{ij} = \dfrac{8\left(\xi_i \, \xi_j\right)^{1/2}\left(\xi_i + r\xi_j\right).r^{3/2}}{\left[1-r^2\right]^2 + 4\xi_i \, \xi_j \, r\left(1+r^2\right) + 4\left(\xi_i^2 + r\xi_j^2\right).r^2}$ and ξ_i is the modal damping.

Overall response R_k in the cross-section k has been obtained by the envelope of combinations of responses alongside the individual excitation directions in the direction of the axes X, Y and Z.

$$R_k = \max\{R_{xk} + 0{,}4R_{yk} + 0{,}4R_{zk}\,;\; R_{xk} + 0{,}4R_{yk} + 0{,}4R_{zk}\,;\; R_{xk} + 0{,}4R_{yk} + 0{,}4R_{zk}\} \tag{3}$$

where R_{xk}, R_{yk} and R_{zk} are the responses in the cross-section k from excitation by the acceleration spectra in the direction X, Y and Z.

Test segment	Static resistance [N]	Dynamic resistance experimentally determined				
		Horizontal force [N]		Vertical force [N]		Ratio [%]
		Min	Max	Min	Max	
1A	3 000	0	1040	450	810	35
2A	12 000	0	6370	2700	4864	53
3A	11 000	0	12530	5400	9730	88

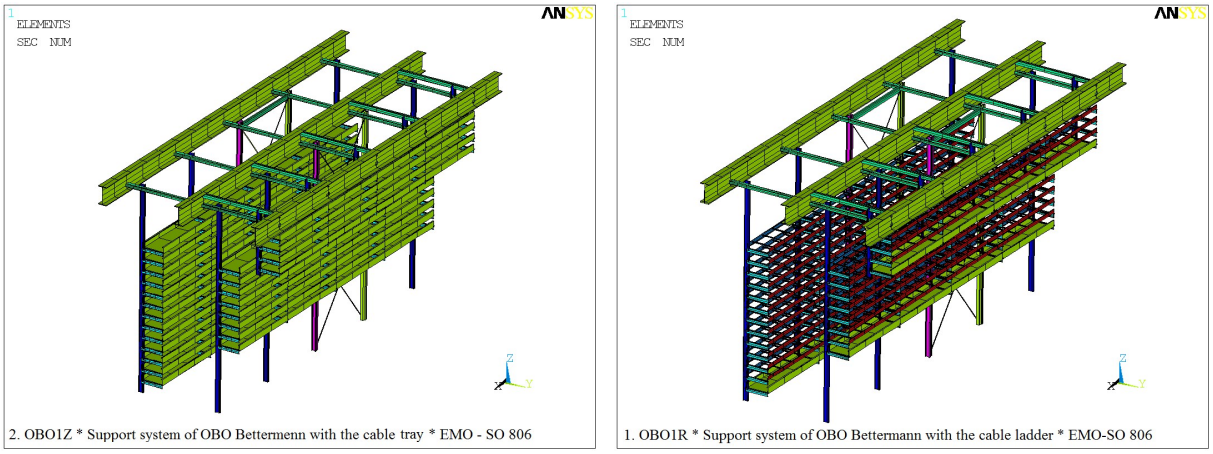
Table 1. Recapitulation of the experimental tests of OBO Bettermann segments

All tested segments were satisfied for the static and dynamic loads defined in Tab.1. In the case of the tested connection OBO2A the plastic deformation of 9mm occurred, but this connection was not damaged. This connection was not used in the final cable trays structures in NPP finally.

4 NUMERICAL ANALYSIS OF THE SEISMIC RESISTANCE

The seismic resistance of the various typical cable support structures based on OBO Bettermann segments were numerically analysed in software ANSYS (Fig.3) [1].

The principal structures was made from the columns 5xI8/3680, beams 6xUS7/1500, consoles 60xAS30/41/410 and the cable segments. These structures were used with the cable trays 48xWKSG140/1500 (OBO1Z) and the cable ladders 44xLG640N/1500 (OBO1R) (Fig.4). The seismic response was solved by the method of the seismic response spectra from the floor spectra envelope in the horizontal direction as well as vertical direction at the level of the ceiling +5,4 m; upon considering 7% damping [1] (Fig.3).



Fiure.2. Calculation models of the support structures with the cable tray EKS640 (OBO1Z) and the cable ladder LG640 (OBO1R)

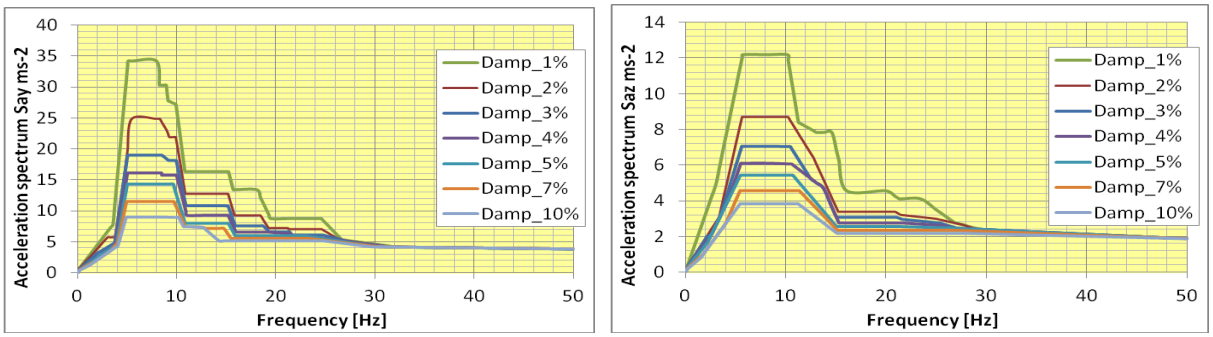


Figure 3. FRS for horizontal and vertical direction at the level of +5,4m of SO805/806

The value of the HCLPF parameter depends on the equipment structure or component resistance (R) and the corresponding effect of action (E) using elastic or inelastic behavior. Generally, it follows

$$\text{HCLPF (CDFM)} = (\text{FS})_{ep} \cdot \text{PGA}_{RLE} = \text{SL-2} \tag{4}$$

Model	f_o[Hz] in direct. X	Part. factor [%]	f_o[Hz] in direct. Y	Part. factor [%]	f_o[Hz] in direct. Z	Part. factor [%]
OBO1Z	10.27	84.8	3.88	84.3	9.64	47.3
OBO1R	0.85	58.5	2.98	76.5	8.99	67.4

Table 2. Principal eigenvalues of the OBO Bettermann structures

Model	Cable masses [kg/bm]	Column [g]	Beam [g]	Console [g]	Bracing [g]
OBO1Z	390	0.33	0.31	5.79	6.85
OBO1R	390	0.18	0.29	0.19	3.70

Table 3. Parameter HCLPF for the segments of OBO Bettermann structures

The optimal configuration of the support systems of the cable trays was determined by the acceleration peaks of FRS, which are in intervals 5-10Hz [1]. The seismic effective structures are with the principal modes out from this interval. There are presented two different conceptions of the structures. The principal frequencies of model OBO1Z and OBO1R are out of this

critical interval in direction *X* and *Y* (Tab.2). The total masses of the structure OBO1Z is equal to 19 719ton and OBO1R is equal to 22 176ton .

The seismic resistance of these support structures is determined by the lowest resistance of the structure segments (Tab.3). The minimal HCLPF parameter of the structure OBO1Z is 0.31g and the structure OBO1R is 0.18g.

5 CONCLUSIONS

This paper presented the methodology of the seismic reevaluation of NPP in Mochovce due to new results from the geological and seismic-tectonic monitoring of this site. The deterministic methodology of seismic design based on CFDM methodology was presented. The synthetic spectrum compatible accelerograms generated in program COMPACEL (created by Králik) were presented in comparison with requirements ASCE4/98 standard. The methodology of the seismic resistance of the cable support structures were described. This methodology was used for the optimal design of the cable support systems from the structural elements of OBO Bettermann experimentally tested.

Abstract

In order to estimate failure probabilities of underground structure under seismic load, probability variables should be considered in reliability analysis. Normally underground structures are applied from both vertical and horizontal loads at the same time, and have nonlinear boundary conditions, so the behavior of structure not correspond to the superposition principle. In first, in order to obtain load(L) in the limit state function(Q=R-L), member forces of underground structure applied combined loads in seismic condition are analyzed from 2D frame model, and then combined probability variables such as means and variances are determined from a new approach developed in this study. Probabilities of failure are calculated on load combinations by using MCS(Monte-Carlo Simulation) technique. As a result, from the estimation of reliability indices on load combinations, target reliability index in seismic condition are determined in order to develop a specification for limit state design of underground structures.

Keywords: Failure Probability, Underground Structures, Seismic Condition, Limit State Function, Reliability Analysis, MCS, Target Reliability Index.

1 INTRODUCTION

Recently AASHTO presented "LRFD 2017 Road tunnel design and construction guide specifications" [1], and BSI suggested "PAS 8810 - Design of concrete segmental tunnel linings - code of practice" [2]. Korea also has been developing the LSD specification for underground structures and has been researching probabilities of variables and establishing of target reliability indices.

In this study, structural analysis is performed to 2D frame model applied all of loads entirely with nonlinear boundary conditions, because analysis of underground structure not correspond to the superposition principle. In order to obtain probability variables of resistance(R) and load (L) for reliability analysis in seismic condition, existing research materials and pre-researched data are considered.

It is calculated to probabilities of failure in the limit state function through MCS (Monte-Carlo Simulation), then, probabilities of failure convert to reliability indices by function described by Nowak and Collins (2013) [3]. The analysis result in strength limit state are made out in order to compare with assessment of underground structure in the general condition, then target reliability index is suggested in final.

2 REVIEW MODEL

2.1 Modeling and Boundary Condition

In this study, the analysis model of underground structure is as shown in Fig. 1, and the model is consist of 2D frame members and nonlinear boundary conditions.

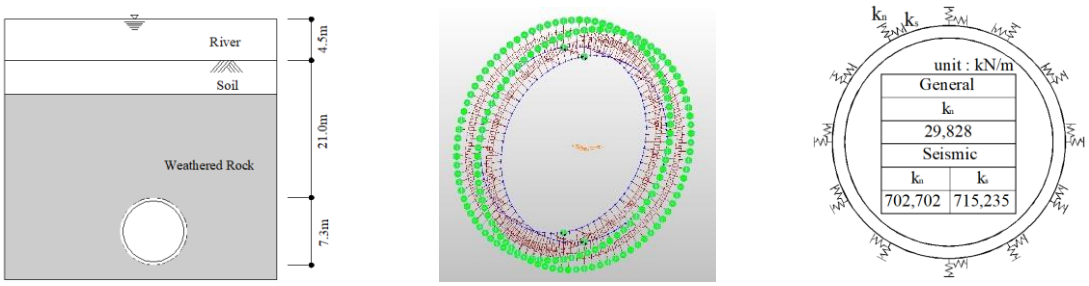

Figure 1: Analysis model of underground structure

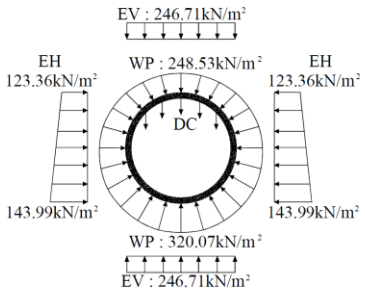
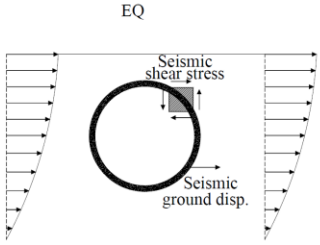
2.2 Applied Loads

The loads applied on underground structure are considered to self-weight, horizontal & vertical earth pressure, water pressure, and earthquake load as shown in Fig. 2.





Type Name		Load Cases
L1	DC	Self-weight (Dead Load)
L2	EH	Horizontal Earth Pressure
L3	EV	Vertical Earth Pressure
L4	WP	Water Pressure
L5	EQ	Earthquak Load

Figure 2: Loads applied on underground structure

3 STRUCTURAL ANALYSIS

3.1 Analysis in the General Condition

The enveloped result of load combinations in the general condition is shown as follows, the results are performed through preliminary study [4].

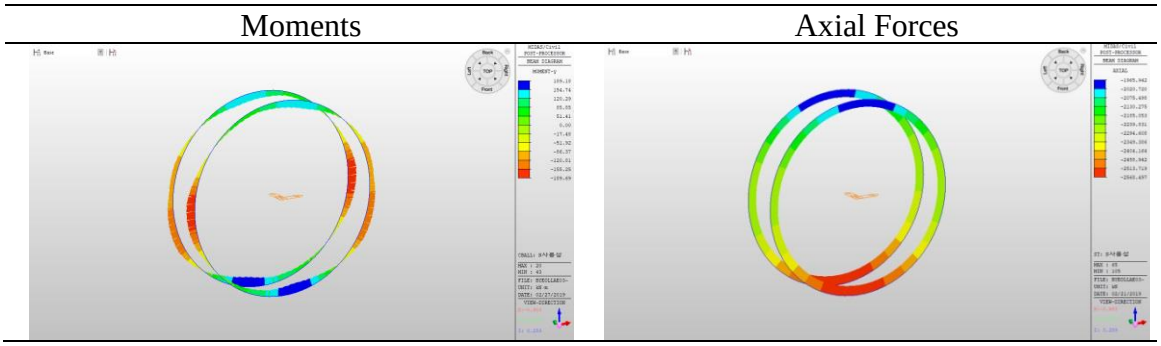


Figure 3: Member forces in the general condition

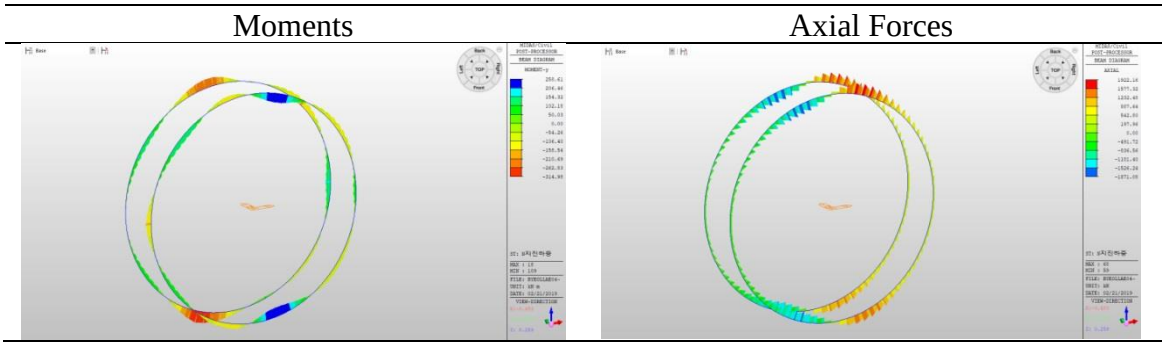
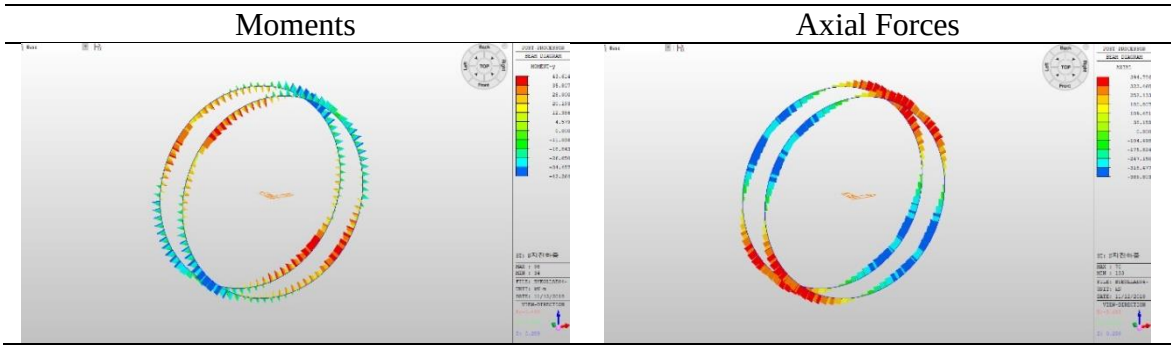
3.2 Analysis in the Seismic Condition

Underground structures in the seismic condition are loaded from inertia force and ground displacement as well as seismic shear stress. Thus, member forces generated by inertia force and ground displacement load are shown in Fig. a, member forces generated by seismic shear stress are shown in Fig. b.



a. Member forces generated by inertia force and ground displacement



b. Member forces generated by seismic shear stress

Figure 4: Member forces in the seismic condition

4 RELIABLITY ANALYSIS

4.1 Probability variables of loads

It is considered to probability variable which is presented by Nowak as shown Table 1 [5]. As mentioned in the introduction, however, variations separately are not applicable to analysis reliability for underground structures because of not corresponding to the superposition principle. Thus, the variance of combined COV of all loads which are proposed through the research process with KICT is calculated and applied for this study.

	Loads	Bias factors	Variations (COV)
L1	Dead load	1.05	0.10
L2	Horizontal earth pressure	0.95	0.15
L3	Vertical earth pressure	1.00	0.14
L4	Water pressure	0.90	0.15
L5	Seismic load	0.95	0.15
L_{comb}	Combined load (Seismic)	0.95	0.15
L_{comb}	Combined load (General)	1.00	0.37

Table 1: Probability variables of loads

4.2 Probability variable of resistance

The probability variable of resistance, COV(coefficient of variation), is used 0.08 which is presented by Nowak and Rakoczy [6].

4.3 MCS (Monte Carlo Simulation)

In this study, MCS program was developed to calculate probabilities of failure, results are obtained as shown in Fig. 5.

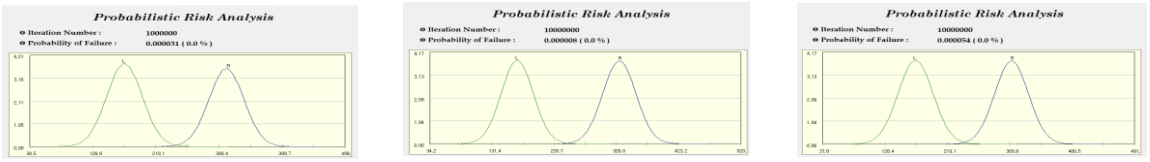


Figure 5: Applied loads on underground structure

4.4 Probability of failure and reliability index

The probability of failure and reliability index for the existing design cases (5sections) in Korea are calculated as following Table 2.

Models	Prob. of failure (P_f)	Reliability Index(β)
M-1	3.10e-5	4.01
M-2	8.00e-6	4.31
M-3-a	5.40e-5	3.87
M-3-b	1.23e-7	5.16
M-3-c	1.00e-11	6.71

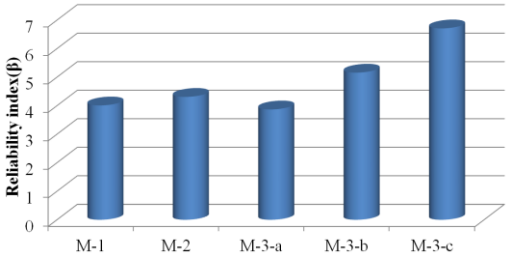

Table 2: Probability of failure and reliability index for the existing design cases.

5 REVIEW OF RELIABILITY INDEX

The load combinations for reviewing the target reliability index are based on the AASHTO LRFD TUNNEL SPECIFICATION (2017) [1], and the load factors that affect the section force are analyzed by calculating the member forces according to the change of load factors in units of 0.05. Also, the sensitivity of the load is identified by analyzing of the reliability index depend on the change of load factors.

5.1 Sensitivity of load factors

The load combinations in this study are considered as follows.

LC 1 : 1.25DC + 1.35EV + 1.35EH + 1.00WA + 1.00EQ

LC 2 : 1.25DC + 1.35EV + 0.75EH + 1.00WA + 1.00EQ

The results according to load combination are as following Fig. 6, from the results, it is confirmed that horizontal earth pressure (EH) and seismic load (EQ) are more sensitive than others in the variation of member forces according to the change of load factors.

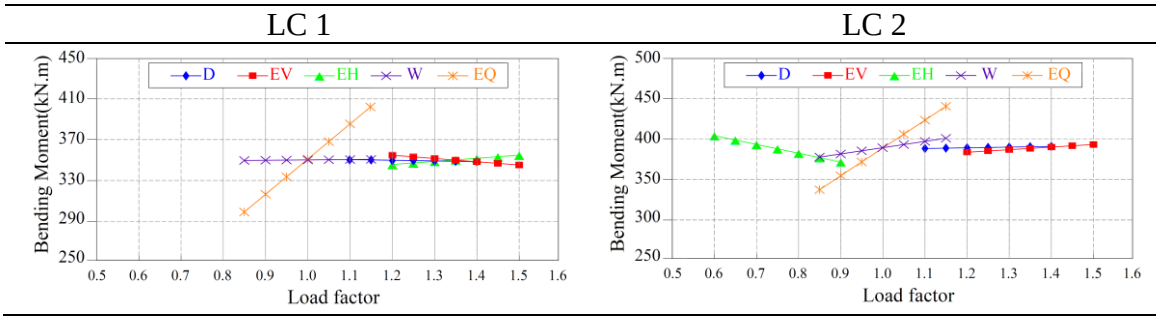

Figure 6: Variations of member forces depend on load combinations

5.2 Review on reliability index according to variation of load factors

The reliability indices according to variation of load factors are calculated as follows, earthquake load (EQ) mainly effects to the variation of reliability index as shown Table 3.

	Adjustment of Factors						
	-0.15	-0.10	-0.05	0.0	+0.05	+0.10	+0.15
EH	2.46	2.37	2.29	2.20	2.11	2.03	1.94
EQ	1.38	1.65	1.93	2.22	2.47	2.74	3.02

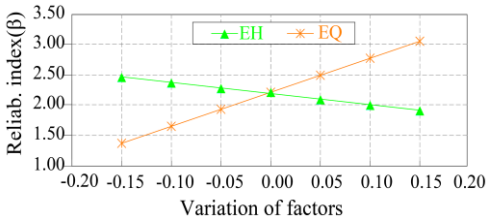

Table 3: Reliability Indices according to variations of load factor.

Earthquake load is not only an extreme load, but also a main load to effect to the variation of reliability index. Thus, it is reasonable to apply the load factor of earthquake load is 1.00, it may be applicable to consider the code calibration of horizontal earth pressure depending on the regional characteristics.

5.3 Target reliability index

For bridge structures, a sufficient number of bridges have studied to establish the target reliability. Nowak presented a normal target reliability index of 3.5 in the NCHRP Report 368

[7], and Ghosn et al. proposed a seismic target reliability index of 2.4 ~ 2.9 in the NCHRP Report 489 [8].

On the other hand, though enough research has not been done yet for underground structures, it may propose that the target reliability in seismic is 2.3 considering the existing research on the bridge and results of this study. And, the target reliability index was proposed through limited number of design sample, so it should be to advance based on sufficient number of samples and data in the future.

6 CONCLUSIONS

- It is conformed that horizontal earth pressure (EH) and earthquake load (EQ) are more sensitive than others in the seismic condition.
- It is presented that the earthquake load factor is 1.00 in this study, and that the code calibration of horizontal earth pressure may be needed depending on the regional characteristics.
- In the study, considering the existing research on the bridge and results of this study, it is supposed that target reliability is 2.3 under seismic condition.

Abstract

The equal displacement approximation is a well-known procedure for estimating the non-linear behavior of structures subjected to earthquake ground motions. This procedure plays a significant role in current seismic design, since it constitutes the basic assumption for defining strength reduction factors. In this paper, calculation of the performance point based on this rule is used to estimate engineering demand parameters such as those obtained by advanced probabilistic non-linear dynamic analysis, NLDA. We present a modification to the classic approach, to improve the predictability of the equal displacement rule. Uncertainties in seismic action and structural properties are considered. Mid-rise reinforced concrete buildings will be used as a testbed. To obtain a representative sample of buildings for statistical analysis, we describe the development through implementation of a numerical tool for calculating probabilistic NLDA. This tool, which is expected to evolve into interoperable software for assessing the seismic risk of structures, is developed within the framework of the KaIROS project. The results presented in this paper could be used to estimate the seismic risk of structures in a very simplified manner.

Keywords: equal displacement approximation, probabilistic non-linear dynamic analysis, mid-rise reinforced concrete buildings, KaIROS project

1 INTRODUCTION

Disaster risk reduction is a major concern of world communities. The 2030 Agenda for Sustainable Development includes 17 goals to end poverty, fight inequality and injustice and tackle climate change. The eleventh goal is *sustainable cities and communities*, as half of humanity now lives in urban areas and almost 60 per cent will live in cities by 2030. Thus, an important target for 2030 is to ensure universal access to basic services and to adequate, safe, affordable housing. Achievement of this target is at risk if the negative impact of catastrophes is not reduced. The importance of resilient communities has been shown in past and recent earthquakes. However, the negative impact of these catastrophic events on mankind is increasing due to

globalization. Sustainability, resilience and well-being are affected negatively at global level. Accordingly, a continuous effort to reduce seismic risk is fundamental to develop a stronger society.

Seismic loss mainly depends on the capacity of civil structures to withstand strong ground motions. Thus, the development of advanced numerical tools for assessing the seismic response of civil structures will contribute positively to the planning of optimal strategies for reducing seismic risk. Currently, several research projects are focused on reducing seismic risk. One is the Kairos project [1], which is aimed at maintaining and increasing the resilience and sustainability of communities against earthquakes. One research area in the Kairos project is the development of numerical tools to estimate the seismic risk of structures. In this paper, we present the development of one of the tools. To correctly estimate seismic risk scenarios, uncertainties in seismic hazard action and in the main features of the structures should be considered. The numerical tool presented herein takes into account uncertainties relating to the geometry of the structure, the mechanical properties of the materials and the seismic action, amongst many others. Moreover, the tool can be used to estimate several engineering demand parameters (EDP), which can be related to seismic damage of structures. The tool is developed through implementation of a hypothetical case study. To achieve this, the probabilistic seismic response of mid-rise reinforced concrete buildings is calculated via NLDA. A thousand numerical models were created and subjected to a set of earthquake records with different properties. The numerical tool, combined with information on variables characterizing the exposure of an urban environment, will help to estimate the seismic risk of the area precisely. However, the main target of the paper was to develop a procedure based on the equal approximation rule for estimating EDPs in a very simple way. Due to the amount of numerical data available, this simplified procedure could be developed easily based on a maximum correlation criterion.

2 PROBABILISTIC CONSIDERATIONS

The main factors affecting earthquake risk are hazard, exposure and vulnerability. Hazard refers to seismic actions and their occurrence probabilities. Probabilistic seismic hazard analysis [2] is estimated based on past seismicity, statistical models, ground motion prediction equations and site effects. Exposure concerns structures, facilities and properties in the stricken area. The quantification of exposure requires a considerable amount of data on facilities, population and built environment, including special and essential buildings and lifelines. Vulnerability is related to susceptibility to damage of exposed goods. It connects hazard and exposure to obtain risk, that is, expected damage and cost. Regarding exposure, it has been a common practice to classify structures with similar features within a structural class. For instance, buildings are often classified as low-rise (1-3 stories), mid-rise (4-7 stories) and high-rise (>7 stories). Of course, many other features are used to identify a structural class. Generally, the seismic behavior of buildings in the same structural class is represented using probabilistic functions. This classification within structural classes simplifies the characterization of exposure when the seismic risk is estimated at urban level. The finer the characterization of the exposure, the more precise is the quantification of the seismic risk. Thus, inventory is a critical issue in risk assessments, and geographical information systems (GIS) can be used to enhance characterization at urban scale. Thus, if precise inventory information is available, it should be included when exposure is modelled.

2.1 Characterizing exposure

It is important to distinguish between two types of random variables when exposure is characterized: those that refer to the population of buildings, for example, in a neighborhood, district or city, and those that refer to intrinsic properties of a building, which can be considered epistemic uncertainty. Consideration of these types of random variables depends on whether the intended application is the classes of structures considered in urban risk assessment or individual buildings. Modeling the random variation in building-to-building structural characteristics within a structural class is standard practice. This modelling must reflect the epistemic uncertainty and how many structural types are grouped together into a single class.

2.2 Building-to-building variation

The main variables that characterize buildings in a structural class are random. In this section, we explain how building-to-building random variation will be considered within a structural class. Buildings belonging to the structural class 'reinforced concrete mid-rise buildings' are used as a testbed. Through implementation of this simulation, a numerical tool will be created that allows consideration of specific distributions within a structural class. Several variables that characterize a building are considered as input random variables. These variables will be the input of the software to be developed, once the simulation is achieved. In real cases, characterization of these random variables strongly depends on the information stored by local institutions. This information can be enhanced using GIS tools. For the purpose of the present study, the distribution of these variables will be assumed, and it will be mainly uniform or Gaussian. Thus, the number of stories, N_{st}, the number of spans, N_{sp}, the story height, H_{st} and the span length, S_l, are considered as the input random variables. N_{st} follows a uniform, discrete distribution in the interval (4, 7); N_v also follows a uniform, discrete distribution in the interval (2, 8). H_{st} is distributed uniformly in the interval (2.8, 3.2) m. S_l is distributed uniformly in the interval (4, 6) m. Functions based on the design of various hypothetical structures belonging to the structural class are used to assign the cross area to the structural elements. These models were designed by supposing that they are located in a moderate seismic area. Based on the results, several functions are developed. Thus, the width, W_c, and depth, D_c, of the columns of the first story will depend on the number of stories of the building and will be calculated using the following equation:

$$W_c \; or \; D_c = c_1 * \ln(N_{st} - c_2) + c_3 * \Phi_{1,0} + c_4 \tag{1}$$

where c_n are coefficients that could be adjusted depending on the data distribution of the analyzed area. For the study, $c_1 = 0.15$, $c_2 = 3$, $c_3 = 0.02$ and $c_4 = 0.35$. $\Phi_{1,0}$ is the standard normal distribution. Note that the columns are not necessarily square, that is, one random sample is generated for the width and one for the depth of the columns according to Equation 1. Moreover, the values generated are rounded to the nearest multiple of 5 cm. Figure 1a shows the size of the columns in the first story and Figure 1b shows the cross-sectional area. For the upper stories, the size of the columns will decrease systematically by 5 cm every two stories. To assign the steel percentage of the columns, ρ_c, a continuous Gaussian distribution is assumed. The mean value is 1.5% and the standard deviation is 0.15%. The width of the beams will also depend on the number of stories of the building model and will be calculated using the following equation:

$$W_b = b_1 * N_{st} + b_2 \tag{2}$$

where b_n are again coefficients that depend on the data distribution of the urban area. For the hypothetical case of study, $b_1 = 0.0053$ and $b_2 = 0.2947$. The depth of the beams will not only depend on the number of stories but also on the span length. The following equation has been used to calculate the depth of the beams:

$$D_b = g_1 * N_{st} + g_2 * S_l + g_3 \quad (3)$$

where g_1 = 0.0157, g_2 = 0.075 and g_3 = -0.0157. A random term was not considered for the beams. Either the coefficients, or the type of equation considered, can be modified so that they better represent the urban environment under consideration. Figure 2a shows the width of the beams as a function of the number of stories and Figure 2b depicts the depth of the beams as a function of the number of stories and the span length. To assign the steel percentage of the beams, ρ_b, a continuous Gaussian distribution is assumed whose mean value is 1% and standard deviation is 0.1%.

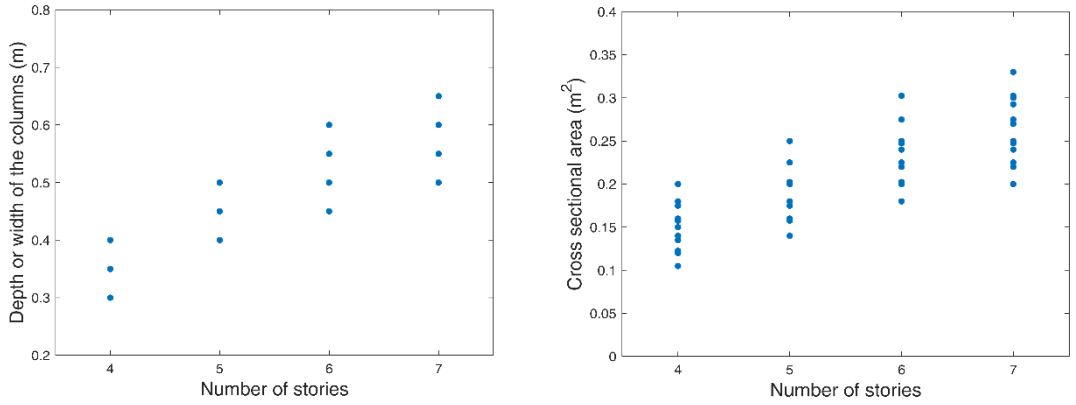

Figure 1 a) Depth and width of the columns of the first story and b) Cross-sectional area

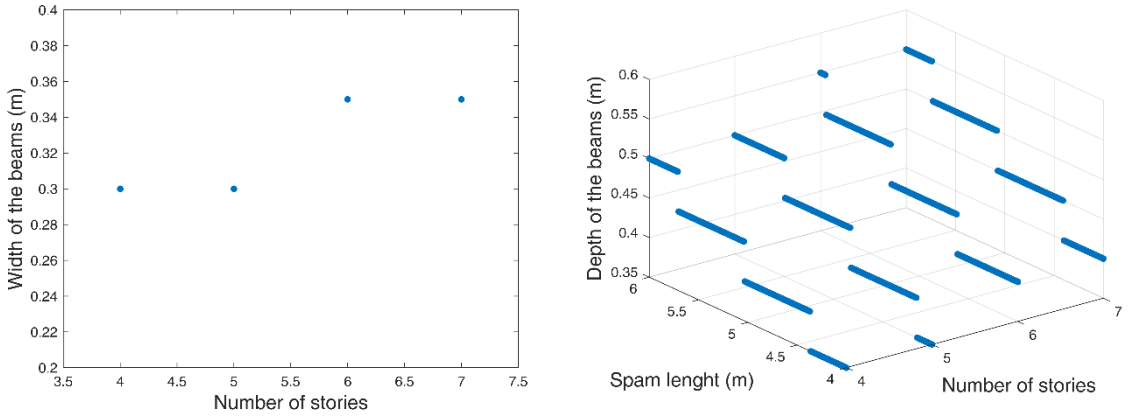

Figure 2 a) Width of the beams as a function of the number of stories and b) Depth of the beams as a function of the number of stories and the span length

2.3 Epistemic uncertainty

Several random variables should be considered when the behavior of a single building is modelled. Amongst many other variables, the mechanical properties of the materials, the loads acting on the structure and the participation of non-structural elements introduce epistemic uncertainty to the system. In this paper, the live loads, *LL*, the superimposed loads, *SL*, the compressive strength of the concrete, *fc*, the tensile strength of the steel, *fy*, the elastic modulus of

the concrete, *Ec*, and the elastic modulus of the steel, *Es*, are considered random variables. A continuous Gaussian distribution is assumed for these variables. The mean values, μ, and standard deviations, σ, are summarized in Table 1.

Variable	μ	σ
LL (kPa)	1	0.15
SL (kPa)	2	0.3
fc (kPa)	2.1e4	2.1e3
fy (kPa)	4.2e6	4.2e5
Ec (kPa)	2e7	2e6
Es (kPa)	2e8	2e7

Table 1 Mean and standard deviation of the random variables

2.4 Monte Carlo simulation

The Monte Carlo method is a relatively modern technique that allows modelling of complex systems with a large number of random parameters. This method has been used to generate 1000 random samples of buildings, according to the established distributions described above. An algorithm was implemented with MATLAB to this end. This algorithm will be part of the source code of the software under development. Figure 3 shows ten building samples generated with this algorithm. In this figure, we can see how the geometrical properties of the models vary within the intervals considered.

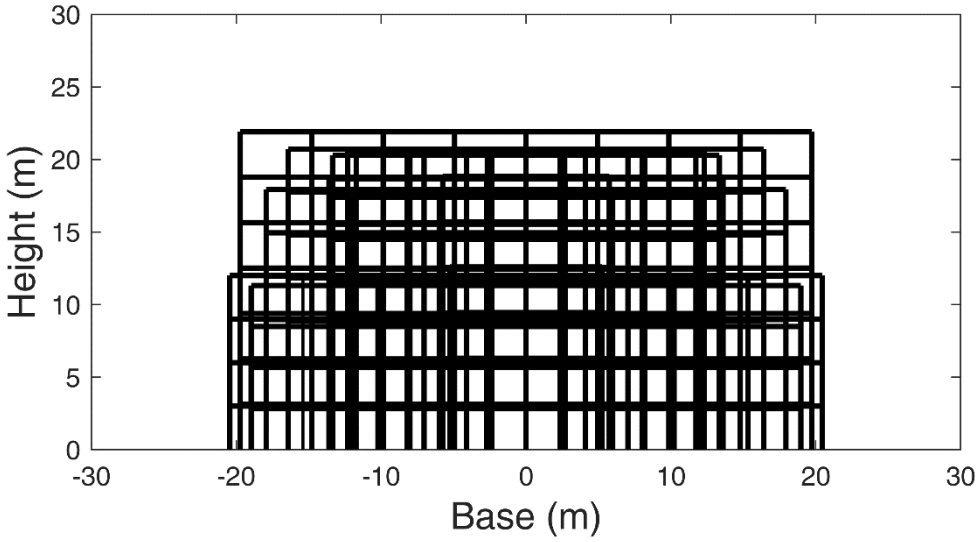

Figure 3 Building samples generated by the code

One question at this point relates to the validity of the models that are generated: do they properly describe the behavior of real structures? This question can be answered by comparing some properties of the models with a physical property of the real structures. For instance, Figure 4a shows a comparison between the fundamental period of the simulated models and those measured in real reinforced concrete buildings [3]. The fundamental periods of the buildings that are generated agree with those measured on real structures. Moreover, if the fundamental periods are tabulated into a histogram (Figure 4b) one can observe that the values are in agreement with those expected, according to the number of stories.

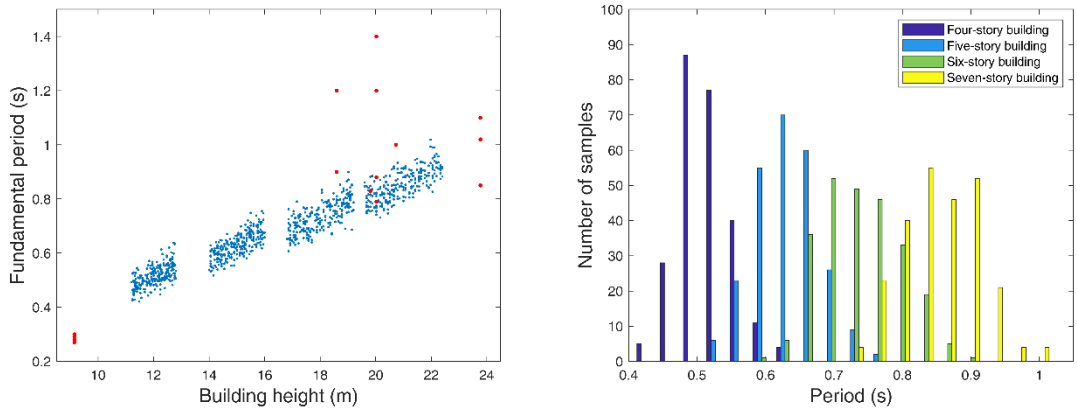

Figure 4 a) Variation in the fundamental period as a function of the building height and b) Histogram of the fundamental periods of the structural models that are generated

3 SEISMIC HAZARD

One of the main important sources of uncertainty in estimations of the seismic risk of structures is the random variability of the ground motion. There are several methodologies to properly select ground motion records that are consistent with the site-dependent spectral shape. However, the main objective of this paper is not to assess the seismic risk of an area, but to develop a simplified procedure for estimating EDPs, like those obtained with NLDAs. With this objective in mind, the most important requirement is to have earthquakes that demand the structural models at different intensity levels. To achieve this, based on the fundamental period range of the generated models (see Figure 4b), groups of earthquakes are selected whose mean spectral acceleration in the interval (0.4-1) s is between a stripe limited by two intensity levels. The intensity levels defining the upper and lower limits of each stripe range from 0 to 1.5 g at intervals of 0.15 g. The objective is to obtain 1000 records (as many as structural models generated) whereby 100 earthquake records per interval should be found. The database of Ambraseys et al. [4] is considered for the earthquake selection. Figure 5 shows 100 earthquake records (approximately 10 per interval) selected according to the procedure described.

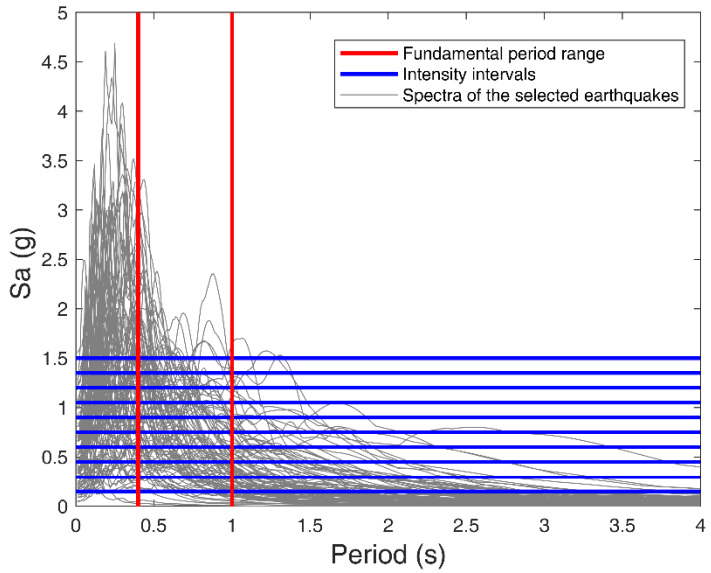

Figure 5 Response spectra of the selected earthquakes

However, because of the high number of earthquakes requested, several will be scaled versions of the ones that naturally fulfil the interval condition. Thus, if an interval does not contain 100 earthquakes records, because there are not enough records within the database, the number of missing records will be selected from the previous interval. This criterion avoids excessive scaling of the earthquake records.

4 NON-LINEAR DYNAMIC ANALYSIS

An NLDA allows simulation of the time history response of a structure, which enters or does not enter the nonlinear range when it is subjected to an earthquake. This analysis allows calculating EDPs such as the maximum displacement at the roof, δ_{roof}, the maximum interstory drift ratio (MIDR) and damage indices, among others. A key issue when an NLDA is performed is the hysteresis law assigned to the structural elements. The modified Takeda hysteresis law [5] has been used to perform the simulations. In-cycle strength degradation has also been considered. The yielding surfaces are defined by the bending moment-axial load interaction diagram for columns and bending moment-curvature for beams. Based on these modeling assumptions, the 1000 NLDA are performed. Ruaumoko software has been used to calculate the structural analyses [6]. Figures 6a and 6b show the histograms of δ_{roof} and MIDR, respectively. These EDP are commonly used in several methodologies to assess the seismic risk of structures. The maximum global drift ratio (MGDR), obtained as the ratio between the δ_{roof} and the height of the building, is also considered as EDP. Note that the MIDR is the envelope of the MGDR, as can be seen in Figure 7. Another important aspect of the relationship between these two EDP is their high correlation, which indicates that if one of them is known an accepted estimation of the other can be made. Pearson's linear correlation coefficient is also presented in Figure 7. This coefficient will always be used in this paper to measure the correlation between two variables. Although NLDA requires a high computational effort, it should be the reference procedure to correctly estimate the seismic risk of structures. Nevertheless, it would be of practical interest to have a simpler methodology to obtain similar results to those based on NLDA.

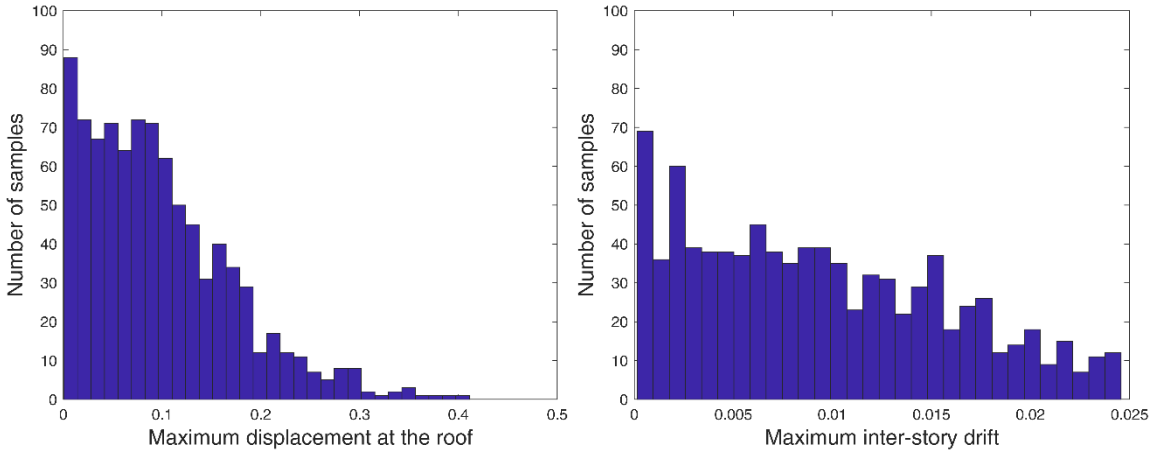

Figure 6 a) Histogram of $\boldsymbol{\delta_{roof}}$ and b) histogram of the MIDR (NLDA)

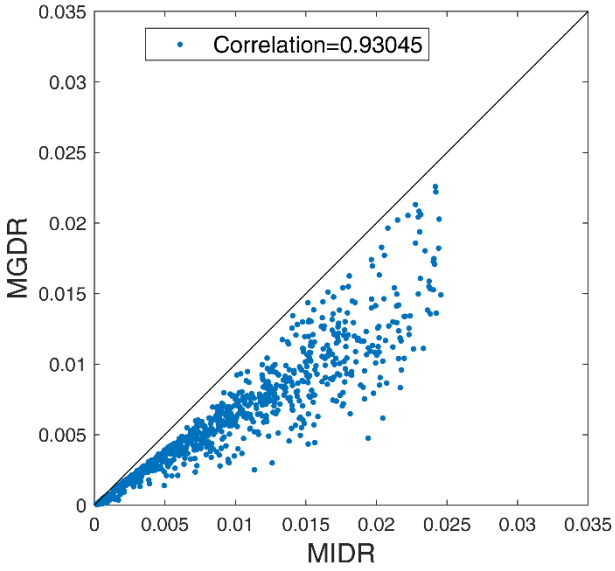

Figure 7 MGDR vs. MIDR

5 EDP ESTIMATION BASED ON THE EQUAL DISPLACEMENT APPROXIMATION

The most simplified assumption, and one of the most commonly used in practice, is to estimate the expected seismic response of the structure based on the equal displacement approximation, EDA. EDA is a well-known empirical rule for the assessment of non-linear behavior of structures subjected to earthquake ground motions. This procedure states that the predicted inelastic displacement response of oscillators is often very similar to the predicted displacement response of elastic oscillators with the same period. Noticeably, oscillators with short periods of less than approximately 0.5 seconds are often significantly larger than the predicted response of elastic structures of the same period. Accordingly, most of the structures analyzed in this paper meet the requirements for a good prediction based on this simplified rule. The displacement calculated using EDA, commonly known as a performance point, corresponds to a single-degree-of-freedom (SDOF) approximation of the structure; if the δ_{roof} of the represented multi-degree-of-freedom system (MDOF) is the target, the spectral displacement should be multiplied by the participation load factor [7], *PF1*, as shown in Equation 4:

$$\delta_{roof,EDA} = PF1 * Sd(T_f) \tag{4}$$

where T_f is the fundamental period of the structure. In this way, after applying the EDA rule to the structural models described above, and factoring the results by *PF1*, the δ_{roof} based on EDA is obtained. Figure 8a shows the comparison between the δ_{roof} obtained using NLDA and EDA methodologies. The dispersion increases as the displacement rises. The EDA rule allows the δ_{roof} of a building to be estimated, but the MIDR cannot be directly estimated based on this approximation. However, an MGDR based on EDA can be calculated by dividing the δ_{roof} by the height of the building, *H*. According to Figure 7, there is a high correlation between MIDR and MGDR. Consequently, it is expected that this correlation also exists between these variables when EDA is applied. Thus, the following equation can be used to estimate the MIDR from the $\delta_{roof,EDA}$:

$$MIDR_{EDA} = \alpha * \frac{\delta_{roof,EDA}}{H} \quad (5)$$

where α is a coefficient intended to minimize the mean square error between the MIDR drift based on NLDA and the MIDR based on EDA. It was found that α=1.3675. Figure **8**b shows this comparison. Noticeably, the correlation between these variables is similar to that observed when δ_{roof} (Figure 8a) is analyzed. Nevertheless, the EDA rule does not consider, explicitly, either the higher mode response or the structural period elongation because of the accumulation of damage.

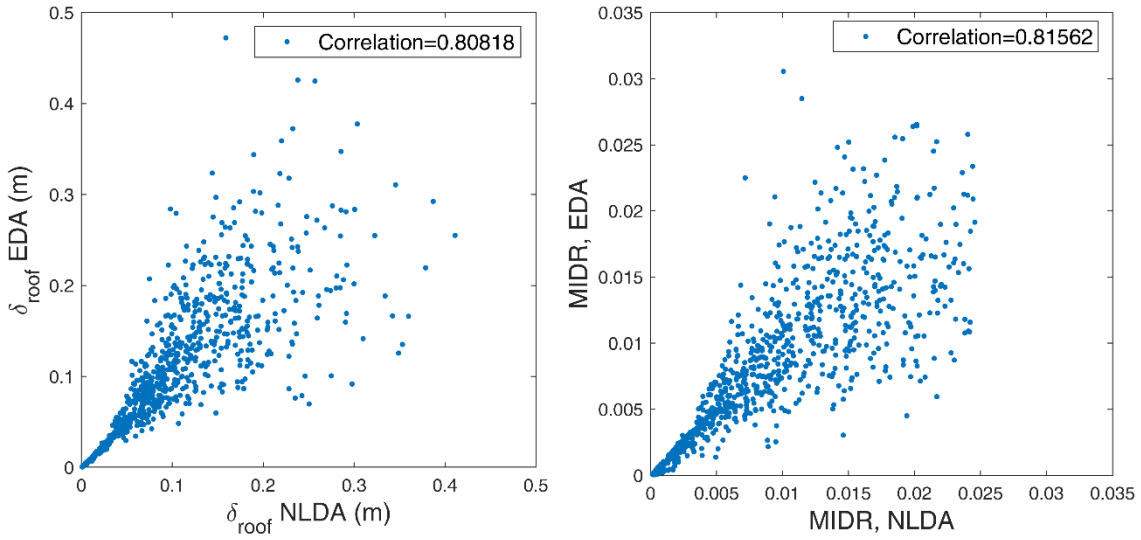

Figure 8 a) Comparison between the $\boldsymbol{\delta_{roof}}$ via NLDA and EDA and b) MIDR comparison obtained via NLDA and EDA

5.1 Modification to the EDA rule

When a structure undergoes inelastic deformation due to a dynamic action, a change of in its vibrational elastic properties is expected, whereby the participation of periods that are longer than the elastic ones becomes important. Moreover, depending on the mass participation factor of higher modes of the structure and the frequency content of the dynamic action, the contribution of these modes can become significantly high, even in low-rise buildings. Neither of these effects are considered explicitly by the EDA rule. More advanced methodologies, also based on the principles of the capacity spectrum method, e.g. FEMA 440 [8], allow such effects to be considered. Nevertheless, these methodologies are intended for spectral shapes that are smooth, and they can provide multiple solutions when real earthquakes are considered. If earthquakes are selected to fit a smooth spectral shape, such as a design or a uniform hazard spectrum, these methodologies provide very good results [9]. The most important aspect of the EDA, at least in our opinion, is its ease of use. Thus, a modification of the EDA rule, aimed at maintaining its simplicity, is presented. The new performance point will be calculated not as the response of the oscillator related to the fundamental period but as the average spectral displacement of several SDOF systems. Therefore, the term *Sd* from Equation 4 becomes the average spectral displacement of several oscillators as follows:

$$\delta_{roof,MEDA} = PF1 * \frac{\sum_{i=1}^{n} Sd(T_i)}{n} \quad (6)$$

Of course, the periods of these oscillators should consider softening of the structure due to the accumulation of damage and the participation of higher modes. These periods will be equally spaced, with an interval of 0.01 s, in the $\beta_{inf} \cdot T_f$ to $\beta_{sup} \cdot T_f$ range. T_f represents the fundamental period of the structure. Moreover, it is expected that β_{inf} <=1 and β_{sup}>=1. We designed an algorithm based on Monte Carlo to find the coefficients β_{inf} and β_{sup} that minimize the mean square error between the δ_{roof} obtained via NLDA and the modified EDA. It has been found that β_{inf} = 0.1 and β_{sup}= 1.8 are the coefficients that fulfil the minimization condition. Figure 9a shows the comparison between the δ_{roof} obtained using NLDA and the modified EDA. A significant increase in the correlation can be seen after the applied modification. Then, to calculate the MIDR based on the modified EDA, the MGDR based on EDA are recalculated and a new α coefficient is obtained. In this case, it has been found that α=1.6976. Figure 9b shows the comparison between the MIDR using NLDA and the modified EDA. Again, the correlation between these variables is similar to that obtained for the δ_{roof} comparison (Figure 9a).

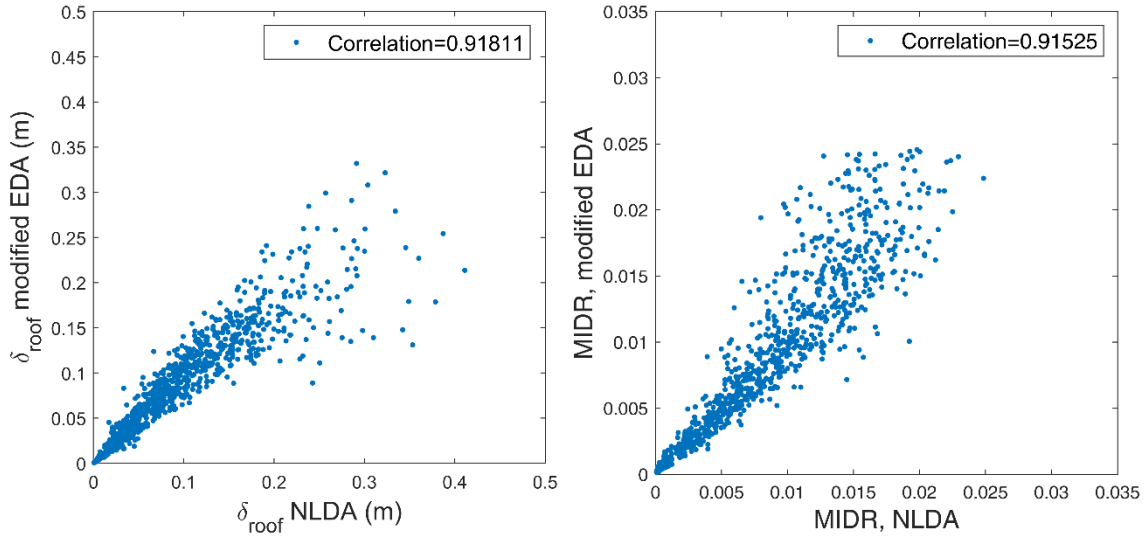

Figure 9 a) Comparison between the maxima $\boldsymbol{\delta_{roof}}$ via NLDA and modified EDA and b) MIDR comparison obtained via NLDA and modified EDA

6 DISCUSSION AND CONCLUSIONS

In this paper two main issues were considered. The first is related to the development of a numerical tool that can be used to estimate the seismic risk of structures through the implementation of a hypothetical case study. This tool considers several sources of uncertainties such as those related to geometry, the mechanical properties of the materials and the seismic hazard. Currently, the source code used to obtain the results presented herein is being reviewed and enhanced. It is expected that an interoperable version for potential users will be created by the end of the KaIROS project [1]. This tool could be used to develop detailed vulnerability models as the one presented in [10]. The second is a statistical analysis of the results aimed at developing a simplified procedure for estimating commonly used EDPs. The EDA rule principle was employed as the basis of a modified version that can be used to calculate similar results to those obtained via NLDA. This simplified procedure can be used to estimate, for instance, fragility curves via cloud analysis [11] without the need to perform NLDAs. Thus, the fragility curves for several damage state thresholds, related to MIDR 0.005, 0.01, 0.015 and 0.02, for the reinforced concrete six-story building shown in Figure 10a will be obtained based on the NLDA

and the modified EDA. The fundamental period of this structure is 0.84 s. Table 2 summarizes the details of the building. The epistemic uncertainties are considered according to the values presented in Table 1.

Story	W_c (m)	B_c (m)	W_b (m)	D_b (m)	ρ_c (%)	ρ_b (%)
1	0.7	0.7	0.35	0.4	1.2	0.8
2	0.7	0.7	0.35	0.4	1.2	0.8
3	0.65	0.65	0.3	0.35	1.1	0.8
4	0.65	0.65	0.3	0.35	1.1	0.8
5	0.6	0.6	0.3	0.3	1	0.8
6	0.6	0.6	0.3	0.3	1	0.8

Table 2 Characteristic of the building analyzed (Figure 10a)

Fifty earthquake records are selected in similar way to the procedure presented in Section 3, but in this case the spectral acceleration is related to the fundamental period of the structure. The values defining the upper and lower limit of each stripe range from 0 to 1 g, at intervals of 0.1 g (Figure 10b).

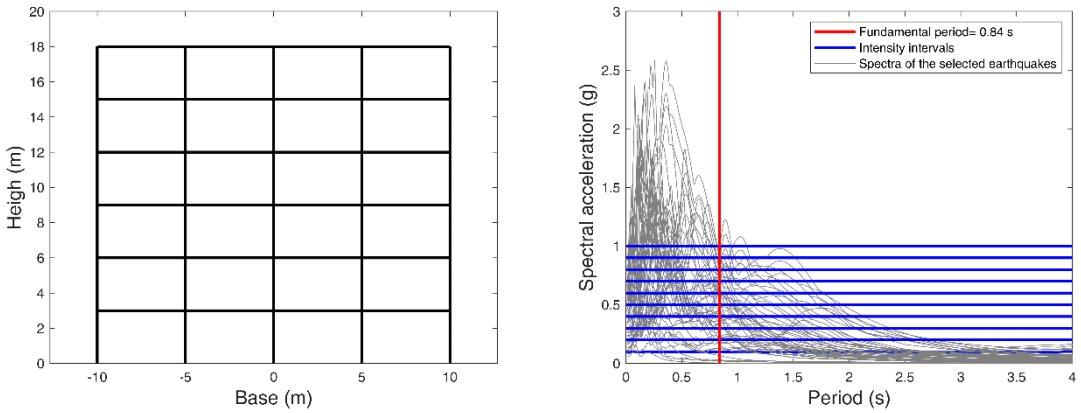

Figure 10 a) Six-story building and b) Spectra of the selected earthquakes

The fragility curves are then obtained using the cloud analysis via NLDA and the modified EDA. Figure 11a shows the comparison between the fragility curves obtained with both approaches. Significant differences can be seen between both curves. Nevertheless, these curves have been calculated for α=1.6976, which is a value that minimizes the error of all the structural models analyzed in the paper. If one analyzes the evolution of α depending on the number of stories, we will find that α increases with the number of stories. This makes sense, because the higher the building the higher the participation of superior modes of vibration. Figure 12 shows the evolution of α as a function of the number of stories. Then, after performing the calculations using α=1.85, obtained from the regression analysis presented in Figure 12, the fragility curves shown in Figure 11b are obtained. Noticeably, a better fit is achieved. This example proves the ability of the proposed procedure to estimate EDP in a very simplified way. Of course, the building that is analyzed should be in the domain of the simulation performed in this paper.

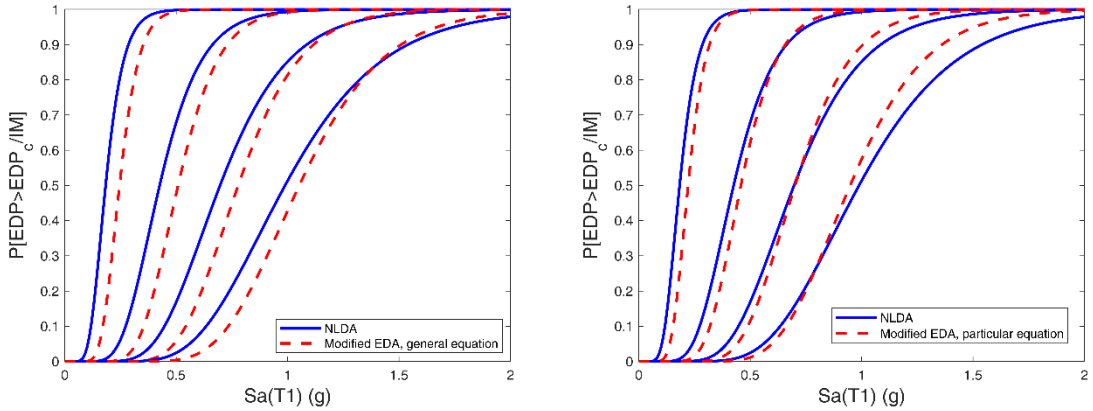

Figure 11 a) Fragility curves via cloud analysis with α=1.6976 and b) α=1.85

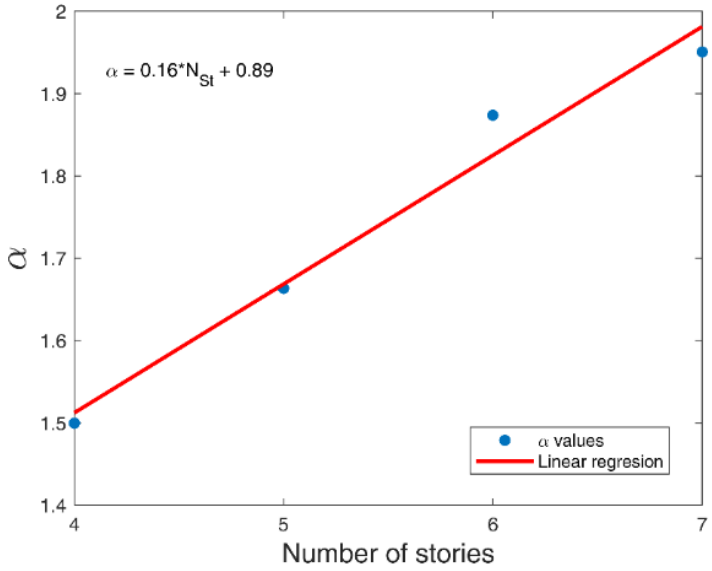

Figure 12 Evolution of α as a function of the number of stories

Finally, the key to reducing seismic risk is to decrease the vulnerability of existing structures and provide new insights to improve the design of new structures and protect them against seismic events. The current capacity of computers, combined with the versatility offered by probabilistic numerical methods, helps face this fundamental challenge in current society.

Abstract

Mapping seismic risk at the territorial scale is a key process in earthquake-prone countries since it allows to understand the spatial distribution of risk and its quantification in economic terms. Seismic risk maps can be used by governments to outline short-, mid- or long-terms risk mitigation and/or transfer actions. The present contribution aims to show how the seismic risk mapping framework detailed by the authors in a companion paper can be used to investigate the financial sustainability of national seismic risk reduction programs, focusing the attention on the specific case of the national residential building stock of Italy.

Keywords: Seismic risk map, Italy, Seismic risk reduction programs, risk mitigation, cost-benefit analysis

1 INTRODUCTION

For practitioners and authorities, seismic risk computation and mapping are fundamental knowledge tools for understanding and managing the risk at which communities are exposed. For these reasons, reliable seismic risk indicators are needed for quantitatively approach the problem of reducing and/or transferring the risk at with an extended territory is exposed. The Expected Annual Loss (EAL) is a widely adopted synthetic risk indicator, considering and weighing all possible loss scenario than can occur in a specific point. Furthermore, it allows quantifying benefits associated to a retrofit intervention and also provides a reasonable estimate the insurance premium that can be expected based on the design or strengthening decision taken [1].

In last years, many applications adopted the EAL for the evaluation of the best seismic strategy to be adopted, but mostly related to specific structures and addressing specific problems, most of time at punctual level and not at regional level. In [2], Beigi et al. performed a cost-benefit analysis for buildings retrofitted using a gapped-inclined brace system (GIB), while [3] discussed the possible criteria for the mitigation of seismic risk and for the structural strengthening in case of reinforced concrete structures [3]. In 2018, Hofer et al. [4] proposed a methodology for determining the most profitable seismic retrofit strategy to be adopted in an industrial productive plant. In this context, seismic risk evaluations have been extended to spatially distributed assets, for assessing seismic risk at regional level. Map of losses, conditioned on a specific return period, have thus been developed with the OpenQuake engine [5] for Portugal [6], Nepal [7], and Turkey [8]. In 2013, Asprone et al. [9] computed a possible seismic insurance premium for five different types of building categories within all the Italian territory, while in 2018 Zanini et al. developed the first seismic risk map in terms of EAL, for the Italian territory [10]. In particular, he performed the calculation for three different level of granularity according to the Italian administrative subdivision, obtaining in this way the Municipal Expected Annual Loss map (*MEAL*), the Provincial Expected Annual Loss map (*PEAL*), and the Regional Expected Annual Loss map (*REAL*). In addition, [10] showed the effect of different granularity levels on the EAL referred to 1 m^2 of build area (€/m^2), highlighting the averaging effect of assuming a less refined granularity.

This work wants to propose a possible seismic retrofit scenario for the entire Italian residential building stock, and accordingly compute the seismic risk maps for the retrofitted assets. From the difference between the two maps, it is thus possible to quantify the benefit associated to the retrofit interventions. Furthermore, this paper provides an insight on the problem of evaluating the profitability of retrofit interventions at national scale when a significant number of vulnerable structures is involved, and thus scale-effects may happen on the cost-benefit analysis. The paper thus proposes a possible sustainable risk reduction program for the Italian residential building stock and shows some possible applications of it. More details, and the complete procedure description can be found in [10, 11].

2 A RETROFIT SCENARIO FOR REDUCING THE CURRENT SEISMIC RISK

2.1 The current seismic risk map of Italy

Zanini et al. [12], showed the construction of the seismic risk map for Italy, computing the Expected Annual Loss for every Italian municipality, province and region. For the hazard representation, [10] adopted the seismogenic model of [13], jointly with the Gutenberg-Parameter of [14], the Ground Motions Prediction Equations of [15], and the soil map of [16].

A suitable building taxonomy have been adopted for representing the seismic vulnerability of the Italian residential building stock, which has been subdivided in eight Taxonomy Classes TCs. Masonry buildings have been subdivided in two TCs, masonry buildings built before and after 1919, respectively TC1 and TC2. Reinforced concrete structures have been subdivided in two main classes, depending if gravity-load design, or seismic-load design. Each one of these two classes have been furtherly subdivided in two classes, on the base of the number of storeys (1-2, or 3+), respectively TC3 and TC4 for the gravity-load design, and Tc5 and TC6 for the seismic-load design. Finally, two more TCs (again Other – gravity design TC7, and Other – seismic design TC8) have been adopted for describing structures other than masonry and RC, mainly combined RC-masonry structures. All parameters of the adopted fragilities can be found in [10].

About exposure data, they have been retrieved from the 15th census database of the National Institute of Statistics [17]. Figure 1 shows the seismic risk maps in terms of *MEAL*, *PEAL* and *REAL*, that are representations of the seismic risk in the so-called *as-built* condition.

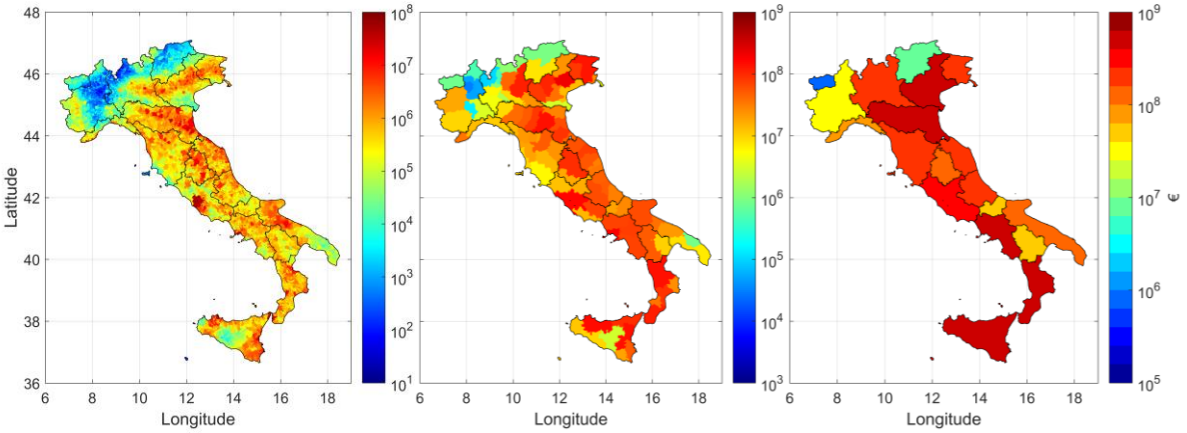

Figure 1: The seismic risk map of Italy in terms of MEAL (left), PEAL (center), REAL (right).

2.2 The seismic risk map of Italy after the retrofit of the building stock

This work investigates benefits of implementing a full seismic retrofit of the Italian residential building stock. For this scope, a seismic retrofit scenario for the entire building asset at national scale, has to be determined, and improved suitable fragilities have to be assumed.

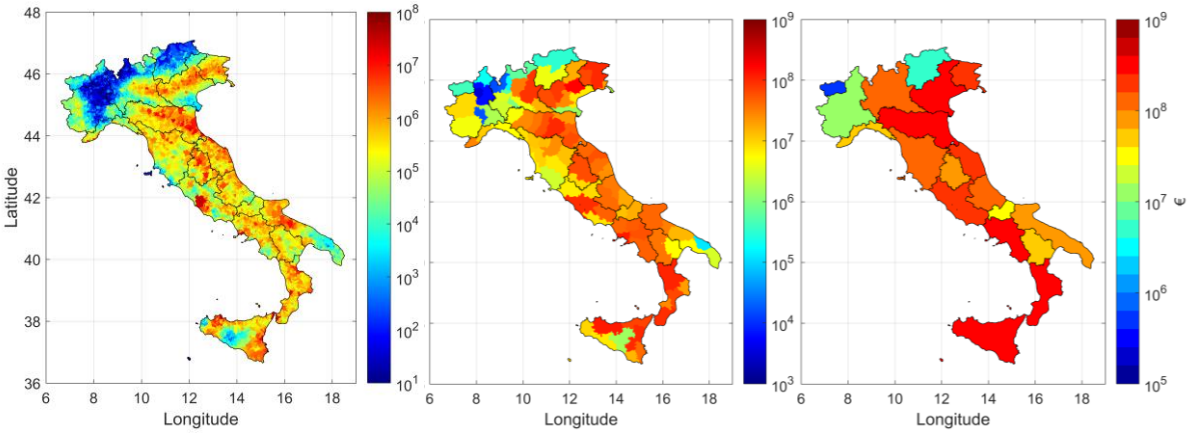

Figure 2: The seismic risk map in terms of MEAL (left), PEAL (center), REAL (right), for the retrofitted asset.

In particular, this paper assumes to improve the structural behavior or masonry buildings (TC1 and TC2), RC gravity load-designed structures (TC3 and TC4), and "Other" gravity load-designed structures (TC7). Retrofitting implies a change of the fragilities for the above-mentioned TCs: in particular it has been assumed that in the retrofitted configuration they behave like the respective seismic-designed classes, i.e. TC1, TC2, TC3 change in TC5, TC4 is modified as TC6, and TC7 is characterized as TC8.Under these assumptions, seismic risk maps have been recomputed for the three level of granularity. Figure 2 shows results in terms of *MEAL*, *PEAL* and *REAL*.

2.3 Assessing the retrofit convenience

For assessing the financial sustainability of the proposed seismic retrofit program, a cost-benefit analysis (CBA) is needed [18]. The main aim of CBA is to assess the profitability of a retrofit intervention, usually performed by computing the break-even time t_{BE}, i.e. the temporal point at which total cost and total revenue are equal. The $t_{BE,x}$ for each x^{th} municipality can thus be computed as:

$$t_{BE,x} = \frac{C_x}{B_x} \tag{1}$$

where C_x represents the cost to be sustained by the x^{th} municipality for retrofitting TC1, TC2, TC3, TC4 and TC7, and B_x is the benefits in terms of EAL provided by the all the retrofit interventions in the x^{th} municipality. B_x can be computed as the different between the *MEAL* in the as-built condition, and the *MEAL* after the structural improvement interventions as

$$B_x = MEAL_{x,as-built} - MEAL_{x,retrofit} \tag{2}$$

Similarly, the benefit due to seismic retrofit can be computed at provincial and regional level. Figure 3 shows the three benefit maps, highlighting how higher benefits are expected in the area of higher Annual Expected Losses.

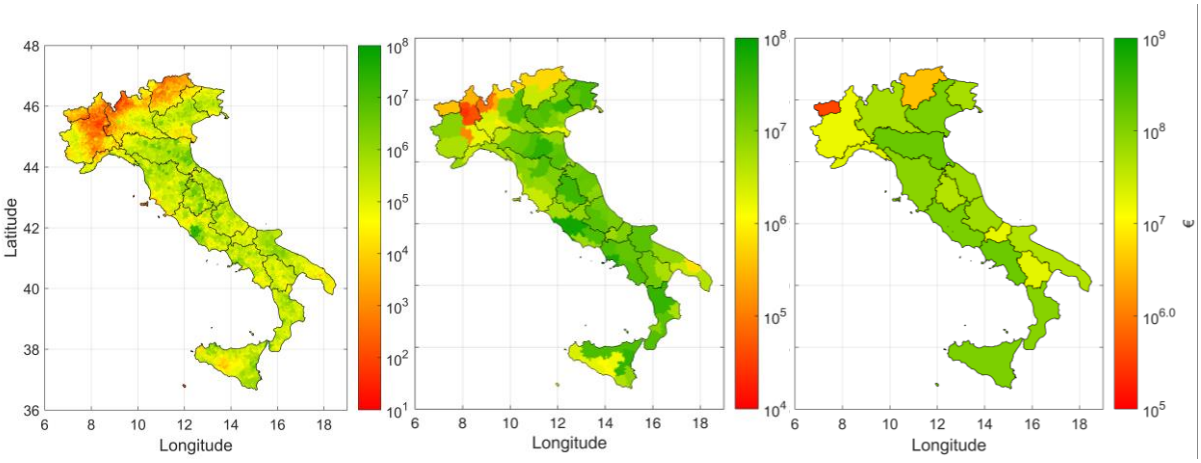

Figure 3: Benefit map at municipal (left), provincial (center), and regional (right) level.

Cost at municipal level C_x in Eq. (1) strictly depends on the planned seismic retrofit interventions for p = 5 TCs that need a structural improvement, and can be computed as

$$C_x = \sum_{y=1}^{p} A_{y,x} \cdot SRC_y \tag{3}$$

where $A_{y,x}$ is the built area of the y^{th} TC that needs seismic retrofit, and SRC_y is the unitary seismic retrofit cost for the y^{th} TC. The SRC_y values have been assumed equal to 68 €/m^2 for TC1, TC2, TC7 structures (i.e. retrofit schemes consisting in the insertion of tie-roads [19] and reinforced plaster) and 34 €/m^2 to for TC3, TC4 buildings (i.e. interventions based in FRP wrapping [20] or reinforced concrete jacketing of RC frame elements) in accordance to Prota [21]. Figure 4 shows the break-even time map, computed at municipal, provincial and regional level. Basing on this indicator, the Italian territory is mainly divided into two parts: in the first zone, coinciding with the Appennini area and northeastern Italy, seismic retrofit is recommended and t_{BE} ranges between few decades till about one hundred years. In the second case, for northwestern Italy, Puglia and the Tyrrhenian coast, retrofit interventions seem not to be convenient, since the break-even time is hundreds of years. Even in this case, the calculation at provincial and regional level, has an averaging effect, increasing the lower t_{BE} values at municipal level, and reducing the higher t_{BE} values.

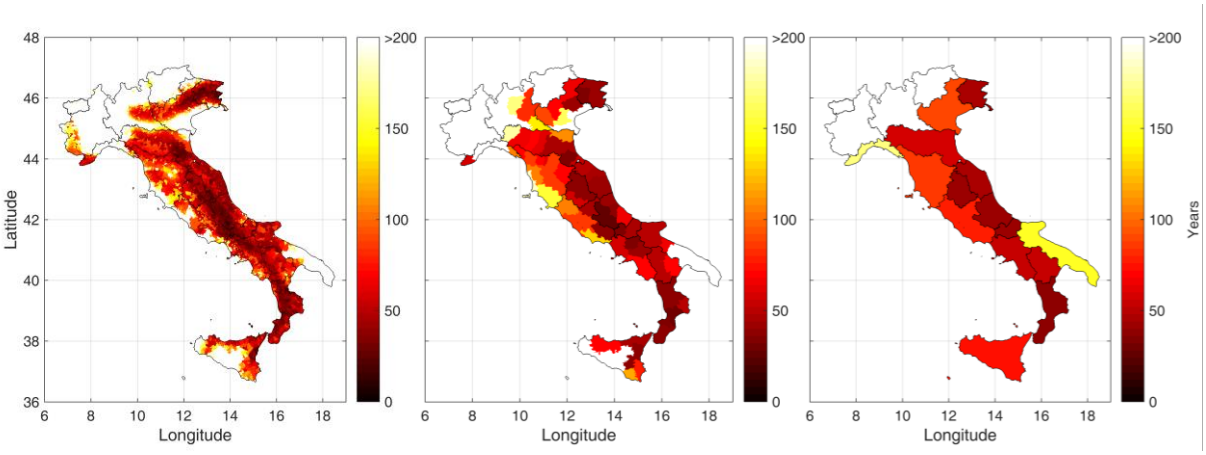

Figure 4: Break-even time map at municipal (left), provincial (center), and regional (right) level.

In general, for the entire national territory, structural retrofit implies gains in a medium-long term, and, except for some municipalities and provinces where it is highly recommended, seems not to be a convenient strategy for reducing seismic risk. However, the safety of citizens and the national risk reduction, cannot be neglected basing on cost-effectiveness analysis. For this reason, a financially sustainable seismic risk reduction program is proposed in the next section.

3 DEVELOPMENT OF SUSTAINABLE RISK REDUCTION PROGRAMS

The financial sustainability of implementing a nationwide retrofit program, has to be investigated in order to guarantee reasonable break-even times. The idea is that the implementation of the national seismic risk reduction program, should be managed by the Italian Government, or, better, by an *ad hoc* national public agency, which have to support the seismic retrofit at municipal level (or provincial and regional). The cost-effectives of the initial investment, and thus a reasonable financial return time, should be guaranteed by increasing benefits due to the seismic retrofit. This can be obtained by introducing for each x^{th} municipality (or Province and Region) a property tax PT_x, that can be seen as an additional income to be summed to the benefit B_x, thus reducing the break-even time:

$$t_{BE,x} = \frac{C_x}{B_x + PT_x} \tag{4}$$

In each x^{th} municipality, PT_x can be computed as a fraction PTR_x (property tax rate) of the total municipal cadastral income

$$PT_x = PTR_x \cdot CI_x \cdot A_x \tag{5}$$

where A_x is the total built area in the x^{th} municipality, and CI_x is the municipal cadastral income in €/m^2: in this application CI has been assumed constant and equal to 484 €/m^2 [22]. From Eq. (4) and Eq. (5) it is thus possible to compute the PTR_x, given a specific t_{BE}, and, on the contrary, compute the break-even time corresponding to a specific PTR_x. Figure 5 shows the map of the break-even time for PTR_x = 1 ‰ while Figure 6 shows the map for PTR_x = 2 ‰. Further examples for PTR_x = 0.5 ‰ and PTR_x = 3 ‰, and the calculation of PTR_x for a specific payback period can be found in [10].

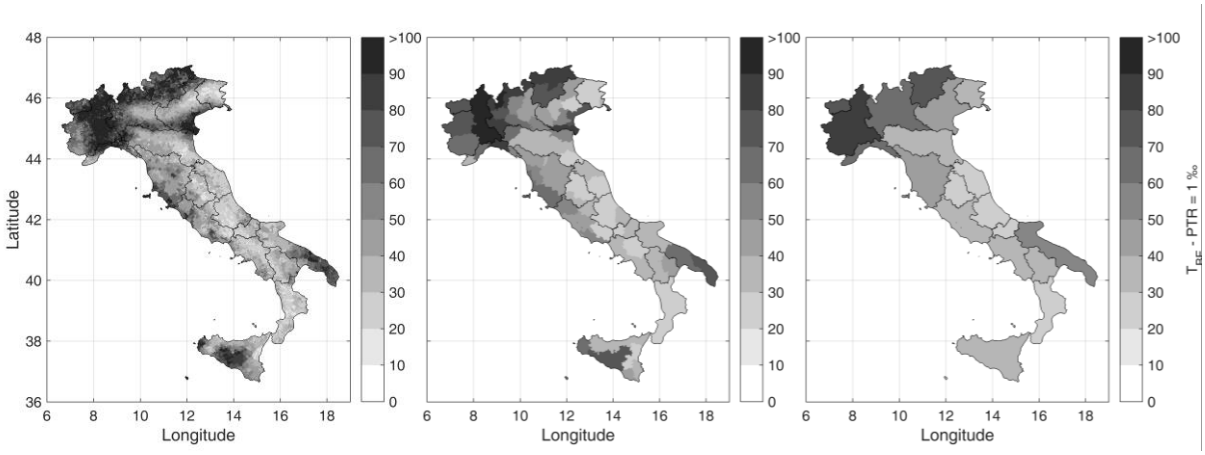

Figure 5: Break-even time map with PTR = 1 ‰ at municipal (left), provincial (center), and regional (right) level.

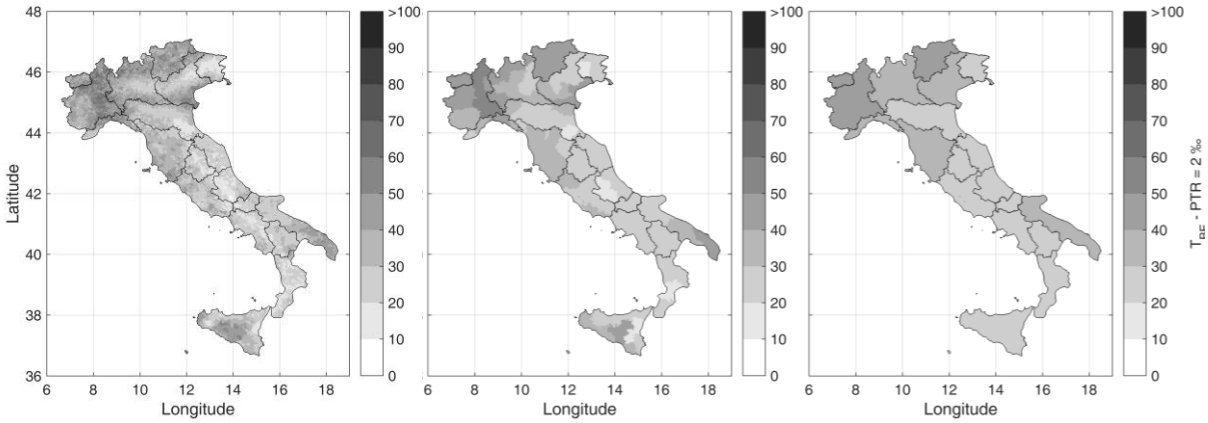

Figure 6: Break-even time map with PTR = 2 ‰ at municipal (left), provincial (center), and regional (right) level.

Figure 5 and Figure 6 clearly show the benefit of introducing this contribution. In particular, with PTR_x = 2 ‰ almost the entire national territory has a payback period lower than 30 years. Even in this case, considering less refined granularity has an averaging effect on t_{BE}, increasing the lower values, and reducing the higher ones.

4 CONCLUSIONS

In earthquake-prone countries, the development of financially sustainable risk reduction programs, is a key issue that has to be addressed starting from a deep knowledge of the risk at which the national territory is exposed. For this scope, suitable hazard, vulnerability and exposure models have to be defined, and then combined for computing the seismic risk map of the area of interest. The seismic risk map is the representation of the current *as-built* condition, from which the benefit due to seismic retrofit has to be computed. It is thus possible to compute the seismic risk map for the *retrofitted* configuration, and by subtraction the map of the expected benefit. The cost-benefits analysis performed for the Italian territory, showed a wide range of variability for the payback period, highlighting Italian regions in which seismic retrofit is highly recommended, and others in which it has a lower impact with high break-even times. For this reason, this work proposed a financially sustainable risk reduction strategy, based on the introduction of a property tax to be paid by citizen for achieving in a shorter time the financial break-even. The Italian Government, or, better, an *ad hoc* national public agency, has thus to support the seismic retrofit, whose cost-effectives is guaranteed by the introduction of this additional contribution. The flexibility of the proposed strategy allows computing the expected payback period corresponding to a given level of property tax rate, or vice versa, the property tax rate to be applied for re-entering the investment in a specific number of years. Results shows as a property tax rate of 2 ‰ assures for almost the entire national territory a payback period lower than 30 years. In this paper, all calculations are performed at three granularity levels, i.e. municipal, provincial and regional level, according to the Italian administrative subdivision. In particular, a less refined granularity has an averaging effect on the final break-even time, increasing the lower values, and reducing the higher ones. The use of different granularity levels is highly informative and, together with the developed maps, allows national authorities to take rational decisions for reducing the impact of future earthquakes that can occur in the Italian peninsula.

RINTC-E: SEISMIC RISK OF PRE-CODE SINGLE-STORY NON-RESIDENTIAL STEEL BUILDINGS IN ITALY

Gaetano Cantisani[1], **Gaetano Della Corte**[1]

[1] Department of Structures for Engineering and Architecture, University of Naples Federico II
Naples, Italy
e-mail: {gaetano.cantisani, gaetano.dellacorte}@unina.it

Abstract

The paper summarizes results from numerical investigations on seismic response of single-story non-residential steel buildings designed and built in Italy during the 1980s-1990s, i.e. prior to code enforcement of modern capacity design and ductility detailing rules. A typical geometry and structural layout were selected to generate an archetype building, considering trussed portal frames in the building transverse direction and concentric braces in the building longitudinal direction. Following the simulated design, the case study building was modelled and analysed using OpenSEES. First, the paper describes the mathematical modelling of the mechanical response of critical building components as well as the global building model. The model represented explicitly the shear force-displacement response of bolted connections for truss members, as well as the axial-shear force-displacement response for column base connections. Low-cycle fatigue of buckling braces was considered following literature models to represent triggering of brace fracture. Two different envelope types were analysed and explicitly modelled. Following description of the finite element model, results from non-linear static analysis are summarized and critical building components are identified. Subsequently, results from response history analysis with multiple sets of ground motions selected for increasing seismic intensity levels are also provided and commented on. Finally, conclusions from the presented numerical results are traced and future developments of the work are discussed.

Keywords: Building, collapse, risk, steel

1 INTRODUCTION

Single story steel buildings are frequently used in Italy for non-residential buildings. Often, in old buildings, trussed beams were employed to carry the gravity loads distributed on large spans, while braced frames were used to obtain out-of-plane member stability and stiffness in the orthogonal direction. Because of the relatively small values of structural and non-structural masses, design of this buildings is dictated by gravity and wind actions, as well as slenderness and other geometric limitations. Besides, due to the absence of capacity design and ductility detailing rules in the old structural codes, post-buckling member behaviour, connection failures and other relatively brittle failure modes are phenomena that could govern response under increasing horizontal actions. Eventually, an adequate model of the building envelope could be necessary, if a realistic estimate of the seismic performance would be required. The case study presented in this paper refers to typical similar structures designed and built in Italy during the years 1980s-1990s. First, the paper provides a description of the case studies and the relevant design assumptions, as well as the main design output. Second, a description of the structural model, including the building envelope, is presented. Finally, results are presented in terms of non-linear static and dynamic analyses on a 3D finite element (FE) model. The paper discusses the results, with a focus on evaluating the building ultimate failure, and the effect on response of the building envelope, in comparison to the bare frame response. The presented work is framed within the activity of a broader research project, the ReLUIS-DPC project named RINTC, aimed at evaluating the seismic reliability of structures in Italy with emphasis on ultimate failure [1, 2]. In specific, the behaviour of existing steel structures is under investigation, following a similar work already carried out for new structures [3].

2 CASE STUDY STRUCTURE

2.1 General design assumption

The building depicted in Figure 1 represents the case study of this work. A simulated design was carried out, according to codes and standards of practice adopted in Italy in the years 1980s-1990s [4,5,6]. The archetype building was made of five portal frames with a main trussed beam in the transverse direction (X), while concentric braced frames were adopted in the longitudinal direction (Y). In addition, Figure 1 highlights the presence of the envelope and their openings in the two main building directions.

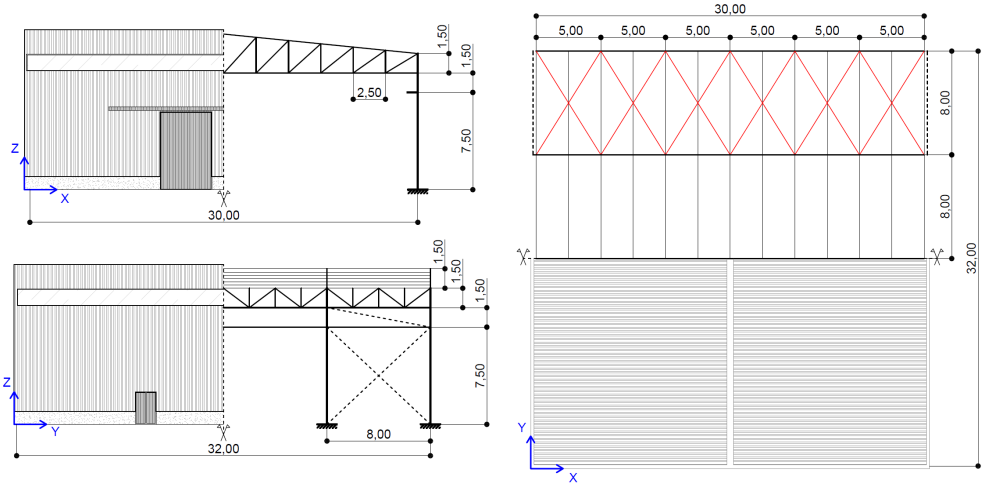

Figure 1: Global geometry of the case study building.

The building was located at L'Aquila (Italy), a small city in central Italy where seismic hazard is significant. The design assumed two main load combinations: (i) a gravity load combination; (ii) a horizontal load combination. The effects of seismic actions were included in the combinations (for both horizontal and vertical actions), but neither capacity design rules nor detailing requirements for ductility were implemented. The simulated design was carried out according to the allowable stress method, considering an old "Fe 430" steel with an allowable stress of σ_a=190 MPa.

2.2 Design results

Figure 2 shows the member cross sections for the main structural members. The choice of the trussed beam element cross sections was governed by the gravity loads, while the column cross section was governed by the horizontal loads. The brace cross sections were selected based on a codified slenderness limitation ($\lambda \leq 200$ for main members and $\lambda \leq 250$ for secondary members).

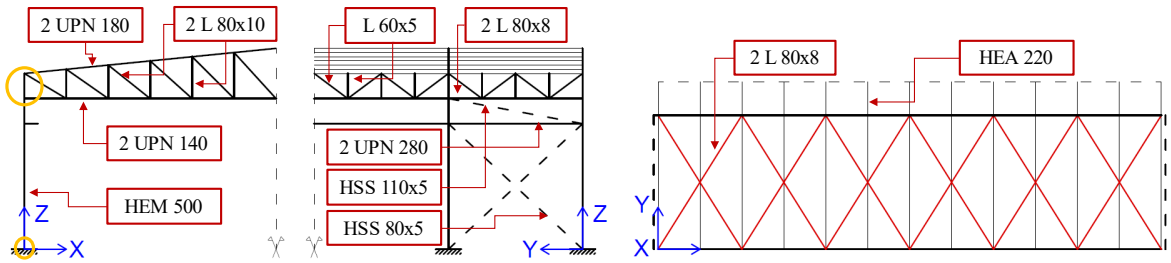

Figure 2: Cross sections of main structural members.

Bolted connections were used for truss members. The gravity load combination led to connections for members at midspan stronger than the connections for members at the column face (Figure 3(a)). Simple column base connections were assumed for the design. Column base anchor cross sections were selected to resist only shear forces, because no tension developed under the design loads. The anchor length was conservatively selected equal to the minimum suggested by the code for tension bars. In addition, to provide stability during column erection, four anchors were used (Figure 3(b)).

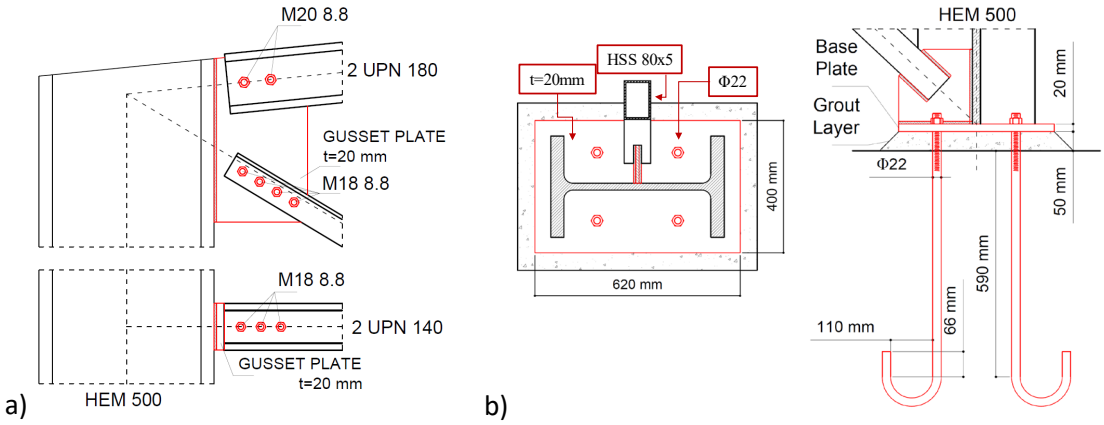

Figure 3: Connection design: (a) Truss-to-Column connection; (b) Column base connection.

Two alternative types of lateral cladding were considered: (i) sandwich panels (Figure 4(a)), and (ii) trapezoidal sheeting (Figure 4(b)). The roofing panels were always made of sin-

gle trapezoidal sheeting, eventually completed on-site with thermal insulation and weather shield. Bolted connections between secondary steelwork and panels were assumed in the case of sandwich panels, because of the experimental results used for modelling the panels [7]. Instead, screw connections were assumed in the case of trapezoidal sheeting, according to the experimental results used for modelling the panels [8].

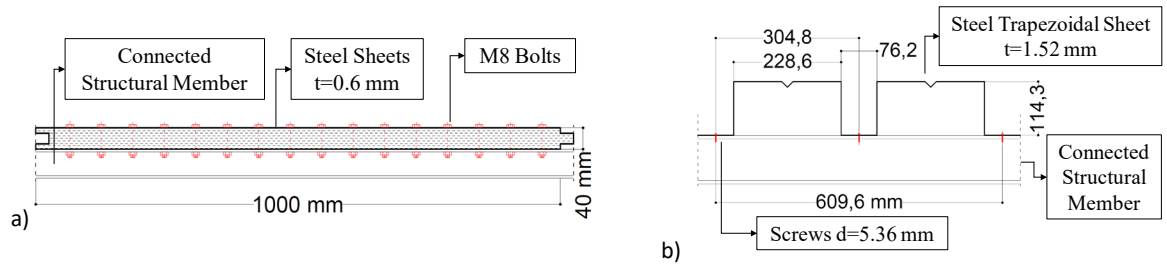

Figure 4: Cladding and roofing elements: (a) sandwich panel detail; (b) trapezoidal sheeting detail.

3 NON-LINEAR MODELLING FOR SEISMIC ASSESSMENT

3.1 General modelling issues

The open source finite element software "OpenSEES" [9] was adopted to analyse the seismic performance of the case study building. The stress-strain relationship was defined by Young modulus E_s = 210 GPa, yielding strength f_y = 316.25 MPa, post-elastic kinematic hardening ratio $E_p = 0.01E_s$, and Poisson ratio ν=0.30.

A classical Rayleigh damping model was adopted, with damping ratio set equal 5% for two main vibration modes in the two main building directions. Generally, members of both transverse and longitudinal trusses were modelled as "truss" elements. An exception is represented by the bottom chords of the main trusses, where "beam" elements were used to provide more realistic out-of-plane stiffness of the truss. Columns were modelled as elastic "beam-column" elements, because preliminary analysis indicated that connection and brace failures anticipated column yielding.

3.2 Structural modelling issues

Figure 5 shows two views of the structure finite element model, highlighting: (i) the main structure elements; (ii) the secondary steelwork elements; (iii) the cladding/roofing panel-equivalent brace elements. Openings (dashed lines) were considered by applying a 50% reduction to both the initial stiffness and resistance [10].

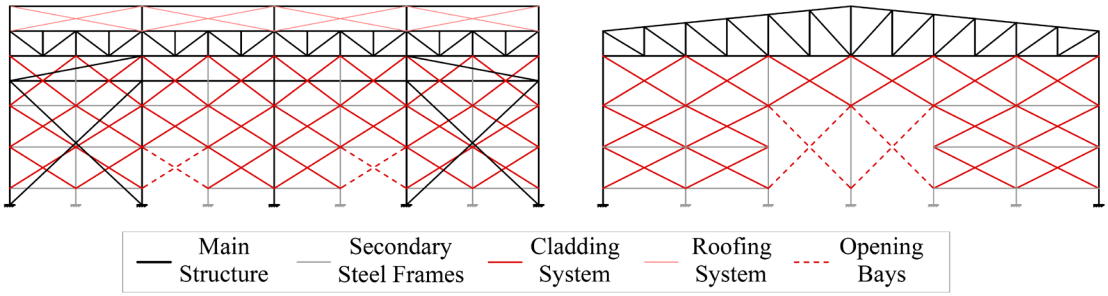

Figure 5: Structure finite element model

Both roof and vertical braces were modelled as non-linear fiber beam-column elements, with equivalent member imperfections calibrated to obtain buckling loads according to the

Eurocode general method [11]. The Giuffré-Menegotto-Pinto uniaxial material model was selected, considering the steel mechanical parameters described previously. The Bauschinger effect was considered assuming values of relevant parameters suggested in the OpenSEES user manual. Figure 6 shows one example of vertical brace modelling: brace discretization and member equivalent imperfection (Figure 6(a)), out-of-plane rotational behaviour of the gusset plate connection (Figure 6(b) and Figure 6(c)) according to Hsiao *et al.* [12]. Figure 6(d) shows an example of component response.

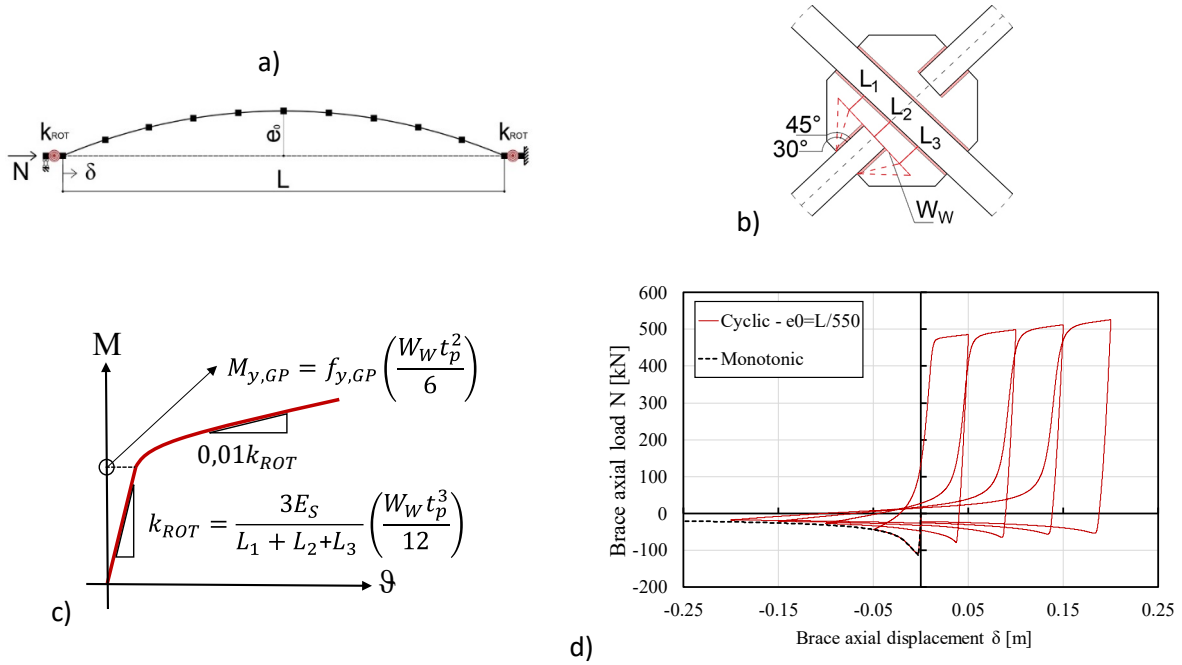

Figure 6: Brace modelling: (a) element modelling; (b) connection detail and (c) model; (d) element response.

Figure 7(a) shows the mechanical model used for the generic element of the main truss, where the flexibility and resistance of end connections was considered [13]. For the bolted connection between the columns and the truss ends, analysis indicated shear failure of bolts and the relevant non-linear behaviour ($\delta_{U,conn}$, $F_{U,conn}$) was modelled using results provided by Henriques *et al.* [14].

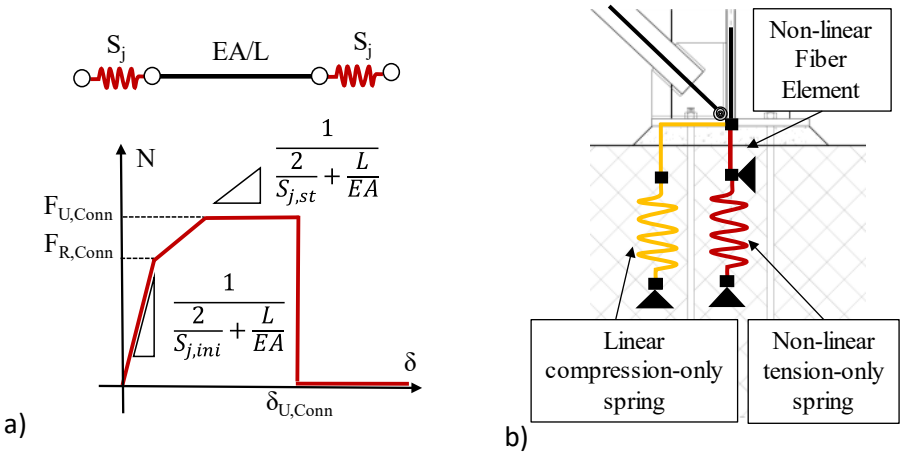

Figure 7: Connection modelling: (a) truss connection model; (b) column base connection model.

Figure 7(b) shows the model for column base connections in the longitudinal braced frame direction. An equivalent circular non-linear fiber element was used to simulate the anchor length outside the foundation block, thus considering the shear-axial force interaction. In addition, a unilateral tension spring was used to simulate the anchor length embedded into the concrete foundation including the hook [15]. The compression behaviour of the connection was considered by means of an elastic unilateral compression spring. Additional information about modelling can be found in Cantisani *et al*. [16].

Figure 8(a) shows the mechanical response of sandwich panels with bolted connections (SPs). The model comprises both the mechanical response of the panel and the non-linear response of the connection between panels and secondary steelwork. According to the experimental results [7], failure of the specimen occurred by bolt bearing against the sheet holes. Figure 8(b) shows the mechanical response of the trapezoidal sheeting (TS), considering the non-linear response of the screw connections. The response for TS comprises also the side-by-side connections between adjacent sheets [8].

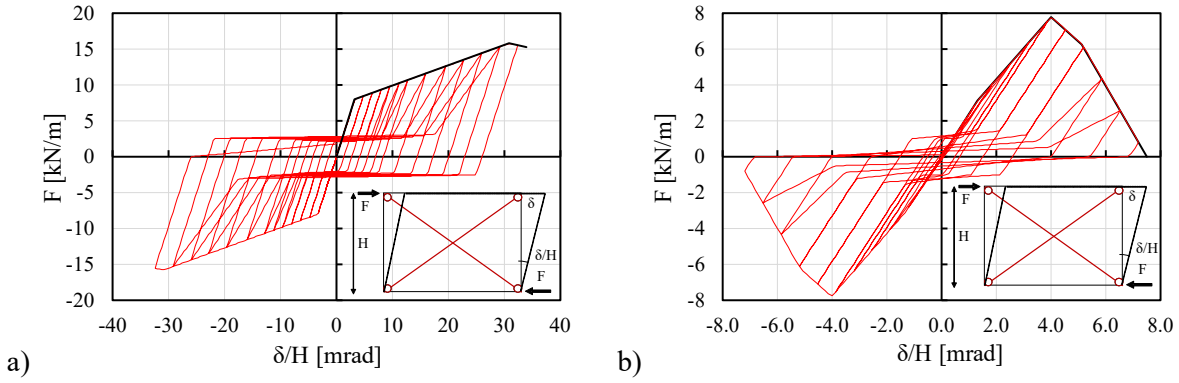

Figure 8: Envelope component modelling: (a) SPs response; (b) TSs response.

In addition to panel and panel-to-frame connection response, the model comprises also the non-linear response of connections between siderails and columns (Figure 9(a)). The shear connection model was implemented following the same rules already used in modelling truss-to-column connections (Figure 9(b)), considering a horizontal zero-length element in each siderail-to-column intersection in both the main direction of the building.

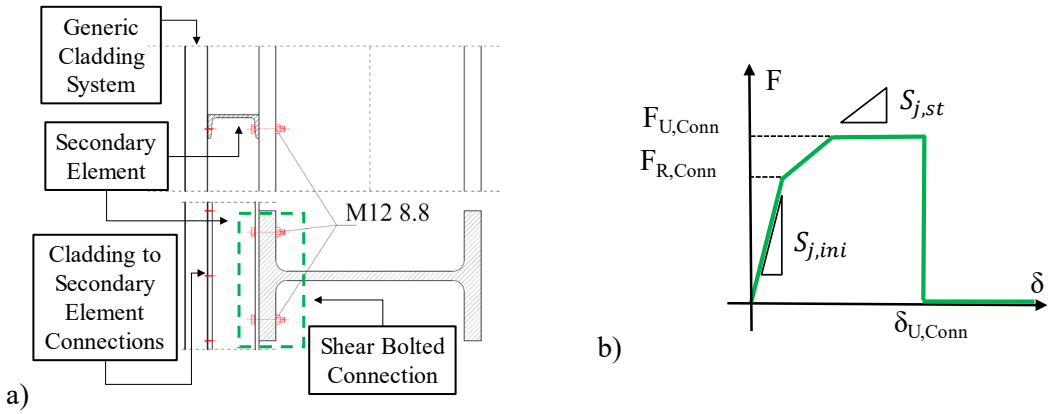

Figure 9: Cladding connection modelling: (a) connection geometry; (b) connection model; (c) connection arrangement.

4 ANALYSIS RESULTS

4.1 Modal analysis results

Table 1 provides information about periods of vibration (T) corresponding to modes having the largest modal participating mass (indicated as m^* in the table, and given as percentage of the total building mass) in the main building directions. Results are shown for different 3D models: (i) a bare frame model (BF), (ii) a model with sandwich panels (SP), and (iii) a model with trapezoidal sheeting. The values of T for the transverse X-direction (i.e., the direction of the main trusses) demonstrate significant increase of stiffness when changing from a bare frame model to a model incorporating envelope panels. Such increase in global stiffness was due to both the diaphragm effect of the roofing panels and the lateral stiffness contribution from the panels located at the two front and back portal frames. The diaphragm effect provided by the roofing panels is demonstrated by the different modes of vibration illustrated in Figure 10 for the bare frame model (Figure 10(a)) and the models with the envelope panels (Figure 10(b)). There was no significant difference between the SP and TS models, because the two models showed almost the same elastic stiffness in the transverse direction. Considering that SP and TS exhibited appreciable difference in their initial stiffness, one can conclude that the increase in the lateral stiffness compared with the bare frame model was mainly due to the diaphragm effect of the roofing panels. Instead, the longitudinal Y-direction (i.e., the direction of the concentrically braced frames) was neither qualitatively nor quantitatively affected to any significant extent by the presence of the envelope panels.

Model	X-direction		Y-direction	
Bare frame (BF) model	T = 1.06 s	m*=59.5%	T = 0.25 *s*	m*=71.2%
Model with sandwich panels (SP)	T = 0.54 s	m*=95.2%	T = 0.22 s	m*=81.6%
Model with trapezoidal sheeting (TS)	T = 0.54 s	m*=95.2%	T = 0.22 s	m*=81.6%

Table 1: Modal analysis results for the 3 cases study

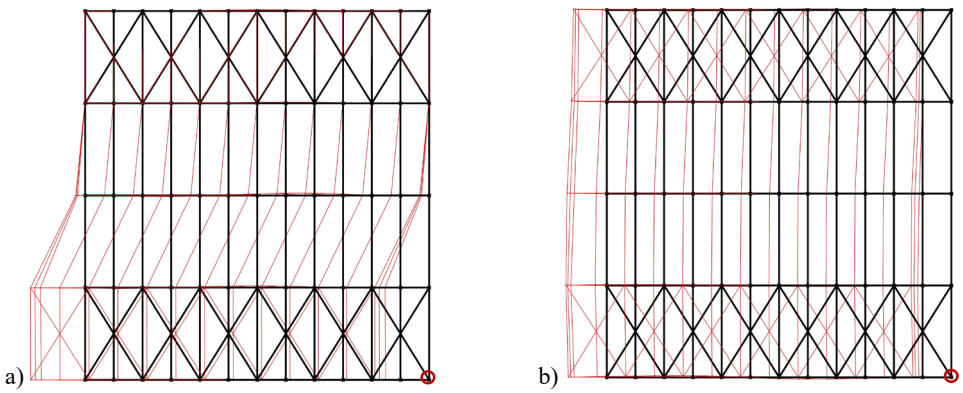

Figure 10: Transverse vibration mode in plain view: (a) BF model; (b) SP/TS model. Note: A circle highlights the control node for the pushover analysis discussed in section 4.2.

4.2 Pushover analysis results

Figure 11 summarizes the results of non-linear static (i.e., pushover) analysis. The figure shows the relationship between the base shear force ($V_{B,X}$ and $V_{B,Y}$) and the column drift ratio (d_X/H and d_Y/H, with H=10.50 m) (the control node is shown in Figure 10). Two types of lateral force patterns were used: (i) a modal force (MF)pattern, in which forces are proportional

to the product of node mass and displacement component of the relevant vibration mode in the direction considered; (ii) a uniform force (UF)pattern, in which forces have the same intensity at all the nodes of the model. The pseudo-static analysis method suggested by Hall [17] was adopted in cases in which convergence problems occurred.

Pushover results show that the structural response is significantly different between the two main directions. Failure of truss-to-column connections leads to collapse of the building in the transverse direction, in all the examined models. The presence of the cladding did not change the collapse mechanism of the building. During the whole loading process until collapse, rather complex interaction developed between claddings and the main structure. A detailed explanation of the interaction phenomena, as well as the evolution of the claddings damage, is provided by Cantisani and Della Corte [18].

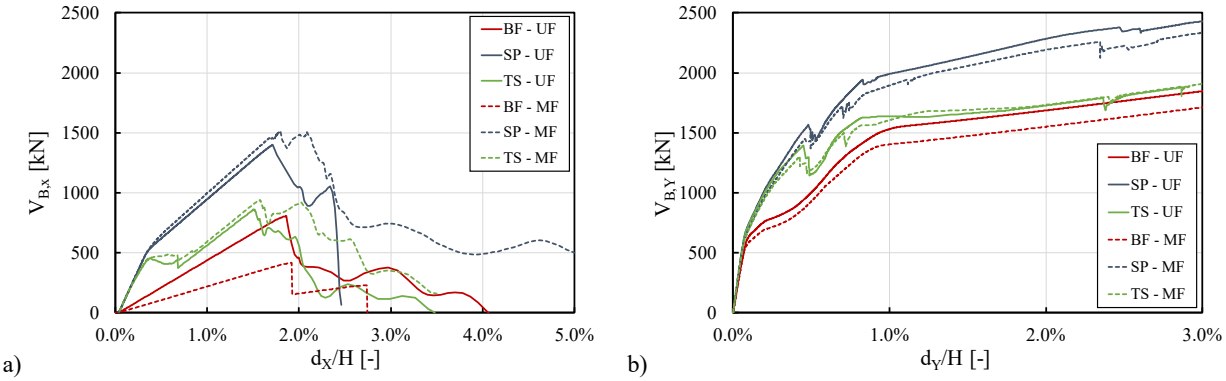

Figure 11: Non-linear static analysis results: (a) transverse direction; (b) longitudinal direction.

4.3 Ultimate failure criteria

Pushover analysis was used to identify the building ultimate failure [1]. Global failure of the building during a generic non-linear dynamic analysis was assumed to occur when the drift ratio at the pushover control node exceeded a limit value. The limit value to the drift ratio was assumed as that corresponding to a 50% loss in the global base shear force resistance obtained from the pushover curve. The drift limits were identified for the transverse response, because of the descending branch of the pushover curves. Ultimate failure for the longitudinal response was monitored by post-processing results in terms of brace and column base anchor strains. In fact, brace fracture was assumed to occur when the maximum brace strain range ($\Delta\varepsilon_{peak}$) reached the limit value by Hsiao *et al.* [12]. Similarly, column base anchor fracture was assumed to occur when the peak strain in the anchors (ε_{peak}) exceeded the expected steel ultimate strain (ε_{u}=34%, [19]).

4.4 Non-linear dynamic analysis results

4.4.1. Seismic hazard and record selection

Non-linear time history analyses were performed using bidirectional ground motions which were selected by the coordinators of the RINTC project [1]. The spectral (pseudo-) acceleration at the system fundamental period of vibration ($S_a(T_1)$) was used as intensity measure (IM). Ten different IM values corresponding to return periods (T_R) varying from 10 years to 100000 years were considered. At each IM value, 20 pairs of ground motions (GMs) were provided. Consequently, a total of 200 non-linear dynamic analyses were carried out. For instance, Figure 12(a) shows the two selected site hazard curves in terms of mean annual frequency of exceedance (λ_{Sa}). Figure 12(b) shows the mean (pseudo-)acceleration elastic response spectra of

ground motions selected with a conditioning period $T = 0.5\ s$ and for each return period, T_R, considered in the analysis.

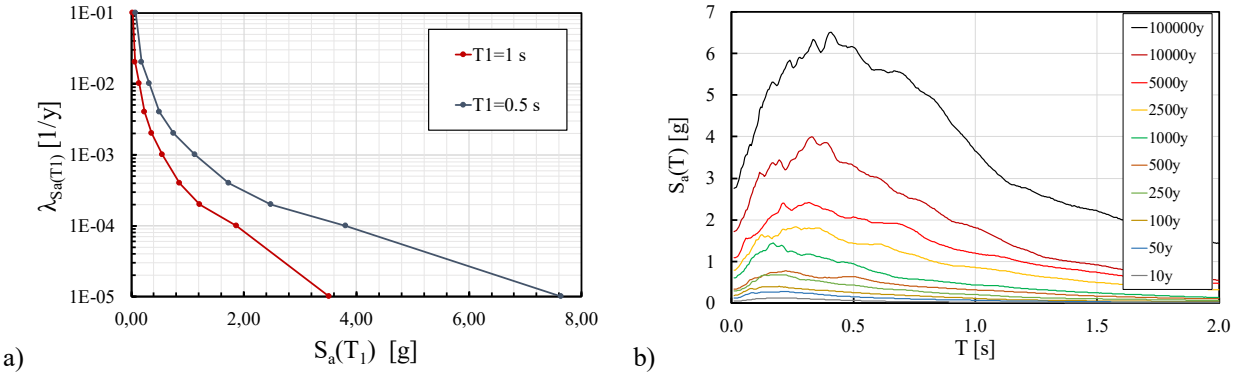

Figure 12: Seismic hazard: (a) Hazard curves for L'Aquila (Italy); (b) mean elastic acceleration response spectra for GMs selected with conditioning period T=0.5 s.

4.4.2. Multi-stripe analysis results

Using the selected ground motions, a multi-stripe dynamic analysis (MSA) was carried out [20]. Figure 13 summarizes the results in terms of relationship between IM and an engineering demand parameter (EDP), which was chosen to represent the global building response. For the transverse direction (X), the peak drift ratio ($d_{X,peak}/H$) among the five portals was selected as EDP. For the longitudinal direction (Y), the brace strain range ($\Delta\varepsilon_{peak}$) among the vertical braces and the anchors peak strain (ε_{peak}) were selected as EDPs, in order to check possibility to trigger steel fracture in braces or anchors. The results are shown for the BF model (Figure 13 (a), (b)), the SP model (Figure 13 (c), (d)), and the TS model (Figure 13 (e), (f)). The figures also report the various ultimate failure limits of the EDPs, as introduced previously.

The MSA of the bare frame model was already described by Cantisani *et al.* [14]. Results are reported here for comparison purposes. The figure shows the number of failure cases (if larger than 0) in a box for each value of IM. As shown in Figure 13, failure in the transverse direction starts to occur at IM = 6 (i.e., $T_R = 1000\ yrs$). Only one failure case was observed in the longitudinal direction due to brace fracture. No anchor fractured in the bare frame model.

Concerning the SP (Figure 13 (c), (d)) and TS models (Figure 13 (e), (f)), results essentially confirmed the pushover results, with ultimate failure cases predominantly occurring in the transverse direction, starting at IM = 6 (i.e., $T_R = 1000\ yrs$) and IM = 7 (i.e., $T_R = 10000\ yrs$) for the TS and SP models respectively. The SP model shows much less failure cases at IM = 7 and IM = 8, while there is practically no difference at IM = 9 and IM = 10. A small number ($\leq$3 for both models) of failures in the longitudinal direction were observed, but they only occurred at IM = 10, when also failure in the transverse direction takes place for any ground motions.

MSA results are reported in terms of peak strains in the column base anchors in Figure 14(a) and (b), for the SP and TS models respectively. Though there were no fractures predicted to occur in column base anchors, large ductility demand could occur, with values as high as 28% for one ground motion at IM=10.

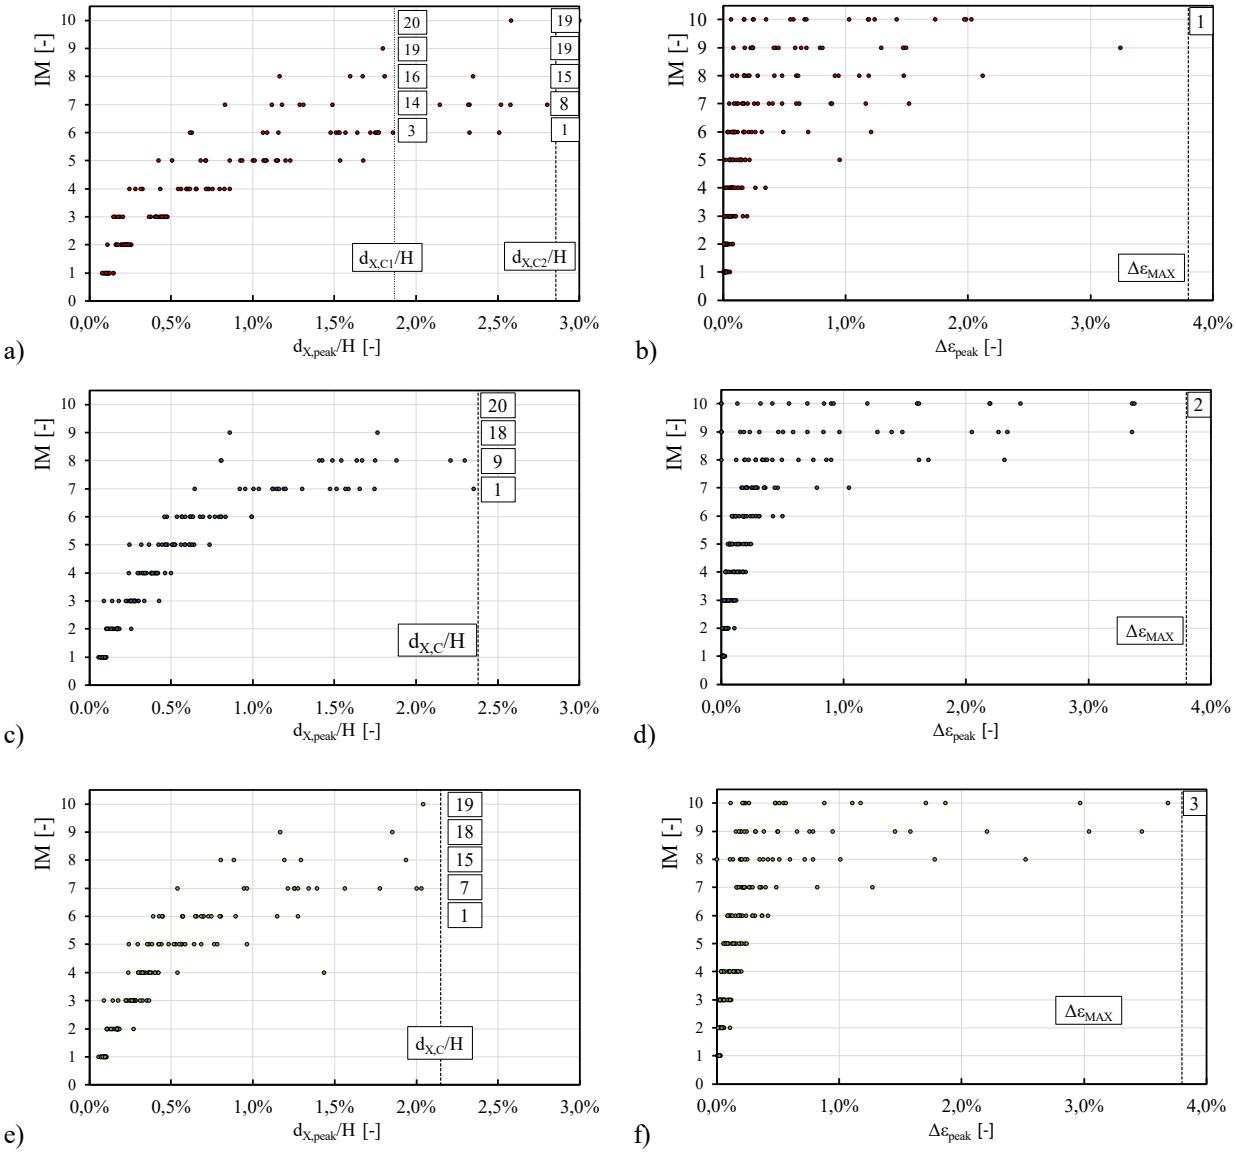

Figure 13: MSA results for the three models: (a) X-BF; (b) Y-BF; (c) X-SP; (d) Y-SP; (e) X-TS; (f) Y-TS.

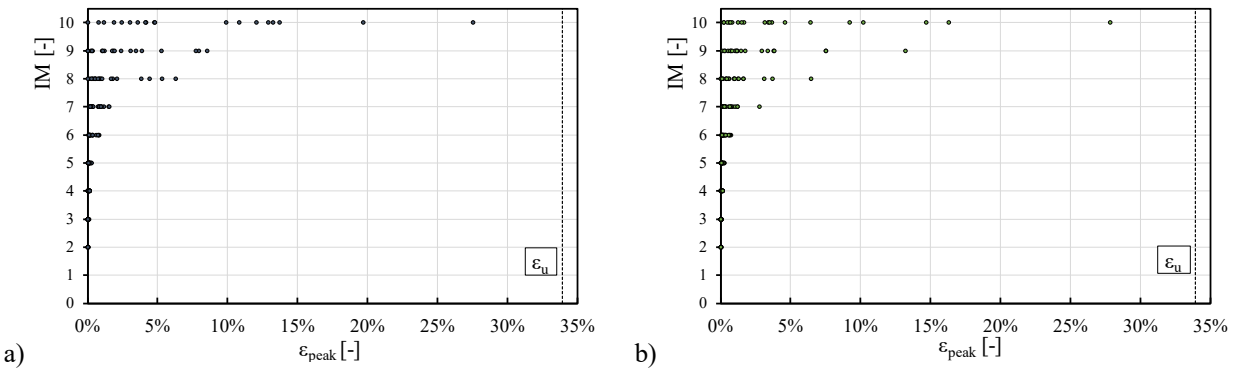

Figure 14: MSA results in terms of column base anchor peak strain: (a) SP model; (b) TS model.

Because of the bi-directional ground motion input, columns were subjected to axial forces and bi-directional bending moments, differently from the pushover analyses. For this reason, and for also investigating any potential difference in the dynamic response compared with the predictions from the static non-linear analysis, column buckling was checked step-by-step during post-processing of the numerical results. Figure 15 shows the peak demand over capacity ratio (*D/C*) for the columns in the SP model (Figure 15(a)) and TS model (Figure 15(b)). The Figure shows the results considering all the GMs at the last two stripes of the analysis (i.e., IM = {9,10}). Since columns were elastic elements in the model, three checks were necessary: (i) resistance check (labelled as *R*); (ii) in-plane buckling check (labelled as *IP*); out-of-plane buckling check (labelled as *OOP*). The member capacities for the *R*, *IP* and *OOP* failure modes were evaluated according to Eurocode 3 [9]. Looking at Figure 15, one can observe that there were no column failures in the SP model, while there was one failure case in the TS model (IM=10, GM=19). However, for this specific GM brace fracture anticipated column buckling. For both models, the ratio *D/C* varies in the range (0.4, 0.8), approximatively.

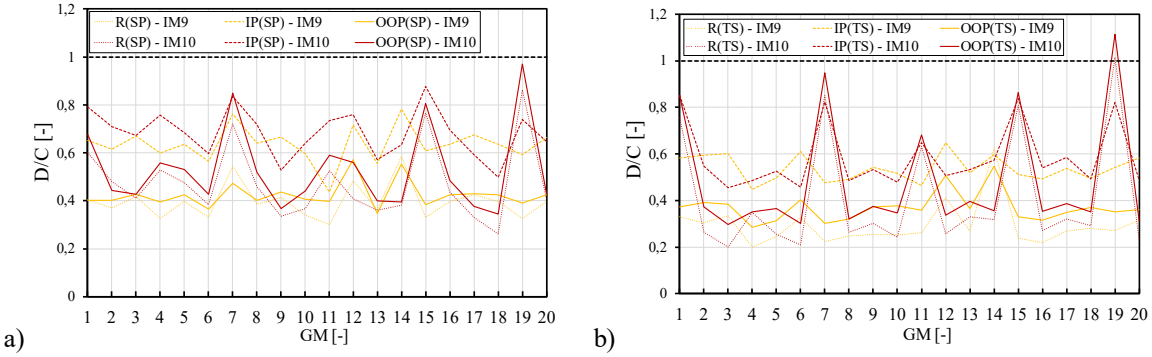

Figure 15: Demand-capacity ratio for columns: (a) SP model; (b) TS model

4.4.3. Model-to-model comparison

Figure 16 provides further comparison between the three analysed models. Figure 16(a) shows statistical comparison among the median values of the peak drift ratio demand ($(d_{X,peak}/H)_m$) in the transverse direction at each IM. IM levels at which global failures occurred (i.e., IM > 6) were discarded in this statistical analysis. The comparison in Figure 16(a) is in agreement with the comparison made by the pushover analysis: the two types of envelope panels shows reductions of displacements compared with the bare frame model in all the analysed intensity. Comparing the models with envelope, although median drift values were similar until IM=6, dispersion between SP and TS became different from IM>4. This assertion is discussed showing the coefficient of variation (*COV*) for the same data as a function of the IM parameter in Figure 16(b). Comparing the results from the two models with envelope panels (i.e., SP and TS plots in the figure), one can observe similar values of *COV* up to IM = 4, whilst the dispersion became larger for the TS model when yielding of TS started (i.e., IM > 5). It is worth noting that one GM at IM=4 for the TS model was excluded from the statistical analysis, because of the anomalously larger value of the peak drift demand in that case. Figure 16(c) summarizes the number of global failures observed for the three examined models as a function of the IM value. The better performance of the building with SPs compared with the BF model response is apparent. On the contrary, the building with TS had a response comparable to the BF model, except at very large IM values for which almost all the GMs produced global failure anyway. The relatively smaller increase in the lateral force resistance

provided by the selected trapezoidal sheeting, and the fact that the panel resistance was completely lost during severe earthquakes, could explain the observed response. Figure 16(d) shows the fraction of global failures (i.e., the ratio between the number of GMs producing global failure at a given IM and the total number of GMs considered) as a function of the $S_a(T_1)$ value. The median value of $S_a(T_1)$ to global failure is also highlighted in the figure. Although number of global failures is similar between the BF and TS models, differences in the hazard curves leads to significant differences in the median value of the first-mode spectral acceleration leading to failure.

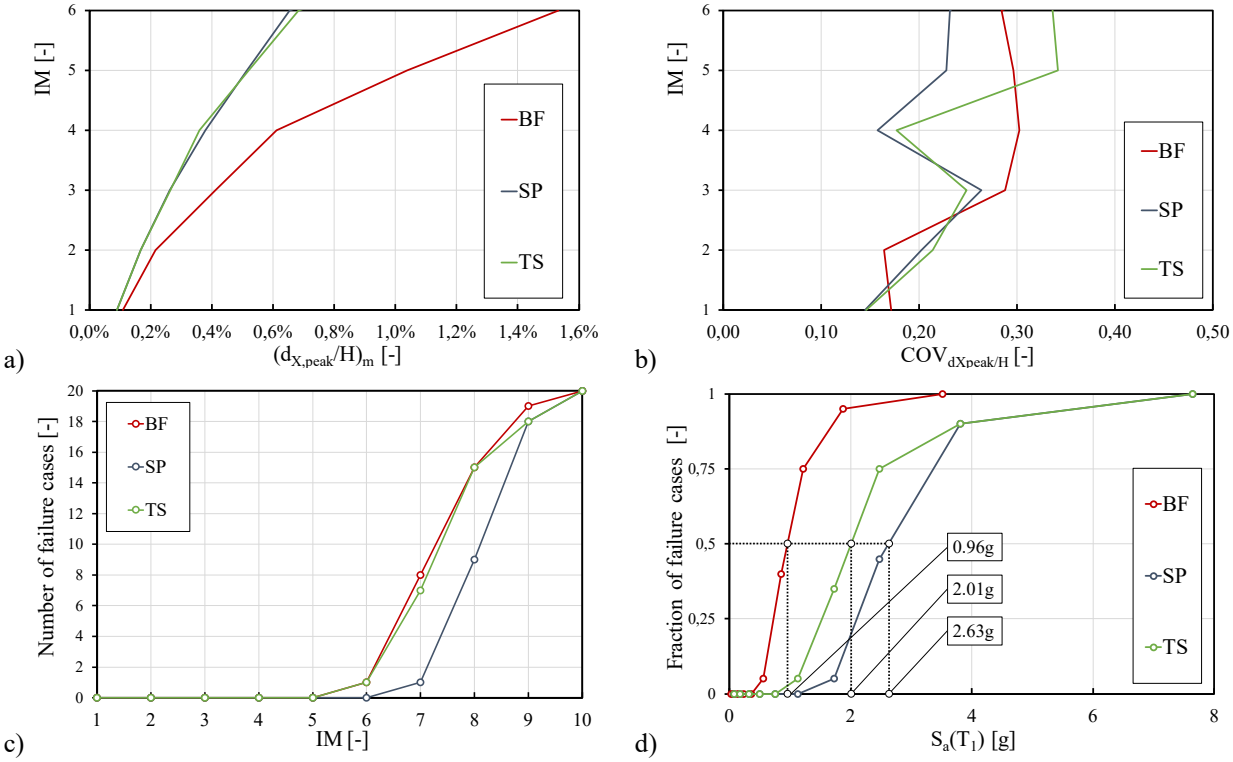

Figure 16: Model-to-model comparison in terms of (a) median peak drift and (b) COV, (c) failure cases and (d) median spectral acceleration that led to building failure.

4.4.4. Components response

This section highlights some aspects of local responses observed in the building components. To this end, Figure 17 shows a sketch of (i) the structural plan layout with a portion of a transverse elevation, (ii) one column where vertical braces are connected in the longitudinal direction, and (iii) a clos-up view of the corresponding column base joints. The sketch of structural layout highlights (i) the location of the transverse trusses (labelled as TR_i), (ii) the location of two critical truss-to-column connections (labelled as TCC_{iL} and TCC_{iR} in the figure), and (iii) the portal frame transverse displacements ($d_X(t)$). To describe the local response at the brace-column-foundation connections, the views on the braced column highlight (i) the column top displacement ($d_{Y,CTD}$) and the displacement of the node at the brace-to-column connection ($d_{Y,CD}$). Knowing these displacements, it is possible to identify the column relative displacement ($d_{Y,CRD}$). Finally, the close-up view of the column base highlights the force and displacement parameters used to describe the column base connection response.

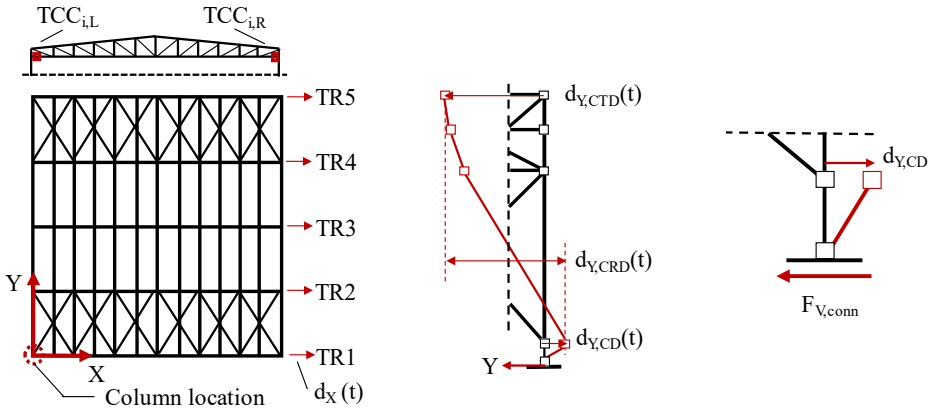

Figure 17: Sketch of trusses and column locations with identification of displacement components.

Figure 18(a) shows response histories of portal frame displacements. In the figure, TR_i identifies the i-th truss (Figure 17). The drift plotted in the figure is the mean value between the two columns for each portal frame. The assumed limit value of the drift for the ultimate failure is also indicated by a dashed line. As shown in the plot, similar drift values were observed among the five portals, especially when the limit value was reached. Figure 18(a) emphasizes the relatively brittle overall system response, with the five portal frames reaching almost simultaneously the limit corresponding to global failure. Divergence of the lateral displacement response at a time during the shaking is also apparent from the plot. This behaviour is further highlighted by the results plotted in Figure 18(b), showing the relationship between the drift of each portal frame and the corresponding shear force in the truss-to-column connections (forces labelled as F_{iL}, F_{iR} corresponding to TCC_{iL} and TCC_{iR} as shown in Figure 17). The figure clearly shows that all the connections reached their deformation capacity.

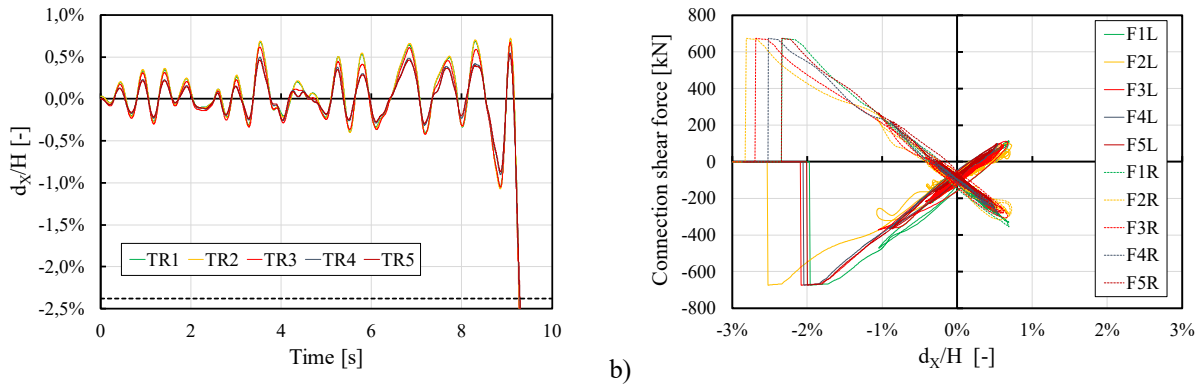

Figure 18: Sample time history response at IM10: (a) transverse drift; (b) forces on truss-to-column connections.

Figure 19(a) shows one sample response history for the column longitudinal displacements. The connection contribution to the column total displacement $d_{Y,CTD}$ was negligible in the first part of the response history, i.e. when the column base connection remained in the elastic range of response. When yielding of the column base connection started, a difference also started to develop between $d_{Y,CTD}$ and $d_{Y,CRD}$, i.e. a difference between total displacement at the column top cross section and column displacement relative to the base. The plot shows that $d_{Y,CRD}$ could either be smaller or larger than $d_{Y,CTD}$ depending on the response time. This behaviour can be explained because of the connection residual deformation that accumulated during the response history, as shown in Figure 19(b).

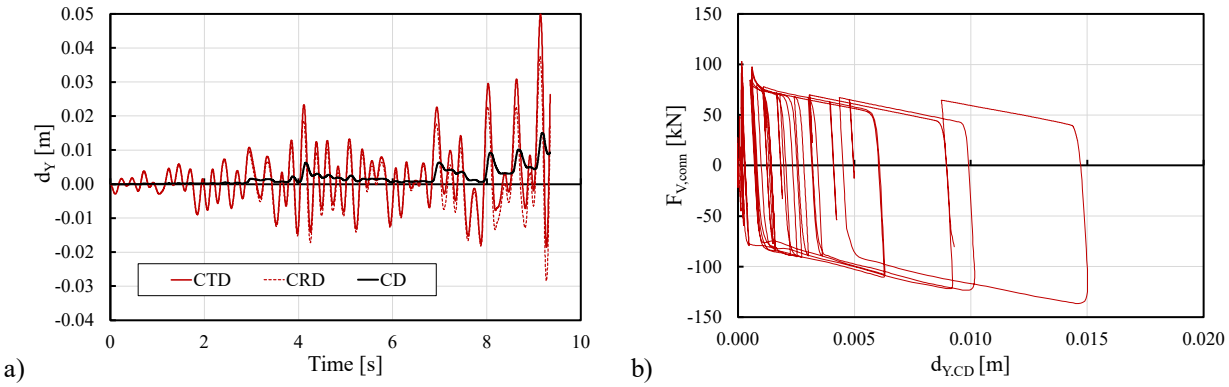

Figure 19: Sample time history at IM10: (a) effect of the column base connection displacements to the column displacement; (b) column base connection response.

5 CONCLUSIONS

This paper presented the results of an ongoing research project on seismic performance evaluation of existing non-residential single-story steel buildings in Italy. Non-linear static and dynamic analyses were carried out on a 3D finite element model of an archetype building. The following main conclusions could be drawn:

- Because of quasi-brittle shear failure of truss-to-column connections, the building response in the transverse direction was much less ductile than in the longitudinal direction. Consequently, global failure of the building was always governed by failures occurring in the trussed beams.
- The envelope panels provided significant benefits to the seismic structural performance. The two types of examined panels, i.e. sandwich panels and trapezoidal sheeting, provided significant increase of the initial lateral stiffness and resistance in the direction of the main portal frames. On the contrary, the effect was much smaller in the longitudinal braced frame direction.

Abstract

Current approaches for the seismic hazard assessment, are mainly based on the classical formulation of the probabilistic seismic hazard analysis, widely known with the acronym PSHA. This procedure is able to compute the annual rate of exceedance of a set of ground motion intensity measures at a site of interest. During years, several efforts were performed for understanding and including the influence of uncertainties underlying the PSHA calculation. PSHA integral is a correct application of the total probability theorem, but it does not account for the uncertainties in model parameters which can be significant, since most of times they are derived from historical data and/or statistical catalogues. For this reason, this work aims to develop a robust semi-analytical formulation, able to assess how uncertainties in model parameters influence the seismic hazard curve's reliability. The proposed mathematical procedure uses the reliability index and its standard deviation for computing a design hazard curve, whose points are characterized by a fixed accepted level of risk. Results show how uncertainties in model parameters affect the hazard curve's dispersion, and how a better parameters' knowledge allows defining lower design values, with the same assumed risk.

1 INTRODUCTION

Current approaches for the seismic hazard assessment, are mainly based on the classical formulation of the probabilistic seismic hazard analysis, widely known with the acronym PSHA**.** For its nature, PSHA deals with several sources of uncertainties and aims describing effects of stochastic and unpredictable events. For this reason, since its early beginning, several efforts have been made for guaranteeing that all uncertainty sources were correctly accounted for [1]. Usually, scientific literature subdivides uncertainties into two main types: aleatory uncertainty and epistemic uncertainty. The former is the variability naturally inherent to a physical phenomenon, while the latter is due to the limited knowledge about the true model describing the aleatory variability ([2], [3]). Currently, on of the most widely adopted strategy for addressing seismic hazard epistemic uncertainty is the so-called logic-tree approach [4]. In the logic-tree, every node represents a potential source of epistemic uncertainty, and the corresponding outcoming branches represent the possible alternatives. This approach is general and considers both the inter-model uncertainty, due to uncertainty in model parameters, and the inter-model uncertainty, due to the uncertainty among models. Despite its wide adoption in PSHA [5], the use of logic trees is often debated, and there are many potential pitfalls that should be considered [6], mainly due to the fact that two potential interpretation of the logic-tree are possible ([7], [8], [9], [10]). For an extended discussion on the subject the reader is referred to [11] and [12]. In any case, logic tree results strictly depend on how logic tree branches are populated and on the weight assigned on each branch. In this context, the present work wants to contribute to the discussion on the reliability of seismic hazard estimate. In particular, this contribution aims to develop a standardized robust semi-analytical formulation, able to assess the influence of all possible source on variability involved in the seismic hazard computation, by treating them as random variables. The proposed method needs a carefully election of the best functional forms to be adopted in the calculation but does not need the definitions of any branches or weights. The formulation herein presented allows thus computing a given quantile of the seismic hazard demand by treating model parameters as random variables. The required computational time is limited, since no sampling or distribution fitting is required.

2 PROPOSED FORMULATION

The proposed formulation introduces a further development to the classical PSHA formulation, that is able to consider the variability of the hazard curve arising from uncertainties in model parameters ([13], [14]). For this reason, only a brief presentation of the consolidated PSHA procedure will be provided in the following, leaving space to a complete and extensive explanation of the proposed method. Classical PSHA integral aims computing the annual rate of exceedance $\lambda_{\mathrm{IM}\geq\mathrm{im}}$ of a set of ground motion intensity measures IM at a site of interest with the following formula:

$$\lambda_{IM\geq im}=\sum_{i=1}^{n_{sources}} \nu_{m_{min,i}} \int_{m_{min,i}}^{m_{max,i}} \int_{0}^{r_{max,i}} P\left[IM\geq im|m,r\right] f_{M,i}\left(m\right) f_{R,i}\left(r\right) dr dm \tag{1}$$

where $\nu_{m_{min,i}}$ is rate of occurrence of earthquakes greater than a suitable minimum magnitude $m_{min,i}$ of the i^{th} seismogenic sources (SZ), $f_{M,i}\left(m\right)$ is the magnitude distribution for the i^{th} ZS and $f_{R,i}\left(r\right)$ is the distribution of the source i^{th} -to-site distance. The exceedance probability of a threshold *im*, given a magnitude *m* and a distance *r* is provided by $P\left[IM\geq im|m,r\right]$. Once

calculating $\lambda_{IM \geq im}$, using the Poissonian distribution it is possible to compute the probability of exceeding each ground motion level *im* in the next *T* years as

$$P\left[IM \geq im,T\right]=1-e^{-T\cdot\lambda_{IM\geq im}} \tag{2}$$

The exceedance annual rate computed in Eq. (1) depends on $v_{m_{min,i}}$ and on parameters which define $f_{M,i}(m)$, $f_{R,i}(r)$ and $f_{IM}(im)$ distributions; in the following, these model parameters are summarized in vector $\boldsymbol{\Theta}$. As a consequence, probability computed in Eq. (2), called in the following P_f (probability of failure), is function of *im*, *T*, and parameters $\boldsymbol{\Theta}$:

$$P\left[IM \geq im,T\right]=P_f\left(im,T,\boldsymbol{\Theta}\right)=1-e^{-T\cdot\lambda_{IM\geq im}(\boldsymbol{\Theta})} \tag{3}$$

Following Gardoni et al. [15] the solid line of Fig. 1 is a point estimate $\hat{P}_f(im,T)$ of P_f calculated by computing $P_f\left(im,T,\boldsymbol{\Theta}\right)$ at a point estimate of $\boldsymbol{\Theta}$ (i.e., $\boldsymbol{\Theta}=\hat{\boldsymbol{\Theta}}$, where $\hat{\boldsymbol{\Theta}}$ could be the mean or median of $\boldsymbol{\Theta}$), or the predictive estimate $\tilde{P}_f(im,T)$ of $P_f\left(im,T,\boldsymbol{\Theta}\right)$ computed as the expected value of over $\boldsymbol{\Theta}$ ($\tilde{P}_f(im,T)=\int P_f\left(im,T,\boldsymbol{\Theta}\right)f(\boldsymbol{\Theta})d\boldsymbol{\Theta}$). The risk-based hazard curve $P_{f,d}(im,T)$ (where *d* stands for design) is characterized by fixed accepted level of risk (Fig. 1); in other words, we want to define a quantile *q* such that the probability of having P_f bigger than $P_{f,d}$ due to uncertainties in model parameters it is equal to *q*; more formally

$$P\left[P_f\left(im,T,\boldsymbol{\Theta}\right)\geq P_{f,d}\left(im,T\right)\right]=q \tag{4}$$

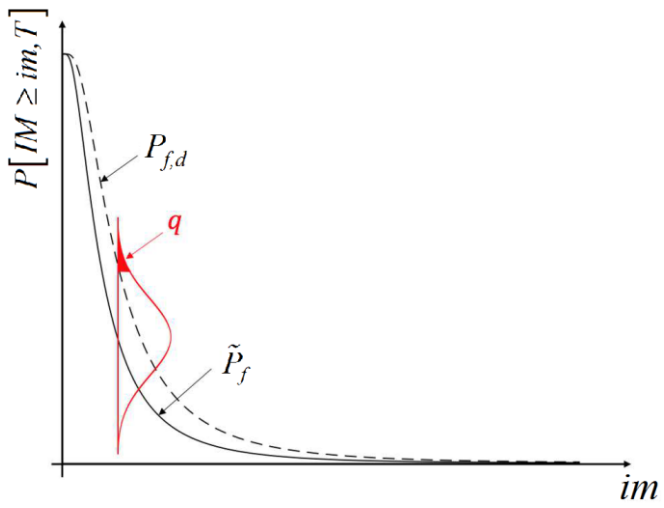

Figure 1: Definition of the $P_f\left(im,T,\boldsymbol{\Theta}\right)$ distribution, $\tilde{P}_f$, $P_{f,d}$ and *q*.

Since the exact evaluation of the $P_f\left(im,T,\boldsymbol{\Theta}\right)$ distribution requires nested calculation ([16]), this formulation adopts approximated quantile obtained by a first order analysis ([15]). The design failure probability $P_{f,d}$ can thus be obtained as

$$P_{f,d}\left(im,T\right)=\Phi\left[-\tilde{\beta}\left(im,T\right)+k\cdot\sigma_{\beta}\left(im,T\right)\right] \tag{5}$$

where $\Phi(\cdot)$ is standard normal cumulative function, $\tilde{\beta}(im,T)$ is the reliability index computed according to the definition of reliability index as $\tilde{\beta}(im,T)=\Phi^{-1}\left[1-\tilde{P}_f(im,T)\right]$ and $k\cdot\sigma_\beta(im,T)$ is the quantile of the distribution reflecting the assumed level of risk. Assuming β normally distributed, *k* is shown to be equal to:

$$k=\Phi^{-1}[1-q] \tag{6}$$

According to [16] the standard deviation of the reliability index σ_β can be computed by using a first order Taylor series expansion around the mean vector of the model parameters $\mathbf{M}_{\boldsymbol{\Theta}}$ as

$$\sigma_\beta{}^2(im,T)\approx\nabla_{\boldsymbol{\Theta}}\beta(im,T)^T\,\boldsymbol{\Sigma}_{\boldsymbol{\Theta}\boldsymbol{\Theta}}\nabla_{\boldsymbol{\Theta}}\beta(im,T) \tag{7}$$

where $\boldsymbol{\Sigma}_{\boldsymbol{\Theta}\boldsymbol{\Theta}}$ is the covariance matrix and contains the variances of the model parameters and their possible correlation. The gradient of β $\nabla_{\boldsymbol{\Theta}}\beta(im,T)$, is computed by applying the chain rule to the definition of reliability index as

$$\nabla_{\boldsymbol{\Theta}}\beta(im,T)=-\frac{1}{\varphi\left[\tilde{\beta}(im,T)\right]}\nabla_{\boldsymbol{\Theta}}P_f(im,T) \tag{8}$$

where $\varphi(\cdot)$ is the standard normal probability density function and $\nabla_{\boldsymbol{\Theta}}P_f(im,T)$ is the gradient column vector of $P_f(im,T,\boldsymbol{\Theta})$ evaluated in $\mathbf{M}_{\boldsymbol{\Theta}}$, that can be numerically computed with the definition of derivative as

$$\nabla_{\boldsymbol{\Theta}}P_f(im,T)=\left[\frac{P_f(im,T,\Theta+\delta\Theta)-P_f(im,T,\Theta)}{\delta\Theta}\right]_{\mathbf{M}_{\boldsymbol{\Theta}}} \tag{9}$$

3 CASE STUDY

The proposed formulation is applied to a case study, represented by a residential building structure (T = 50 years) located in Gemona (13.145, 46.288) and built on a soil-type C [17]. Two seismogenic zones SZs of the Italian source model are considered, SZ 904 and SZ 905 [18]. Main model parameters for each zone are derived from Barani et al. [19] and are reported in Tab. 1

	$m_{max,i}$	$m_{min,i}$	b_i	$v_{m_{min,i}}$
i = 1 – SZ 904	5.5	4.3	0.939	0.05
i = 2 – SZ 905	6.6	4.3	0.853	0.316

Table 1: Main parameters of each SZ.

Fig. 2 shows a map representing the site of interest and the considered seismogenic zones. Calculations are performed referring to two *IMs*, i.e. Sa (T = 0 sec.), the so-called Peak Ground Acceleration (PGA), and for Sa (T = 0.1 sec.). In this work, the ground motion prediction equation GMPE proposed by Bindi et al. [20] has been adopted.

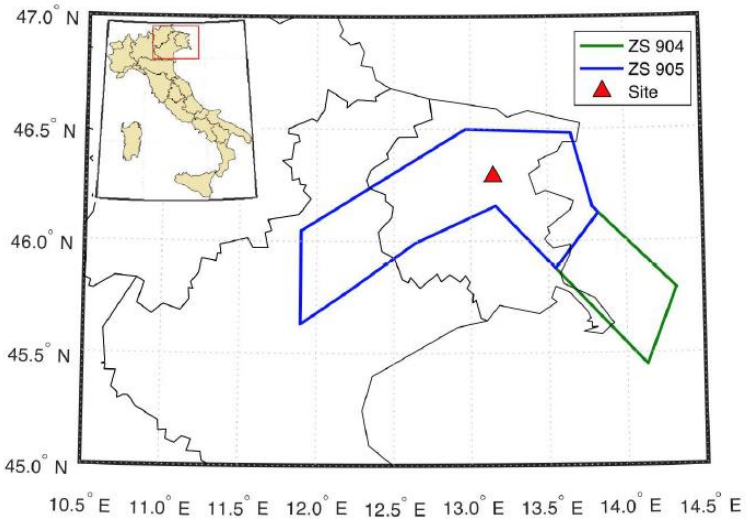

Figure 2: Site of interest and adopted SZs

The parameters that have been assumed as random are the G-R law parameters ($m_{max,i}$, $m_{min,i}$, b_i and $v_{m_{min,i}}$), and the main parameters contained in the adopted GMPE, i.e. e_1 that is the constant term of the regression, F_S and F_{sof} representing respectively the site amplification and the faulting mechanism, and σ_{tot} that is the standard deviation of the predicted *IM* logarithm. The final vector of model parameters $\boldsymbol{\Theta}$, is thus composed by the following 12 elements

$$\boldsymbol{\Theta}=\left[m_{max,1},m_{max,2},m_{min};b_1;b_2;v_{m_{min,i}};v_{m_{min,i}};e_1,F_S;F_{sof,1};F_{sof,2};\sigma_{tot} \right] \tag{9}$$

In this way, all the main possible sources of uncertainty, associated to model's parameters involved in the PSHA calculation, are considered. Table 2 lists the mean value and the standard deviation of each parameter, where the mean values are the elements of the vector $\mathbf{M}_{\boldsymbol{\Theta}}$, while the variances represent the diagonal term of the covariance matrix $\boldsymbol{\Sigma}_{\boldsymbol{\Theta\Theta}}$. For $m_{max,i}$, m_{min}, b_i, $v_{m_{min,i}}$ and σ_{tot}, a coefficient of variation $\delta=\sigma/\mu$ has been assumed, since no information on the parameters' standard deviation was available.

	$m_{max,1}$	$m_{max,2}$	b_i	b_i	$v_{m_{min,i}}$	$v_{m_{min,i}}$	m_{min}	σ_{tot}
μ	5.5	6.6	0.939	0.853	0.05	0.316	4.3	0.337
σ	0.55	0.66	0.0939	0.0853	0.005	0.0316	0.43	0.0337
δ = σ/μ	0.1	0.1	0.1	0.1	0.1	0.1	0.1	0.1
	e_1	F_S	$F_{sof,1}$	$F_{sof,2}$	e_1	F_S	$F_{sof,1}$	$F_{sof,2}$
	Sa (T = 0 sec.)				Sa (T = 0.1 sec.)			
μ	3.672	0.24	-0.0544	0.105	3.796	0.247	-0.0451	0.111
σ	0.316	0.0322	0.0355	0.0296	0.365	0.0357	0.0367	0.0351
δ = σ/μ	0.086	0.134	0.652	0.282	0.096	0.145	0.814	0.316

Table 2: Mean value and standard deviation of the adopted parameters.

Finally, two percentile values have been assumed $q=\{0.05,0.15,0.25\}$ corresponding to $k=\{1.64,1.04,0.67\}$; when q = 0.5, P_f is computed (Eq. (2)), without any further information related to parameter uncertainties (k = 0). When $k \approx \pm 1$ the approximate 15% and 85% per-

centile bounds of P_f are calculated. Fig. 3 shows results of the proposed formulation which allows characterizing P_f uncertainty and its distribution; each design hazard curve is characterized by a constant level of assumed risk q (for completeness also curves corresponding to (1- q) have been plotted). The two different spectral accelerations show a similar behavior; in particular, quantiles of Sa (T = 0.1 sec.) are less close, in absolute terms, to the hazard curve computed without considering parameters uncertainties.

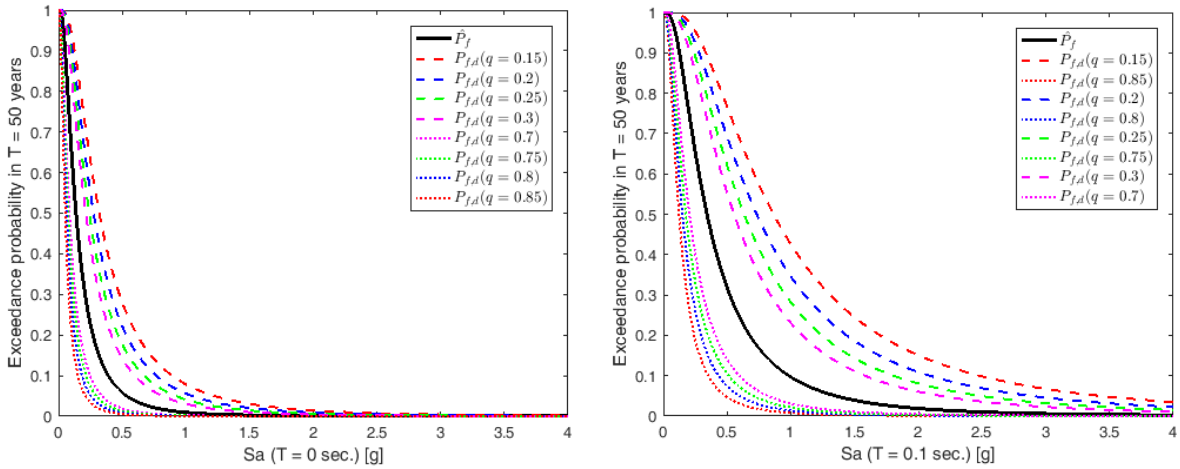

Figure 3: Hazard curve for different values of *q:* a) Sa (T = 0 sec.), b) Sa (T = 0.1 sec.).

For sake of completeness and for showing the influence of the covariance matrix, a smaller fictitious covariance matrix $\boldsymbol{\Sigma}_{\boldsymbol{\Theta\Theta}}^{\text{small}}$ is assumed with the coefficient of variation of all parameters equal to $\delta^{\text{small}} = \delta / 2$ representing a hypothetical case in which a more accurate knowledge of the distribution parameters is available. Table 3 lists the mean value and the standard deviation of each parameter adopted in this second case.

	$m_{max,1}$	$m_{max,2}$	b_i	b_i	$v_{m_{min,i}}$	$v_{m_{min,i}}$	m_{min}	σ_{tot}
μ	5.5	6.6	0.939	0.853	0.05	0.316	4.3	0.337
σ	0.275	0.330	0.047	0.043	0.003	0.016	0.215	0.017
δ = σ/μ	0.050	0.050	0.050	0.050	0.050	0.050	0.050	0.050
	e_1	F_S	$F_{sof,1}$	$F_{sof,2}$	e_1	F_S	$F_{sof,1}$	$F_{sof,2}$
	Sa (T = 0 sec.)				Sa (T = 0.1 sec.)			
μ	3.672	0.24	-0.0544	0.105	3.796	0.247	-0.0451	0.111
σ	0.158	0.016	0.018	0.015	0.182	0.018	0.018	0.018
δ = σ/μ	0.043	0.067	0.326	0.141	0.048	0.072	0.407	0.158

Table 3: Mean value and standard deviation of the adopted parameters.

Fig. 3 shows as that $P_{f,d}$ curves are closer to the one computed without considering parameters' variability. This behavior is clearly due to the lower uncertainty associate to the input parameters. In other words, a better initial knowledge allows considering a lower seismic hazard curve with the same assumed level of risk q.

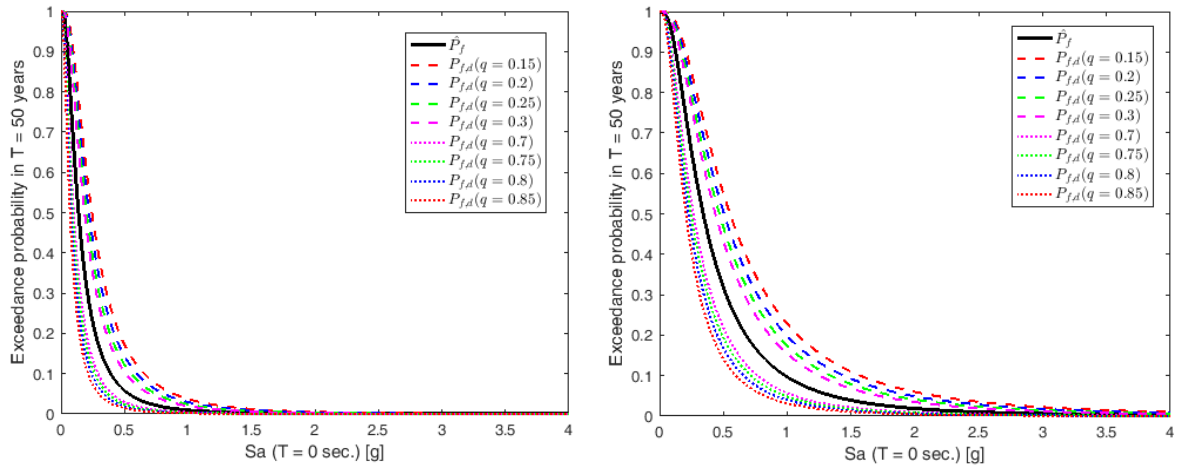

Figure 3: Hazard curve for different values of q computed with a reduced covariance matrix $\boldsymbol{\Sigma}_{\boldsymbol{\Theta\Theta}}^{\text{small}}$: a) Sa (T = 0 sec.), b) Sa (T = 0.1 sec.)

4 CONCLUSIONS

This work presented a mathematical formulation able to consider the effect of parameters' uncertainty, on the seismic hazard curve. In particular, a procedure for the seismic hazard computation based on a fixed level of risk was proposed. The proposed framework allows computing a specific target quantile of the hazard curve, by mean of an immediate semi-analytical procedure that does not need any sampling or distribution fitting. The formulation is general and flexible and can be easily extended to hazard curve obtained by considering the entire seismic sequence, with foreshocks and aftershocks. Furthermore, the proposed methodology is also an important knowledge tool, since it allows finding the most impacting parameter on final results without running extensive analysis.

SOIL NON-LINEARITY ON HIGH SPEED RAILWAY LINES

Abstract

Increases in operational train speed have resulted in an elevated probability that dynamic effects will occur inside the railway track and subgrade structure. This is problematic because it causes soil non-linearity, thus resulting in reduced soil stiffness. Therefore, this paper outlines a numerical semi-analytical frequency domain model to compute and analyse non-linear stiffness degradation below railway lines. An equivalent linear approach is used to incorporate non-linear stiffness and damping changes into a thin-layer element frequency-wavenumber domain formulation. The model is validated using published data and then used to analyse non-linearity. It is shown that non-linearity plays an important role in track-ground response, with track displacements increasing significantly in magnitude. It is also shown that the critical velocity can be reduced significantly, which is important because many high speed lines set their dynamic threshold at 70% of the linearly calculated value. Similar findings are made for track velocities and soil strain levels, thus indicating it is vital to consider soil non-linearity when modelling high speed rail track behaviour.

Keywords: Railway track dynamics, non-linear soil, thin-layer element method

1 INTRODUCTION

Operational railway speeds have increased over the past 40 years since the inception of high speed rail. This means it is increasingly likely that trains will induce high levels of dynamics within the track-soil structure. This occurs when the trains peed approaches the natural wave speeds of the track-ground system. The speed at which maximum dynamic amplification occurs is the 'critical velocity' ([1], [2]). This is undesirable because it is a safety risk, increases track degradation and can induce ground-borne vibration ([3],[4], [5]).

To analyze critical velocity, early approaches modelled the problem analytically [6]. Then, with the aim of simulating more complex ground conditions (e.g. layered soil), integral transform methods [7] were proposed. To allow for the track to also be modelled in a more detailed manner, 'two-and-a-half' dimensional models (2.5D) were also developed ([8], [9], [10]). These assumed the track was invariant in the direction of vehicle travel, thus allowing the problem to be discretized in 2D. This provided greater model flexibility, while maintaining a relatively low number of degrees of freedom.

The majority of railway vibration models are formulated in the frequency-wavenumber domain, meaning they are typically limited to considering linearly elastic material behavior. This assumption is suitable for many situations, however limits the analysis of non-linearity's such as wheel-rail contact ([11]) and soil stiffness degradation. Soil stiffness degradation is particularly important on heavy haul and high speed rail lines were the elevated loads and high speeds can cause high strain levels. These strains can then reduce the soil stiffness by a significant percentage, thus causing higher track deflections.

To include non-linear material effects, [1] manually adjusted the soil shear wave velocity at different speeds to account for the reduced stiffness effect. A challenge with this approach is that manually choosing stiffness' values is open to error and difficult to apply over multiple soil regions. Therefore [12], [13] proposed 3D time-domain constitutive non-linear time domain formulations and validated results against field data recorded in Sweden. A challenge with this approach is that such models are computationally intensive and often require a large number of material input properties that are challenge to quantify.

As an alternative, [14] proposed the use of a frequency-wavenumber domain 2.5D finite/infinite element model which although was linear, used an iterative procedure implement non-linearity. Again the model was compared to the data recorded in Sweden and strong agreement was found but with reduced run times compared to the 3D constitutive approach.

This paper builds upon this iterative linear equivalent approach. Instead of a 2.5D model though, a semi-analytical approach is preferred because it further reduces run times thus allowing for larger sensitivity studied to be performed. The track is modelled analytical while the soil is modelling using the thin-layer element method. It is validated and then used to make findings into the effect of non-linearity of dynamic amplification curves.

2 NUMERICAL MODEL

The model uses a semi-analytical method to compute vertical track deflections. It consists of an analytical track model, and a semi-analytical thin-layer element model for the soil. These sub-models are formulated in the frequency-wavenumber domain, and then coupled assuming a relaxed boundary condition at their interface. To do so, although the 2 models have different numbers of degrees of freedom, they are only coupled in the vertical direction. As will be shown, this approach produce accurate results, yet allows for the simulation of deep-wave propagation in an efficient manner [15].

2.1 Track model

The track is modelled upon a generic slab track, using springs for the railpads and beam elements for the rail and slab (Figure 1). The equations of motion are formulated in the wave-number-frequency domain and shown in Equation 1. Further details of the track formulation are found in [15].

$$\begin{bmatrix} EI_r k_x^4 + k_p^* - {}^2 m_r & -k_p^* \\ -k_p^* & EI_s k_x^4 + k_p^* - \omega^2 m_s + k_{eq} \end{bmatrix} \begin{Bmatrix} \tilde{u}_r(k_x,\omega) \\ \tilde{u}_s(k_x,\omega) \end{Bmatrix} = \begin{Bmatrix} \tilde{P}(k_x,\omega) \\ 0 \end{Bmatrix} \quad (1)$$

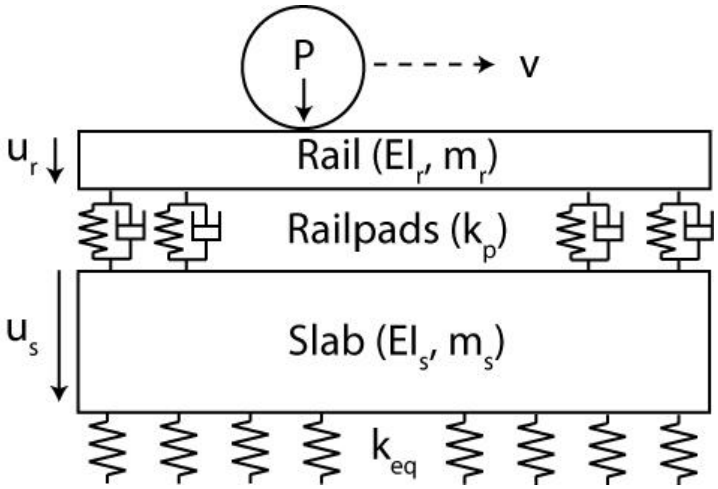

Figure 1: Track model

2.2 Ground model

The ground behavior is simulated using the thin-layer element method. First the soil stratum is discretized into a series of thin and horizontal elements, each with 3 nodes (Figure 2). This ensures that the stresses and strains are accurately reproduced, which is important for the linear equivalent updating procedure. Again, the equations of motion are formulated in the frequency-wavenumber domain as shown in Equation 2, where **K** and **M** are the global stiffness and mass matrices respectively, **U** is displacement, ω is frequency and **P** is the load.

$$([\mathbf{K}] - \omega^2[\mathbf{M}])\mathbf{U} = \mathbf{P} \quad (2)$$

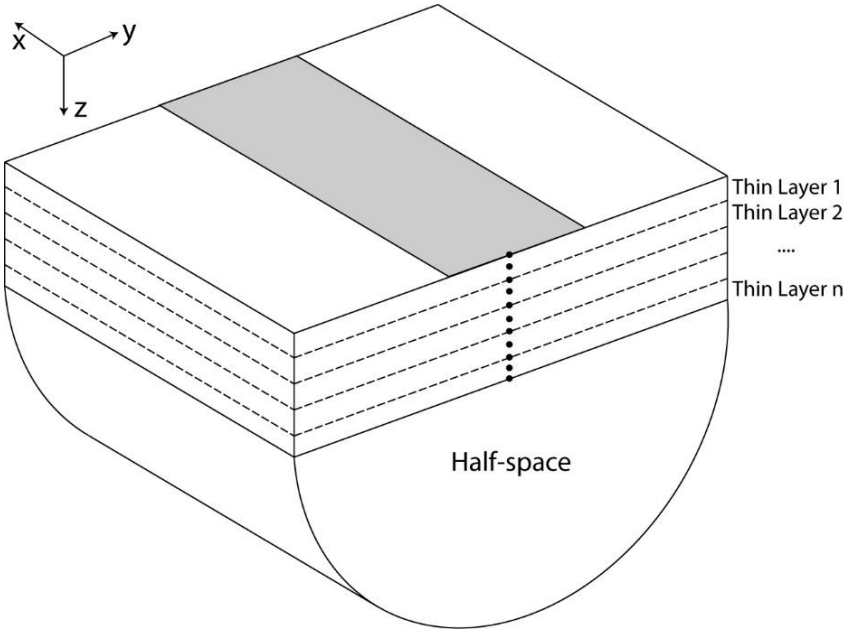

Figure 2: Soil model

2.3 Track-soil coupling

The track model and soil model are coupled using a frequency-wavenumber dependent stiffness. This is computed using the thin-layer method and assumes that there is an equilibrium of loads and a compatibility of displacements at the track-ground interface. It is important that the interaction across this boundary is accurately resolved because when the train speed nears the critical velocity there is very significant wave propagation within the soil stratum.

2.4 Linear equivalent implementation

At high train speeds, large strains can be induced in the underlying soil, causing a reduction in its stiffness, as illustrated in Figure 3. To capture this non-linear behaviour, a 'linear equivalent' approach is implemented.

This is useful because it can be implemented with frequency domain models, to approximate non-linear soil behavior in a much faster timeframe in comparison to time-domain constitutive models. By definition, it means that while the analysis remains linear, the soil properties are updated as function of the strain level, thus simulating non-linear type effects. It is implemented within the thin-layer formulation using the following steps:

- Low strain properties assumed for all thin-layer soil elements
- Strain time histories computed for all elements and determine effective octahedral shear strain values
- Use the maximum strain value to update the element stiffness, based upon stiffness-strain reduction curves (e.g. [14])
- Use the maximum strain value to update the element damping, based upon damping-strain reduction curves
- Repeat the above steps until convergence between consecutive iterations is below 3%

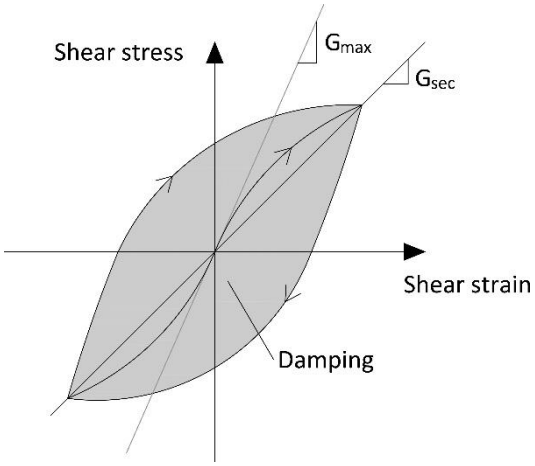

Figure 3: Stress-strain path

3 VALIDATION

The model was validated using field data recorded at Ledsgard, Sweden. This site was subject to large rail deflections and suspected high soil non-linearity during the passage of X2000 trains shortly after opening. This occurred because the track was constructed over soft ground, with a sandwiched layer of uncharacteristically soft organic clay. The detailed track and ground properties, including soil degradation curves, are given in [14], [16] and [17].

Figure 4 shows the time history response of the field the TLM signals at a train speed of 70 km/h. It is seen that the numerical model replicates the field result accurately in terms of magnitude and shape. The same is true for the faster speed of 180km/h, which is shown in Figure 5. Additional speeds were also computed with similar findings. Therefore is was concluded that the model was able to accurately predict track response in the presence of non-linear soil behavior.

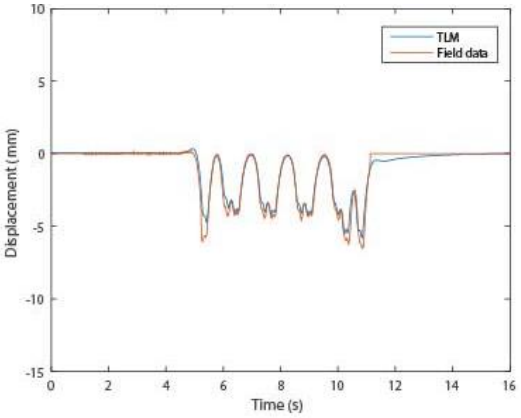

Figure 4: Displacement time history at 70km/h

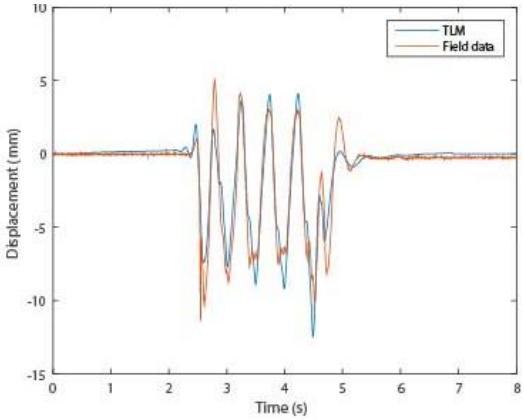

Figure 5: Displacement time history at 180km/h

4 NUMERICAL ANALYSIS

To investigate the role of soil non-linearity on high speed lines in more depth, an infinitely deep, homogenous soft soil was analysed. It had a small-strain stiffness of 45MPa, a Poisson's ratio of 0.35, a density of 1800kg/m^3 and damping of 0.03. The stiffness and damping degradation curves were identical to those used for the validation case. The vehicle was a single 18 tonne axle load moving at speeds ranging between 10-140m/s.

Figure 6 shows the rail dynamic amplification curve across the full speed range. It is seen that the linear and linear-equivalent curves have similar shape. The linear response yields lower displacements at the majority of speeds, except around its critical velocity peak at 90m/s. Further, the linear equivalent case has 29% higher maximum rail deflections compared to the linear case. Also, the critical velocity for the non-linear case reduces by 21% compared to the linear case. Both the change in deflection magnitude and critical speed are due to the drop in soil stiffness below the moving load, thus allowing the track to deflect more. However, it should be noted that the result is for a single wheel and that non-linearity is highly sensitive to multiple-wheel spacing and loading magnitude.

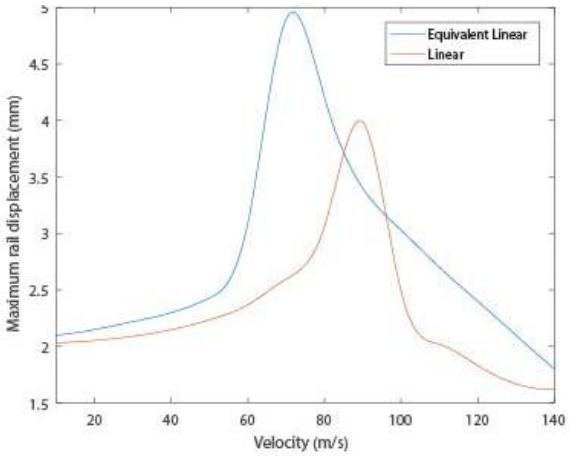

Figure 6 – DAF curves for linear and non-linear behavior

Finally, Figure 7 shows the effect of vehicle speed on strain levels with depth. Two speeds are shown: 10m/s (well below the critical speed) and 70m/s (at the linear equivalent critical speed). It is seen that the maximum strains occur for both speeds close to 1m below

the soil surface. However, at all depths, the maximum octahedral strains are significantly lower for the linear case. This is the primary cause of the reduction of soil stiffness and the ultimate increase in rail deflections.

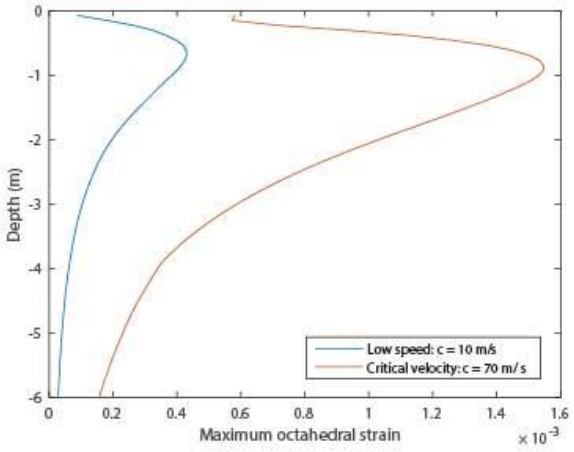

Figure 7 – Strain versus depth for linear and non-linear behavior

5 CONCLUSIONS

This paper presented a wavenumber-frequency domain model to predict railway track displacements in the presence of non-linear soil stiffness degradation. Analytical expressions were used for the track and the soil was simulated using the thin-layer method. Linear equivalent soil behavior was implemented using an iterative procedure where the soil strains were calculated during train passage and then used to update the stiffness and damping material properties. The model was validated using field data collected on a railway line with high non-linearity in Sweden. Finally, the model was used to investigate the effect of non-linearity on a homogenous half-space. It was found that the linear equivalent approach showed yielded significantly higher deflections compared to the linear case and that the critical speed was also lower.

Keywords: Soil-Structure Interaction (SSI), Wave Propagation Theory, Hybrid frequency–time domain (HFTD), Nonlinear Soil, 3D Effects, Integral Transform Method (ITM)

Abstract. *The simulation of the behavior of soil-structure interaction (SSI) systems subjected to seismic waves can be conveniently carried out in the frequency domain, to account for the frequency-dependent properties of the infinite soil. However, the soil exhibits nonlinear behavior even at small values of the strain level, so that its shear modulus and damping ratio vary as a functions of the strain. It is important to consider the strain- and frequency-dependent properties of the soil in a seismic SSI simulation. Since frequency domain (FD) analyses are not suitable for nonlinear systems, time domain (TD) integration algorithms are commonly adopted. An accurate way of including the frequency-dependent soil into a transient analysis is to use convolution integrals, which requires linearity of the system and leads to a high computational cost. Hybrid frequency–time domain (HFTD) methods represent an efficient alternative. Most of the existing HFTD methods idealize the soil behavior according to the one-dimensional (1D) wave propagation theory, which is a major simplification of the complex three dimensional (3D) theory.*

In this contributions we present a HFTD method, where the soil is described as a 3D continuum governed by Lamé's equation of elastodynamics and the problem is solved with the integral transform method (ITM). The shear modulus and the damping of the soil are nonlinear functions of the strain level. The seismic waves (the loading) can be represented by spatial waves with an arbitrary distribution in time and space. The response of the soil to the seismic waves is first solved in the FD assuming a linearized elastic soil subjected to input waves, the response is transformed into the TD and the maximum strain is evaluated at different depths. According to the maximum strain, the shear modulus and the damping at different depths is updated and the process is iterated until convergence. The proposed method is compared to the reference 1D nonlinear method and it is applied for a multi-dimensional analysis of a nonlinear soil. The limitations of the method are also described.

1 INTRODUCTION

Structures and the underlying soil can exhibit nonlinear behavior during strong earthquakes. Nonlinearities can arise in the structure, in the soil, or/and at the interface between structure and soil (i.e. base isolation, uplift). In order to simulate the nonlinear interaction between the soil and the structure during a seismic event, transient analyses in the time domain are necessary. It is common to use discretized numerical models for simulating structural problems in civil engineering; in particular, the finite element method (FEM) is the most established approach, thanks to its suitability for nonlinear and anisotropic materials.

However, the FEM fails to represent the real endless dimension of the soil because the energy cannot be transported to infinity. A possible solution is to enlarge the soil domain and move its boundary away from the structure at a sufficient distance. This leads to a model with a large number of elements, for which the run time becomes prohibitive.

Another complex aspect of nonlinear seismic analysis is the correct estimation of the seismic loads, which do not act directly on the structures but result from the spatial and temporal variation of the seismic displacement field. The latter, in turn, can be influenced by the foundation and the structure. This aspect must be taken into account when selecting the analysis method.

In the past decades, much effort has been made in order to find valid alternatives to the classical FEM representation for nonlinear soil-structure interaction (SSI) problems. The different methods can be classified into two main groups: direct methods and substructure methods. In both cases the aim is to overcome the difficulty of modeling the unbounded domain of the soil, accounting for the radiation conditions at infinity and the nonlinearities of the system due to seismic events.

In the direct methods, the structure and part of the soil near the foundation (near field) are modeled using the same technique, usually the FEM. In order to satisfy the radiation condition, mathematical artifacts at the boundary of the soil's near field must be added. These are called transmitting boundaries (TB) and are local approximations of boundary conditions (local in time and space) and their coefficients are frequency-independent. Direct methods can account for nonlinearities in the structure as well as in the soil's near field and can be solved using direct time integration methods such as central difference method or Newark method. The soil's far field is assumed to remain linear. Applications of direct methods can be found in [8]. The direct method for nonlinear SSI system is computationally demanding.

The substructure methods involve the application of different techniques for different parts of the systems and their coupling at the interaction surfaces. Usually the FEM is used for the structure and a different numerical method is used for the soil. If nonlinearities occur, the soil model must be defined in the TD and this would involve convolution integrals. In this case, the SSI boundary conditions are global in time and space, as they require the information of all the time steps from the beginning and all the degrees of freedom (DoF) at the substructure interface. Substructure methods can account for nonlinearities in the structure as well as at the soil-structure interface, whereas the soil is assumed to remain linear. A classical reference for the theory of substructure methods is Wolf [23]. An example of application can be found in [18].

Alternatives to transient analysis are the hybrid time-frequency domain (HTFD) approaches, where the system of equations is solved iteratively transforming back and forth from the TD to the FD and vice versa. The existing HFTD methods assume the soil approximated as a one-dimensional system (either as a compressional bar for P-waves or as a shear beam for S-waves).

In this contribution we present an extension of the HTFD, where the three-dimensionality

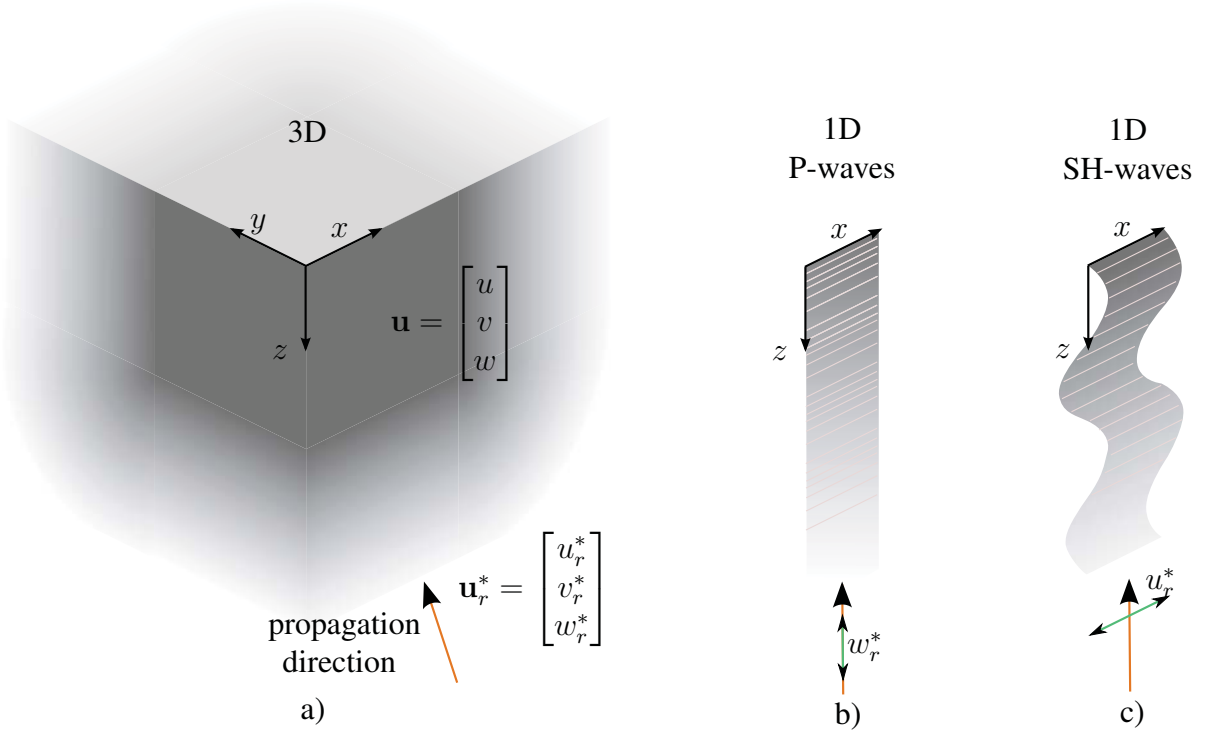

Figure 1: a) 3D free field, b) 1D representation of the free field subjected to P-waves, c) 1D representation of the free field subjected to S-waves.

of the problem can be account for and the solution is found iteratively using both time- and frequency-domain results. The focus in on the nonlinear response of the free field and the equations are derived only for the nonlinear soil. However, a coupling to a nonlinear structure using transfer functions is straightforward.

2 THREE-DIMENSIONAL PROPAGATION OF SEISMIC WAVES

Let us first analyze a linear isotropic soil. The propagation of seismic waves through the soil can be described using the theory of elasticity applied to a three dimensional homogenous half space. Different forms of waves (shear, compressional and *Rayleigh* waves) can propagate simultaneously, generating a complex three dimensional displacement field $\mathbf{u}$. In seismic analysis it is of interest 1) how the soil amplifies or de-amplifies the signal as the waves propagate through the medium towards the structure, and 2) how its flexibility influences the overall dynamic response of the structure. For both aspects, the extent of the effects depends on the properties of the soil and on the frequency content and spatial distribution of the seismic excitation. The propagation of seismic waves through a non-homogenous half space is even more complicated, because of additional *Stoneley* waves, *Lov*e waves and evanescent modes.

The problem is shown in Fig. 1a and can be described with the *Lamé* equation in index notation:

$$G u^i|_j^j + (\lambda + G) u^j|_j^i - \rho \ddot{u}^i = 0 \quad \text{with} \quad i, j = x, y, z \tag{1}$$

where $u^x = u$,$u^y = v$ and $u^z = w$ are the componenet of the displacement vector $\mathbf{u}$, ρ is the soil mass density, λ and G are the *Lamé*-constant and can be estimated from the *Youngs*'s modulus

E and *Poisson*'s ratio ν:

$$G = \frac{E}{2(1+\nu)} \quad \text{and} \quad \lambda = \frac{\nu E}{(1+\nu)(1-2\nu)} \quad . \tag{2}$$

The *Lamé* equation, Eq. (1), is defined in the original space (x, y, z, t) and is valid for a linear elastic isotropic and homogeneous continuum. Using the *Helmholtz* decomposition and a threefold *Fourier* transformation one obtains a system of four decoupled ordinary differential equations which can be solved with an exponential approach in the image space (k_x, k_y, z, ω) [4]. This approach is referred to as integral transform method (ITM). The solution expressed in terms of potentials $\bar{\phi}$ and $\bar{\psi}_i$ reads:

$$\begin{aligned} \bar{\phi}(k_x, k_y, z, \omega) &= A_1 e^{\lambda_1 z} + A_2 e^{-\lambda_1 z} \\ \bar{\psi}_i(k_x, k_y, z, \omega) &= B_{i1} e^{\lambda_2 z} + B_{i2} e^{-\lambda_2 z} \quad \text{with} \quad i = x, y, z \end{aligned} \tag{3}$$

$$\text{with} \quad \lambda_1 = -i\sqrt{\frac{\omega^2}{c_p^2} - k_x^2 - k_y^2} \quad ,$$

$$\lambda_2 = -i\sqrt{\frac{\omega^2}{c_s^2} - k_x^2 - k_y^2} \quad , \tag{4}$$

$$k_p = \frac{\omega}{c_p} \quad \text{and} \quad k_s = \frac{\omega}{c_s}$$

where c_p and c_s are the compressional and shear wave velocity respectively and k_x and k_y are the horizontal wave numbers. One can demonstrate that the potential $\bar{\psi}_z$ can be set to zero, still maintaining the complete correct 3D solution [6]. The displacements in the image space can be obtained as:

$$\bar{\mathbf{u}} = \begin{pmatrix} \bar{u} \\ \bar{v} \\ \bar{w} \end{pmatrix} = \underbrace{\begin{bmatrix} ik_x & ik_x & 0 & 0 & -\lambda_2 & \lambda_2 \\ ik_y & ik_y & \lambda_2 & -\lambda_2 & 0 & 0 \\ \lambda_1 & -\lambda_1 & -ik_y & -ik_y & ik_x & ik_x \end{bmatrix}}_{\boldsymbol{K}_{\bar{\mathbf{u}}}} \underbrace{\begin{pmatrix} A_1 e^{\lambda_1 z} \\ A_2 e^{-\lambda_1 z} \\ B_{x1} e^{\lambda_2 z} \\ B_{x2} e^{-\lambda_2 z} \\ B_{y1} e^{\lambda_2 z} \\ B_{y2} e^{-\lambda_2 z} \end{pmatrix}}_{\boldsymbol{c}} \tag{5}$$

where the vector $\boldsymbol{c}$ contains the 6 unknown coefficients of the solution. The stresses can be estimated and expressed as:

$$\begin{pmatrix} \bar{\sigma}_x \\ \bar{\sigma}_y \\ \bar{\sigma}_z \\ \bar{\sigma}_{xy} \\ \bar{\sigma}_{yz} \\ \bar{\sigma}_{zx} \end{pmatrix} = G \underbrace{\begin{bmatrix} -(2k_x^2 + \frac{\lambda}{G}k_p^2) & -(2k_x^2 + \frac{\lambda}{G}k_p^2) & 0 & 0 & -2ik_x\lambda_2 & 2ik_x\lambda_2 \\ -(2k_y^2 + \frac{\lambda}{G}k_p^2) & -(2k_y^2 + \frac{\lambda}{G}k_p^2) & 2ik_y\lambda_2 & -2ik_y\lambda_2 & 0 & 0 \\ 2k_r^2 - k_s^2 & 2k_r^2 - k_s^2 & -2ik_y\lambda_2 & 2ik_y\lambda_2 & 2ik_x\lambda_2 & -2ik_x\lambda_2 \\ -2k_xk_y & -2k_xk_y & ik_x\lambda_2 & -ik_x\lambda_2 & -ik_y\lambda_2 & ik_y\lambda_2 \\ 2ik_y\lambda_1 & -2ik_y\lambda_1 & \lambda_2^2 + k_y^2 & \lambda_2^2 + k_y^2 & -k_xk_y & -k_xk_y \\ 2ik_x\lambda_1 & -2ik_x\lambda_1 & k_xk_y & k_xk_y & -(\lambda_2^2 + k_x^2) & -(\lambda_2^2 + k_x^2) \end{bmatrix}}_{\boldsymbol{K}_{\bar{\boldsymbol{\sigma}}}} \boldsymbol{c} \tag{6}$$

with

$$k_r^2 = k_x^2 + k_y^2 \tag{7}$$

In short notation, we can write:

$$\begin{aligned} \bar{\mathbf{u}} &= \boldsymbol{K}_{\bar{\mathbf{u}}}\boldsymbol{c} \quad , \\ \bar{\boldsymbol{\sigma}} &= \boldsymbol{K}_{\bar{\sigma}}\boldsymbol{c} \quad . \end{aligned} \tag{8}$$

The two matrices $\boldsymbol{K}_{\bar{\mathbf{u}}}$ and $\boldsymbol{K}_{\bar{\sigma}}$ depend on the excitation circular frequency ω, the soil material and the horizontal wave numbers k_x and k_y. Based on given boundary conditions at certain z-coordinates the unknown coefficients vector $\boldsymbol{c}$ can be found.

The application of the the material law delivers the strain components in the original space :

$$\begin{aligned} \sigma_x &= \lambda\widehat{\varepsilon} + 2G\varepsilon_x & \tau_{xy} &= \tau_{yx} = G\gamma_{xy} \\ \sigma_y &= \lambda\widehat{\varepsilon} + 2G\varepsilon_y & \tau_{yz} &= \tau_{zy} = G\gamma_{yz} \\ \sigma_z &= \lambda\widehat{\varepsilon} + 2G\varepsilon_z & \tau_{zx} &= \tau_{xz} = G\gamma_{zx} \end{aligned} \tag{9}$$

with

$$\widehat{\varepsilon} = \varepsilon_x + \varepsilon_y + \varepsilon_z \quad . \tag{10}$$

Adding σ_x, σ_y and σ_z, $\widehat{\varepsilon}$ is estimated as:

$$\widehat{\varepsilon} = \frac{\sigma_x + \sigma_y + \sigma_z}{3\lambda + 2G} \quad . \tag{11}$$

The strain components ε_x, ε_y and ε_z result from inserting Eq. (11) into Eq. (9). The three shear strain components γ_{xy}, γ_{yz} and γ_{zx} can be estimated directly from the respective shear stress through division by the shear modulus G. Thus, a matrix formulation of the stress-strain relationship reads:

$$\underbrace{\begin{pmatrix} \varepsilon_x \\ \varepsilon_y \\ \varepsilon_z \\ \gamma_{xy} \\ \gamma_{yz} \\ \gamma_{zx} \end{pmatrix}}_{\boldsymbol{\varepsilon}} = \underbrace{\begin{bmatrix} \frac{1}{2G}(1 - \frac{\lambda}{3\lambda+2G}) & -\frac{1}{2G}\frac{\lambda}{3\lambda+2G} & -\frac{1}{2G}\frac{\lambda}{3\lambda+2G} & 0 & 0 & 0 \\ -\frac{1}{2G}\frac{\lambda}{3\lambda+2G} & \frac{1}{2G}(1 - \frac{\lambda}{3\lambda+2G}) & -\frac{1}{2G}\frac{\lambda}{3\lambda+2G} & 0 & 0 & 0 \\ -\frac{1}{2G}\frac{\lambda}{3\lambda+2G} & -\frac{1}{2G}\frac{\lambda}{3\lambda+2G} & \frac{1}{2G}(1 - \frac{\lambda}{3\lambda+2G}) & 0 & 0 & 0 \\ 0 & 0 & 0 & \frac{1}{G} & 0 & 0 \\ 0 & 0 & 0 & 0 & \frac{1}{G} & 0 \\ 0 & 0 & 0 & 0 & 0 & \frac{1}{G} \end{bmatrix}}_{\boldsymbol{K}_{\varepsilon\sigma} = \boldsymbol{K}_{\bar{\varepsilon}\bar{\sigma}}} \underbrace{\begin{pmatrix} \sigma_x \\ \sigma_y \\ \sigma_z \\ \sigma_{xy} \\ \sigma_{yz} \\ \sigma_{zx} \end{pmatrix}}_{\boldsymbol{\sigma}} \tag{12}$$

The assumption of linearized elastic material allows the application of the material law also in the image space. Thus,

$$\begin{aligned} \boldsymbol{K}_{\varepsilon\sigma} &= \boldsymbol{K}_{\bar{\varepsilon}\bar{\sigma}} \quad \text{and} \\ \bar{\boldsymbol{\varepsilon}} &= \boldsymbol{K}_{\bar{\boldsymbol{\varepsilon}}\bar{\boldsymbol{\sigma}}}\bar{\boldsymbol{\sigma}} \quad . \end{aligned} \tag{13}$$

Combining Eq. 8 and Eq. 13, the relationship between the strains $\bar{\boldsymbol{\varepsilon}}$ and the vector of the unknowns coefficients $\boldsymbol{c}$ is established:

$$\bar{\boldsymbol{\varepsilon}} = \underbrace{\boldsymbol{K}_{\bar{\boldsymbol{\varepsilon}}\bar{\boldsymbol{\sigma}}}\boldsymbol{K}_{\bar{\boldsymbol{\sigma}}}}_{\boldsymbol{K}_{\bar{\boldsymbol{\varepsilon}}}}\boldsymbol{c} \quad . \tag{14}$$

For a layered half space with N isotropic layers, the system of equations is obtained by overlapping the matrices of the adjacent layers and by enforcing continuity and equilibrium

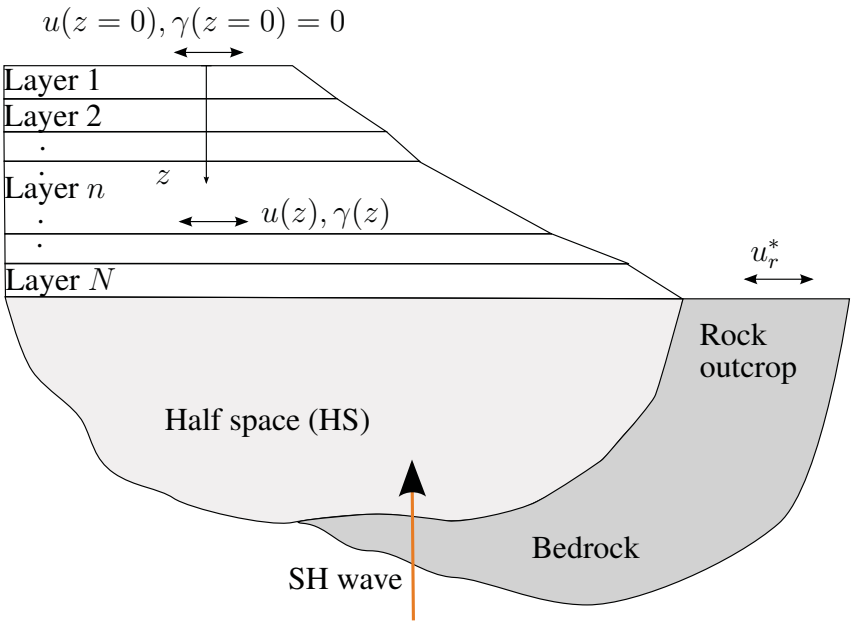

Figure 2: One-dimensional representation of the load application for a seismic analysis of the free field.

at their interfaces. If at the base of the layers there is a bedrock, a fixed boundary condition is enforced at the base and the system has $6N$ unknowns. If the layers are underlain by an homogenous half space, the radiation condition must be satisfied and the system has 6(N-1)+3 unknowns.

The unknowns are found with the additional boundary conditions concerning the load. For a free field (soil without a coupled structure) subjected to a seismic excitation, one of the boundary conditions is the zero-stress condition at the surface. A further boundary condition is the equilibrium of stresses at the location where the seismic excitation is applied, which leads to a condition between stresses and displacements at that location and therefore to the remaining unknowns of the problem.

The definition of the seismic input and its location depends on the available information about the seismic event and on the aim of the analysis. In this contribution, according to Kausel [11][1], we assume that the seismic input is known in form of a motion $\mathbf{u}_r^*$ at the rock outcrop, which is the surface of the rock without taking into consideration the layers (see Fig. 2).

If at the base of the layers there is a bedrock, $\mathbf{u}_r^*$ can be directly used as a root-point-excitation condition, after transformation into the image space. If the layers are underlain by an homogenous half space, equivalent seismic stresses are computed according to Kausel [11] and applied at the interface between half space and layers.

Once the problem is solved in the image space, the solution is transformed back into the original space for further calculations (see Fig. 3). In the following paragraphs, $\bar{...}$ indicates the quantity in the image space.

2.1 Three-Dimensional Transfer Functions for the Free Field

Using the ITM, it is possible to express the relationship between various response parameters of the soil, such as displacements, velocities, accelerations, stresses and strains, and an input motion parameter such as the bedrock displacement vector $\mathbf{u}_r^*$. This relationship is referred

[1]Pages 356-357

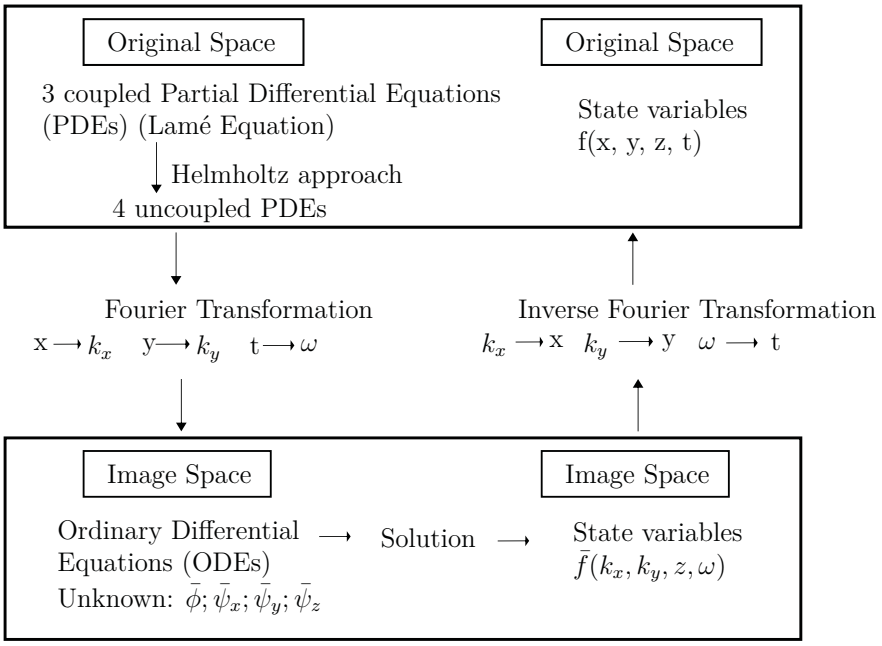

Figure 3: Integral transform method for the solution of the *Lamé* equations.

to as transfer function. This paragraph explains how to obtain the three-dimensional transfer functions for the displacements and the formulation is shown for a single stratum with thickness h subjected to input motions, to maintain clarity. The same procedure can be applied to any arbitrary horizontally layered soil over a bedrock or an elastic half space.

For a stratum subjected to input motions at the bedrock level, the boundary conditions are:

- BC 1: zero stresses at the soil surface
  $\rightarrow [\bar{\sigma}_z(k_x, k_y, z = 0, \omega), \bar{\sigma}_{yz}(k_x, k_y, z = 0, \omega), \bar{\sigma}_{zx}(k_x, k_y, z = 0, \omega)]^T = [0, 0, 0]^T$,
- BC 2: the displacements at the interface bewteen bedrock and stratum are given
  $\rightarrow [\bar{u}(k_x, k_y, z = h, \omega), \bar{v}(k_x, k_y, z = h, \omega), \bar{w}(k_x, k_y, z = h, \omega)]^T = [\bar{u}_r^*, \bar{v}_r^*, \bar{w}_r^*]^T$,

which lead to the following expression:

$$\begin{pmatrix} A_1 \\ A_2 \\ B_{x1} \\ B_{x2} \\ B_{y1} \\ B_{y2} \end{pmatrix} = \left[\underbrace{G \begin{bmatrix} 2k_r^2 - k_s^2 & 2k_r^2 - k_s^2 & -2ik_y\lambda_2 & 2ik_y\lambda_2 & 2ik_x\lambda_2 & -2ik_x\lambda_2 \\ 2ik_y\lambda_1 & -2ik_y\lambda_1 & \lambda_2^2 + k_y^2 & \lambda_2^2 + k_y^2 & -k_xk_y & -k_xk_y \\ 2ik_x\lambda_1 & -2ik_x\lambda_1 & k_xk_y & k_xk_y & -(\lambda_2^2 + k_x^2) & -(\lambda_2^2 + k_x^2) \\ ik_xe^{\lambda_1 h} & ik_xe^{-\lambda_1 h} & 0 & 0 & -\lambda_2 e^{\lambda_2 h} & \lambda_2 e^{-\lambda_2 h} \\ ik_ye^{\lambda_1 h} & ik_ye^{-\lambda_1 h} & \lambda_2 e^{\lambda_2 h} & -\lambda_2 e^{-\lambda_2 h} & 0 & 0 \\ \lambda_1 e^{\lambda_1 z} & -\lambda_1 e^{-\lambda_1 h} & -ik_ye^{\lambda_2 h} & -ik_ye^{-\lambda_2 h} & ik_xe^{\lambda_2 h} & ik_xe^{-\lambda_2 h} \end{bmatrix}}_{\boldsymbol{K}_{BC}} \right]^{-1} \begin{pmatrix} 0 \\ 0 \\ 0 \\ \bar{u}_r^* \\ \bar{v}_r^* \\ \bar{w}_r^* \end{pmatrix} \tag{15}$$

The coefficients A_1, A_2, B_{x1}, B_{x2}, B_{y1}, B_{y2} are then introduced in Eq. 8 to find the displacements and stresses in the image space. Finally, the inverse *Fourier* transformation leads to the spatial and temporal distribution of the ground motions due to the input motions $\mathbf{u}_r^*$. Because both input $\mathbf{u}_r^*$ and output $\mathbf{u}$ have three components and each component depends on the position in space and time, it is not possible to establish a simple definition for the three-dimensional transfer functions, which usually relate scalar values.

However, for the method proposed in this contribution, it is necessary to choose a representative value of the strain vector for each horizontal plane in the middle of each layer, which will be used in the nonlinear material model. This can be done either observing a specific point of horizontal coordinate $\widehat{x}$ and $\widehat{y}$ or using a spatial averaging method to estimate a representative value.

In order to overcome this difficulty, in most studies on free field response analysis, a major assumption is commonly adopted: the seismic input was generated far enough from the area of interest, so that the wavefront can be considered plane and all the point in the horizontal plane moves in phase and experience the same motion. In the image space, this condition is represented by a function which is equal to zero everywhere except for k_x=k_y=0. In this special case, Eq. 5 and Eq. 15 shows that $\bar{u}$ only depends on A_1 and A_2 (related to $\bar{\Phi}$, P-waves), which in turn only depend on u_r^*, so that a straightforward definition for the transfer function u/u_r^* is possible. Analogously, this apply for v/v_r^* and w/w_r^*. This means that for k_x=k_y=0, the three dimensional problem can be treated as a one dimensional problem, where each component of the displacement vector can be treated independently.

2.2 One-Dimensional Transfer Functions for the Free Field

Under the assumption of a plane horizontal wavefront (k_x=k_y=0), the problem in x-direction is uncoupled from the problem in y- direction and the axial and shear motions do not affect each other. Fig. 1b and Fig. 1c shows that, in 1D, P-waves and SH-waves can be treated separately and the vertical and horizontal transfer functions for a layered soil, $w(z)/w_r^*$ and $u(z)/u_r^*$ respectively, can be computed independently at different soil depths. The transfer functions are defined in frequency domain and take into account the frequency-dependent steady-state response of the 1D free field.

We consider a soil made up of N layers with thickness h_n, shear wave velocity $c_{s,n}$, shear modulus G_n and density ρ_n underlain by a homogenous half space, subjected to a SH-wave. The transfer functions $\boldsymbol{F}_1$ for the displacements, evaluated at the top of each layer, are obtained using the stiffness matrix of the soil $\boldsymbol{K}$:

$$\boldsymbol{F}_1(\omega) = \begin{pmatrix} u_1/u_r^* \\ u_2/u_r^* \\ u_3/u_r^* \\ \dots \\ u_n/u_r^* \\ u_r/u_r^* \end{pmatrix} = \boldsymbol{u}_{1D}/u_r^* = \boldsymbol{K}^{-1} \begin{pmatrix} 0 \\ 0 \\ 0 \\ \dots \\ 0 \\ K_{HS} \end{pmatrix} \tag{16}$$

where $\boldsymbol{K}$ is the stiffness matrix of the layered soil and K_{HS}=$i\omega\rho_{HS}c_{s,HS}$ is the stiffness of the underlying half space. The dependency on the circular frequency ω is omitted for clarity.

This transfer matrix can be applied also to estimate the velocity at different z-coordinates:

$$\frac{\dot{\boldsymbol{u}}_{1D}}{\dot{u}_r^*} = \frac{i\omega\boldsymbol{u}_{1D}}{i\omega u_r^*} = \frac{\boldsymbol{u}_{1D}}{u_r^*} = \boldsymbol{F}_1 \tag{17}$$

For the purposes of this contribution, it is necessary to define a second transfer function type, $\boldsymbol{F}_2$, which estimates the shear strain transfer functions w.r.t the velocity of the seismic excitation $\dot{u}_r^*$. This transfer function $\boldsymbol{F}_2$ is obtained from the relationship between shear strains and displacements:

$$\boldsymbol{\gamma}_{1D} = \boldsymbol{F}_{\boldsymbol{\gamma}\mathbf{u}}^{1D}\boldsymbol{u}_{1D} \tag{18}$$

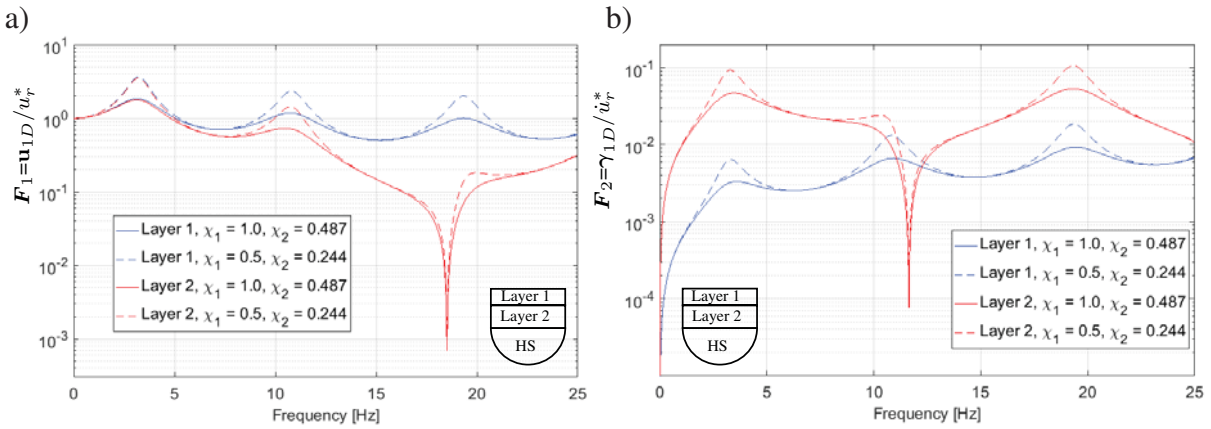

Figure 4: a) Displacement transfer function $\boldsymbol{F}_1$ and b) strain transfer functions $\boldsymbol{F}_2$, for the soils investigated in paragraph 2.3.

where the matrix $\boldsymbol{F}^{1D}_{\boldsymbol{\gamma}\mathbf{u}}$ of the N-layered soil system reads:

$$\boldsymbol{F}^{1D}_{\boldsymbol{\gamma}\mathbf{u}} = \begin{bmatrix} -F_1 & F_{12} & 0 & ... & 0 & 0 \\ -0.5F_{12} & 0.5(F_1-F_2) & 0.5F_{23} & 0 & ... & 0 \\ 0 & -0.5F_{23} & 0.5(F_2-F_3) & 0.5F_{34} & ... & 0 \\ ... & ... & ... & ... & ... & ... \\ 0 & ... & ... & -0.5F_{N-1,N} & 0.5(F_{N-1}-F_N) & 0.5F_{N,N+1} \\ 0 & ... & ... & 0 & -0.5F_{N,N+1} & 0.5(F_N+F_{HS}) \end{bmatrix} \tag{19}$$

with

$$\begin{aligned} n_n &= \omega/c_{s,n} \\ F_n &= n_n cot(n_n h_n) \quad \text{and} \quad F_{n,n+1} = n_n sin^{-1}(n_n h_n) \\ F_{HS} &= \frac{K_{HS}}{G_{HS}} = \frac{i\omega\rho_{HS}c_{s,HS}}{G_{HS}} \end{aligned} \tag{20}$$

Inserting Eq. (17) in Eq. (18), the functions $\boldsymbol{F}_2$ can be obtained from the functions $\boldsymbol{F}_1$:

$$\begin{aligned} &\boldsymbol{\gamma}_{1D} = \boldsymbol{F}^{1D}_{\boldsymbol{\gamma}\mathbf{u}}\mathbf{u}_{1D} = \boldsymbol{F}^{1D}_{\boldsymbol{\gamma}\mathbf{u}}\frac{1}{i\omega}\dot{\boldsymbol{u}}_{1D} = \boldsymbol{F}^{1D}_{\boldsymbol{\gamma}\mathbf{u}}\frac{1}{i\omega}\boldsymbol{F}_1\dot{u}_r^* = \boldsymbol{F}_2\dot{u}_r^* \\ \rightarrow &\boldsymbol{F}_2 = \boldsymbol{\gamma}/\dot{u}_r^* = \boldsymbol{F}^{1D}_{\boldsymbol{\gamma}\mathbf{u}}\frac{1}{i\omega}\boldsymbol{F}_1 \end{aligned} \tag{21}$$

The 1D transfer functions are a special case of the 3D relationships between input and output. It can be demonstrated that the 1D transfer functions $\boldsymbol{F}_1$ and $\boldsymbol{F}_2$ can be obtained from the 3D procedure described in paragraph 2.1 by setting k_x=k_y=0.

2.3 Example: 1D Linear Transfer Function of a Layered Soil

This example shows the transfer functions for a layered soil both in terms of $\boldsymbol{F}_1$ and $\boldsymbol{F}_2$. The investigation is carried out for two different soils, both made up of two undamped layers underlain by an elastic half space. The displacements transfer functions $\boldsymbol{F}_1$ are evaluated at the top surface of each layer, while the strain transfer functions $\boldsymbol{F}_2$ are evaluated at the center of each layer.

For both soils, the two layers have different thicknesses and shear velocities but same mass density:

- Thickness h_1 = 2.1336 m and h_2 = 3.9624 m
- Mass density $\rho_1 = \rho_2$ = 1922 kg/m^3
- Shear wave velocity $c_{s,1}$ = 158 m/s and $c_{s,2}$ = 0.488 $c_{s,1}$ = 77 m/s

The ratios χ_i, which relate the impedance of the layers with the impedance of the half space, vary according to Tab. 1. Fig. 4 shows the linear transfer functions and the influence of the ratios χ_i on the amplification effect of the soil layering on the seismic input.

	$\chi_1 = \frac{\rho_1 c_{s,1}}{\rho_{HS} c_{HS}}$	$\chi_2 = \frac{\rho_2 c_{s,2}}{\rho_{HS} c_{HS}}$
Soil 1 (continuous lines in Fig. 4)	1.0	0.488
Soil 2 (dashed lines in Fig. 4)	0.5	0.244

Table 1: Impedance ratios for the soils investigated in paragraph 2.3.

3 NONLINEAR SOIL BEHAVIOUR

Experiments and past seismic events have shown that the soil material behaves non linearly when the strain exceeds 10^{-5}, which is often the case during strong earthquakes [20, 3]. Adequate three-dimensional models for the description of the inelastic soil behavior are still under investigation today (for example in [15]). The salient characteristics of the behavior of the material is the degradation of the stiffness and the increasing dissipation with increasing strain. Fig. 5 shows typical degradation curves for the shear modulus G normalized to the maximum shear modulus G_0 and for the hysteretic damping ξ as a function of the cyclic strain γ for sand material. The gray areas are the envelopes of experimental data according to [14], which show the influence of the confining pressure p and of the void ratio e on the degradation curves.

The most common models are based on the one-dimensional wave propagation theory and consider only one stress and one strain component at a time. Most of these models assume the behavior to be rate independent and fully characterized by the initial loading curve, or backbone. The most widely used stress-strain constitutive law is the Masing's rule [17]. This model assumes that unloading and reloading paths are scaled and/or inverted replicas of the initial stress–strain path for monotonic loading. In this model, when unloading or re-loading, the history of some or all of the reversal points must be tracked, so that when an unloading or re-loading episode intersects a previously taken path, that previous path is reestablished. Hence, this nonlinear model has memory of the previous strain history, but the path does not depend on the deformation speed. One can simulate any rate-independent, inelastic material obeying Masing's rule by means of a set of elasto-plastic springs in parallel [10]. The implementation of this model is much easier than the one for a non-linear backbone where many reversal points need to be tracked [7]. Other 1D models are the hyperbolic model [21] and the Ramberg-Osgood [19, 16] model and more recent extensions of them, e.g. [5]. These assume that the stress-strain curve is independent of the cycle number, the void ratio, the confining pressure and the sand type.

In this contribution, we focus on the Assimaki et al. model [2], called MITS1, which is defined by 4 parameters and gives the strain-dependent values for the shear modulus and the hysteretic damping (or material damping) and takes into account the confining pressure.

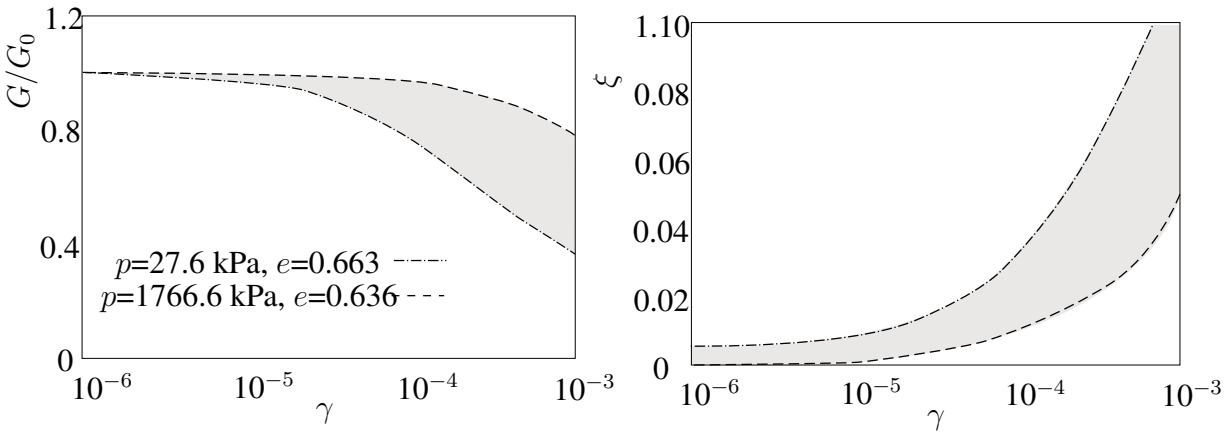

Figure 5: Experimental evidences of the dependency of the shear modulus G and of the material damping ξ on the strain γ, the confining pressure p and on the void ratio e (adapted from [2]).

Furthermore, to obtain a scalar measure of the shear deformation on a given point from the 3D strain vector, we use the octahedral shear strain [9]:

$$\gamma_{\text{oct}} = \frac{2}{3}\sqrt{(\varepsilon_x - \varepsilon_y)^2 + \varepsilon_y - \varepsilon_z)^2 + (\varepsilon_z - \varepsilon_x)^2 + 6\gamma_{xy}^2 + 6\gamma_{yz}^2 + 6\gamma_{zx}^2} \tag{22}$$

where ε_i are the normal strains and γ_i are the shear strains. This value is used as a reference for the degradation curves of the material model. It is important to notice that, if only shear strains in one direction would occur (ε_x=ε_y=ε_z=γ_{xy}=γ_{yz}=0, $\gamma_{zx} \neq$0), the octahedral shear strain γ_{oct} does not coincide with the 1D shear strain γ_{zx} (γ_{oct}=1.63γ_{zx}).

4 1D HFTD Method

When a nonlinear constitutive material for the soil is assigned to the model, a time-integration algorithm is necessary, because the properties of the soil depends on the strain and the model must be updated at each time step. This task is computationally demanding and produces a large database of transient signal, which are difficult to interpret. An alternative to time integration schemes are the hybrid frequency-time domain (HFTD) methods, which assume a linearized material and solve the problem iteratively.

In the one dimensional case, the HFTD method involves the following steps:

1. discretize the soil in N thin numerical layers;
2. assume initial linearized soil parameters;
3. evaluate the strain spectrum $\bar{\gamma}_n(\omega)$ at the center of each n-th numerical layer using the transfer functions $\boldsymbol{F}_2$, described earlier;
4. transform the response back into the time domain $\gamma_n(t)$ and evaluate the maximum of the signals;
5. for each layer, use this maximum to scale the strain spectrum, obtaining an effective strain spectrum $\bar{\gamma}_{n,\text{eff}}(\omega)$;
6. for each frequency ω of the spectrum, read the effective spectral strain value $\bar{\gamma}_{n,\text{eff}}(\omega)$ and use the constitutive laws (for example the hyperbolic model or the MITS1 model) to update the shear modulus $G_n(\bar{\gamma}_{n,\text{eff}}(\omega))$ and the material damping $\xi_n(\bar{\gamma}_{n,\text{eff}}(\omega))$;

7. repeat the analysis until the maximum of the strain of two subsequent analysis converge.

With these procedure the frequency- and amplitude-dependent nature of the strains is approximated, which in turn requires the model's material to be frequency-dependent.

The effective strain spectra obtained in step 5 can be smoothed before using the strain value in the constitutive laws, in order to obtain a more stable iterative algorithm. The HFTD procedure presented by Kausel et al. [12] is summarized in Fig. 6.

4.1 Example: 1D HFTD Analysis of a Nonlinear Stratum

As an example, a layer underlain by a bedrock (a stratum) is computed considering a linear and a nonlinear material. The soil properties are taken from [12]-Example 1. The total depth h of the stratum is 25 m, the density ρ is 2000 kg/m^3, the shear velocity c_s 200 is m/s and the material damping ξ_s is 5%. The nonlinear behavior follows the material model MITS1 [2]. The stratum is subjected to a transient signal of the Kobe Earthquake scaled to a maximum acceleration of 0.5g. The physical layer is discretized into 10 numerical layers and the exponential smoothing technique described in Fig. 6 is used.

Fig. 7a shows the influence of the nonlinearity on the displacement transfer function $\boldsymbol{F}_1(\omega)$ evaluated at the surface. In the nonlinear case, the amplitudes of the peaks are decreased and the peaks for the first three resonances occur at lower frequencies then in the linear case. Fig. 7b,c and d show the spectrum of the strains at the center of the top layer, the transient accelerations and the transient displacements at the surface respectively, for the linear and non linear case.

Several alternative smoothing functions can be used to improve the method. Kwack et al. [13] compared different smoothing techniques found in literature. Wang and Zhao [22] proposed a smoothing method based on a moving average method and a different scaling technique for the computation of the effective strain. Fig. 8 shows the influence of the different smoothing techniques for the effective strain (Fig. 8d) on the converged results, e.g. on the accelerations of the free field at the surface (Fig. 8a) and on the displacement transfer functions (Fig. 8b). The moving average method (MAM) gives the most stable and realistic results.

Fig. 8c shows the frequency-dependent behavior of the material parameters for the MITS1 model using different smoothing techniques, evaluated at the center of the physical layer. It can be observed that the shear modulus is strongly degraded at low frequencies. The opposite applies to the hysteric damping, which decreases strongly at high frequencies. This is also confirmed in Fig. 9, where the distribution of the material properties with depth is shown for different frequencies, for the converged solution.

Fig 10 shows a validation of the 1D HFTD method against a fully transient nonlinear analysis carried out with the aid of a series of elasto-plastic springs, according to the *Ivan*'s Model [11][2]. The comparison shows the great agreement between the two approaches, confirming the suitability of the hybrid method.

5 3D HFTD Method

All the existing studies on HFTD methods for the SSI simulations neglect the effects of the three dimensions of the system and focus only on one strain component at time. Therefore, we propose to extend the HFTD methods by computing the three dimensional strains for the free field and iteratively solve the problem analogously to the 1D procedure. Fig. 11 shows the proposed algorithm for the 3D HFTD methods. The main difference between the 1D and the

3D lies on the computation of the strains: in the 1D case, the strains at different depths in the free field are obtained through the 1D transfer functions $\boldsymbol{F}_2$ according to Eq. (21); in the 3D case, the strains are obtained with the ITM according to Eq. (13).

In the 3D HFTD method, it is possible to consider a complex spatial distribution of the input at the rock outcrop or at any point of the soil. Consequently, also the displacements and strains become a function of the coordinates x, y and z. These can be used to update the soil properties locally, thus obtaining a non-homogenous anisotropic soil. However, one of the assumption of the ITM method is that the soil has the same properties in x-direction and y-direction and that the properties in z-direction are homogenous within each horizontal layer. Therefore, for the iterative part of the method, we approximate the 3D strain distribution through a distribution which is constant for each horizontal layer and the reference strain vector $\boldsymbol{\varepsilon}_n$ for each layer n corresponds to the octahedral shear strain evaluated at the coordinate z_n (depth of the center of each layer), $\widehat{x}$ and $\widehat{y}$ (horizontal coordinate of the evaluation points, e.g. directly underneath the potential structure coupled to the free field). With the components of the reference strain vector, the octahedral shear strain according to Eq.(22) is computed and used to update the material properties of each layer with the chosen nonlinear material law. The more horizontal numerical layers are considered, the more accurate is the approximation. Alternatively one can used directly the 6 components of the the reference strain vector $\boldsymbol{\varepsilon}_n$ and a 3D nonlinear material model to update the soil model.

5.1 Comparison Between the 1D and 3D HFTD Method

In order to compare the 1D and 3D results, a free field subjected to a plane S-wave is considered. The wave propagates vertically while the particles move horizontally in x-direction (v_r^*=w_r^*=0, $u_r^* \neq$0) according to the Kobe earthquake signal[12]. In each plane x-y, all the particles experience the same horizontal motion, therefore the three dimensional case coincide with a one-dimensional problem. The soil is made up of a physical layer underlain by an elastic half space and the properties are specified in Tab. 2. The physical layer is divided into 10 numerical layers. The evaluation points for the ITM quantities are at the coordinate x_n=y_n=0 and at the z_n corresponding to the depths of the center of the N numerical layers.

For the solution of the ITM, the following boundary conditions are applied:

- BC 1: zero stresses at the soil surface;
- BC 2: the product of the dynamic stiffness of the half space with the relative displacements at the lowest interface of the layer is equal to the stresses at this interface,

$$\begin{aligned}&[\bar{\sigma}_{zx}(z=h), \bar{\sigma}_{yz}(z=h), \bar{\sigma}_z(z_1=h)]^T = \\ &\mathbf{K}_{HS}\left[(\bar{u}(z=h)-\bar{u}_r^*), (\bar{v}(z=h)-\bar{v}_r^*), (\bar{w}(z=h)-\bar{w}_r^*)\right]^T;\end{aligned}$$

- BC 3: continuity at interfaces between layers.

Where h is the thickness of the physical soil layer. By applying these boundary conditions, the coefficient vector $\boldsymbol{c}$ can be found and consequently the free field soil response in the image space (k_x, k_y, z, ω) is obtained. The solution in the original space (x, y, z, t) is computed through the inverse *Fourier* transformation.

The strain at the layer center and the acceleration at the surface resulting from 1D (blue curves) and 3D-model (red curves) are plotted in Fig. 12a and c. It can be seen that strains and accelerations resulting from both models is nearly identical. The 3D model achieved the convergence after eight iterations while the 1D model required six iteration steps. Also the

degradation curves and the dissipated energy shows agrrement between the 1D and the 3D method.

5.2 3D HFTD Method Considering a Spatially Varying Seismic Excitation

In this example a layered soil is subjected to a seismic excitation with a non-constant horizontal distribution, applied at the interface between layer and half space, as shown in Fig 13. The material properties are shown in Tab. 3. Fig. 14 shows the transient signals and the spectra of the input u_r^* in x-direction and of v_r^* in y-direction, applied to all the particles of the area highlighted in Fig 14. The loaded area is 0.625 m $\times$ 0.625 m, symmetric with respect to the point (x, y) = (0, 0). Because of the small size of the loaded area, the excitation which would results from this excitation would be very small. Therefore, the equivalent seismic loads $[\bar{\sigma}_{zx}(z=h), \bar{\sigma}_{yz}(z=h), \bar{\sigma}_z(z_1=h)]^T$ are scaled with a factor of 1200 in order to introduced enough energy into the system. This scenario does not represents a real seismic loading condition but serves the purpose of showing the effect of a localized excitation. The soil is discretized into 10 numerical layers and the MITS1 material model is assumed. The reference strains for the iterative process are evaluated at the center of each layer and the the points (x, y) = (0,0). The results of this scenario are compared to the results of the same scenario considering a linear material behavior.

Fig. 15 shows the time history of the displacement response of the soil surface at (x,y,z) = (0,0,0), and the strain response at a depth of 5m (center of the physical layer), for the nonlinear and linear case. Fig. 16 shows the contour of the displacement response in x- and y-direction over the considered area on the soil surface at a chosen time t = 5.5s. Finally, Fig. 17 shows the transfer functions $F_{1,x} = u/u_r^*$ and $F_{1,y} = v/v_r^*$ (defined as in the 1D case) as well as the spectrum of the total displacements $u_{tot}(\omega, x = y = z = 0) = \sqrt{u^2 + v^2 + w^2}$ at the soil

surface for the linear and the nonlinear case. The results show the influence of the nonlinear behavior on the frequency response and on the transient response.

5.3 Limitations of the 3D HFTD Method

The proposed method owns several advantages with respect to fully transient nonlinear analysis such as efficiency, simplicity of application and recued amount of output data. However, several limitations are also present and discussed in the following:

- Linearization: as in the 1D HFTD method, we assume that the transient nonlinear behavior of the 3D ground can be approximated by a superposition of steady-state linearized frequency-dependent responses. The convergence criteria focuses on the strain and affect the accuracy of the iterative process. This assumption needs to be investigated in more details, with a comparison against a fully transient nonlinear analysis.

(b) Spectrum of the total displacement response on the soil surface

Figure 17: Comparison of the transfer functions and total displacement spectrum at the soil surface at (x, y) = (0, 0) - Linear versus nonlinear soil system.

- Material model: most of the nonlinear material model for soils are one-dimansional and the material parameters are defines as a function of the shear deformation. In the 3D HFTD method, one obtains a more detailed picture of strain deformation with 6 components, which could be the input of a realistic three-dimensional model for the description of the inelastic soil behavior. However, 3D material models are still under investigation. Therefore, we opted for established 1D material models, such as the MITS1, which depend only on one component of the strain. Here, we take the octahedral shear strain as a scalar measure of the shear deformation on a given point. This aspect can be improved integrating more complex 3D material models.

- Spatial averaging: in the 1D HFTD method, the system is approximated by a one dimensional model and all the particles in the x-y-planes, perpendicular to the depth-direction (z-axis), moves in phase and with the same amplitude. In the 3D HFTD method, the distribution of the motions and strains in the x-y-planes is not constant, being the input arbitrarily spatially distributed. One could use this information to update the soil model locally. However, in the current formulation of the ITM, we assume that each horizontal layer is isotropic. Therefore, the material properties, such as G and ξ, are constant for the whole x-z-plane and over the whole depth of the layer. For this reason, we have to summarize the spatial distribution into one reference value, for example observing one specific horizontal point $(\widehat{x},\widehat{y})$ to obtain the reference strain for the material model. In future developments, we plan to reformulate the method including spatial averaging based on energy consideration and to extend the ITM solution for anisotropic and locally inhomogeneous soils.

6 CONCLUSIONS

In this contribution we gave an overview of the one-dimensional (1D) hybrid frequency-time domain (HFTD) method for the simulation of the seismic response of nonlinear soils. The 1D HFTD method does not takes into account the three dimensional (3D) effects that characterize the wave propagation in the soil. To fill this gap, we presented a 3D HFTD method, where the seismic input motions can be applied at any point of the soil and can be spatially variable. The effective strains in the soil are computed based on the 3D theory of elasticity through the integral transform method (ITM). The 3D strain vector is used to find the linearized properties of the nonlinear soil and the problem is solved iteratively transforming from the image space into the original space and viceversa and updating the soil properties until convergence. Several examples show the comparison between the 1D and the 3D formulations and between linear and nonlinear simulations.

In the proposed method the main assumptions are that the soil is isotropic in the horizontal plane and that the properties of the material are homogenous within each horizontal layer. Moreover, the nonlinear material model used to update the materiel properties is one-dimensional. In future works, the 3D HFTD method will be extended for anisotropic soils and for three dimensional non linear material models.

Abstract

Several studies have revealed that the inclined bedrock at the sides of the basins bring about the concentration of damages, which well known as basin edge effect. As a seismically active area much of the Turkey lies on the Anatolian Plate. This small plate bounded by two major strike-slip fault zones, the North Anatolian Fault and East Anatolian Fault. During the history, Turkey has been the site of devastating earthquakes.

Severe structural damage at basin sides during recent major earthquakes around the world strongly pointed out the importance of basin edge effect. Some of its notable examples can be tracked in Turkey. With respect to the fact that Turkey is among the top 20 percent of all countries exposed to earthquake hazard with regard to mortality and economic losses, the necessity of the investigation and consideration of the basin edge effect in earthquake design codes is revealed. In this study, the dynamic behavior at the edge of two real basins is investigated. In this study, at the first, the basin edge model of the basins are extracted from the data obtained from extensive microtremor surveys and geotechnical investigations as well as in-situ studies including SPT, CPT, PS logging tests. Then, the idealized geometry of the Dinar and Duzce basins edge models are proposed.

Afterwards, the basins are subjected to the collection of strong ground motions using a fully nonlinear method which works based on explicit finite difference scheme FLAC3D code. The

idealized 2D model of the Dinar and Duzce basins are subjected to the collection of sixteen strong ground motions with different peak ground accelerations (PGA) level of 0.1, 0.2, 0.3 and 0.4 g, four motions for each PGA level. For missing the effect of soil layers on selected real accelerograms they have been chosen from among those recorded on stiff layers during real earthquakes, or deconvoluted to the corresponding bedrock motion.

After the application of the strong ground motions from the bottom of the models in time domain, the acceleration of the surface points were recorded. For each surface point, the maximum spectral amplification factor under each earthquake is calculated then the average of resulted spectral amplification for four earthquakes of the same PGA level was estimated and reported.

The results of the dynamic analysis of Duzce basin showed the dominant effect of the inclined bedrock at the basin edge. Also, variation of its effect under excitations with different PGA levels is evident. At this basin the highest amplification factor occurs under the motions with PGA of 0.2g. Also, unlike the rest of the curves, a de-amplification of 0.85 along about 200 meters from the basin edge occurred at Duzce basin edge which shows that the basin edge can sometimes have decreasing effect on amplification. Regarding the influenced distance by the basin edge, while this distance is bout 800m and 1000m for the motions with the PGA of 0.1g and 0.2g, it increases to 1250m and 1500m for the motions with the PGA of 0.3g and 0.4g, respectively.

For asymmetric Dinar basin, two different amplification behaviors were seen at the eastern and western edges of the basin in terms of amplification amount and influenced distance by the basin edge. The higher basin edge effect at the eastern part with lower bedrock inclination with respect to western part was seen. This shows the higher effect of bedrock with lower angles. While the highest amplification factor at the western side occurs under the motions with PGA of 0.3g, it happens under the motions with PGA of 0.1g at the eastern side. Also, it was seen that at the eastern part of the basin has affected the distance about 1500 m from the outcrop while this distance for the steeper bedrock angle at the western side is about 700 m from outcrop. Between these distances 1D behavior is dominant.

The results show that the dynamic behavior of the both Dinar and Duzce basins at their sides is under the effect of basin edge in terms of amplification amount and influenced distance by the basin edge. At the basin edges, comparable amplification amounts with respect to the inner parts of the basins were seen.

1 INTRODUCTION

Several studies have revealed that the inclined bedrock at the sides of the basins bring about the concentration of damages, which well known as basin edge effect [1-3]. Ashigara Valley [4] and Ohba Valley [5] in Japan, Parkway Valley in New Zealand [6], Coachella Valley in southern California [7], Volvi Basin in Greece [8], Heathcote Valley in the Christchurch City of New Zealand [9] are among the sites with extensive seismic array observation instruments that have been used for validation of the theoretical studies regarding basin effects. In the meantime, investigations carried out at basins like Miyagi and Fukushima (Japan) [10], Fraser Delta [11] and Euroseistest site [12], among others, provided more accurate data about the basin edge effect.

As a seismically active area much of the Turkey lies on the Anatolian Plate. This small plate bounded by two major strike-slip fault zones, the North Anatolian Fault and East Anatolian Fault. During the history, Turkey has been the site of devastating earthquakes. A devastating earthquake hit the city of Duzce on November 12, 1999 with a moment magnitude (Mw) of 7.2 causing heavy damage and fatalities in Duzce province. The seen damage pattern during 1st October 1995 earthquake at Dinar town, Turkey, where located at the edge of an alluvial basin is another example of such effect. With respect to the statistical investigations, the resulting losses place Turkey in the top 20 percent of all countries exposed to earthquake hazard with regard to mortality and economic losses [13]. Severe structural damage at basin sides during recent major earthquakes around the world strongly pointed out the importance of basin edge effect and land-use planning [14-15]. Some of its notable examples can be tracked in Turkey. The recorded damage patterns during 1996 Dinar earthquake [16] as well as November 12, 1999 Duzce earthquake [17] revealed the necessity of the consideration of the basin edge effect in earthquake design codes. In this study, the different dynamic behavior at the edge of two basins with respect to the basin center is investigated. The results of such investigations can be used as the critical data in land-use planning projects as instrument of earthquake hazard mitigation.

In this study, at the first, the edge models of are extracted from the data obtained from performed microtremor surveys as well as geotechnical investigation. In this way, the basin stratification and shear wave velocity profile as well as geotechnical properties of the layers are obtained. Based on these data, the idealized geometry of Dinar and Duzce basins are proposed. Then, in order to estimate the dynamic behavior of the basins, a fully nonlinear method based on explicit finite difference scheme which solve the full equations of motion using FLAC3D code [18] is performed.

2 BASIN EDGE EFFECTS AT DINAR AND DUZCE BASINS

The existence of the inclined bedrock underlying the Duzce Basin has aroused the ideas of the effect of the basin edge on the dynamic behavior of basin. Also, the concentration of the damages at the edges of the non-symmetric alluvial Dinar basin indicates the involvement of the inclined bedrock in the different dynamic behavior of the basin at its sides [19-20].

2.1 Geology and seismo-tectonics of the basins

Dinar town is located at the edge of an alluvial basin in the southwest Anatolia, Turkey. To reveal its geology and geotechnical conditions, extensive in-situ studies including SPT, CPT, PS logging tests as well as microtremor measurements were carried out throughout the town [21].

There are two main fault systems around Dinar Town. One of them is Dinar-Civril fault which lays in the NW-SE direction and the other is Akdag fault with N-S direction. The Di-

nar-Civril fault has got a 75 km long normal fault with a slight oblique left lateral component [22]. These two fault systems had caused to form a seismotectonic structure consisting of two grabens and a horst.

In order to estimate the shear wave velocity profile of soil layers, at two of the pre-drilled boreholes suspension PS-logging tests until the approximate depths of 40 m were done. In Fig. 1 a characteristic geological section of Dinar laying in the E-W direction which reveals the horst-graben structure as well as an example of the results of the SPT and PS-logging test that were carried out at Dinar meteorological station site are presented.

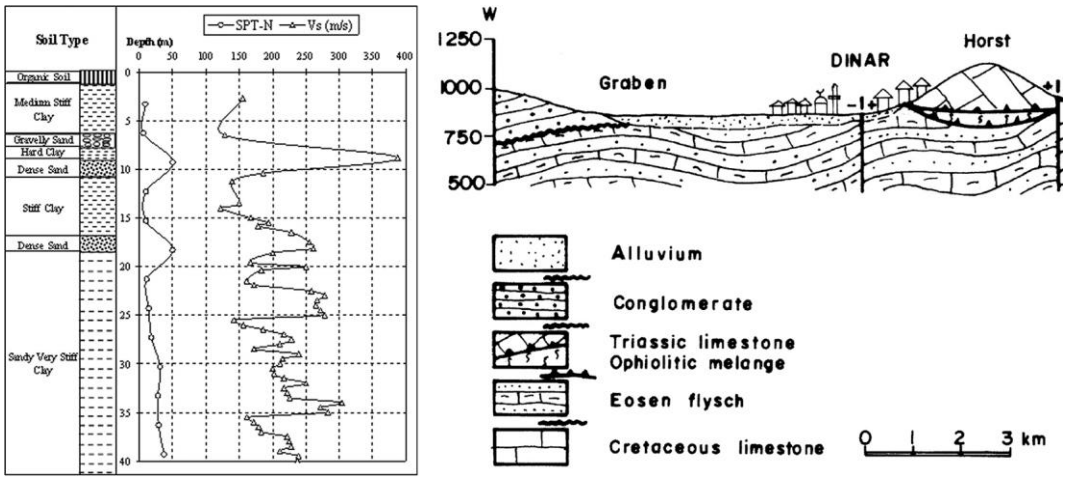

Figure 1: East-West geological section of Dinar basin and an example of the SPT and PS-logging test results.

Duzce basin is a graben-like basin which was formed by the activities of the North Anatolian Fault. From geological point of view there is a low inclined topography toward the southwest (toward Lake Eftani). In order to constitute the basin model and extract shear wave velocity profile of the Duzce basin a microtremor survey was performed. Also, Single point microtremor measurements were carried out at 25 different points in the basin along an S-N line. The thickness value for each top layer was estimated by providing the best fit between the H/V curve and theoretical Rayleigh wave ellipticity [23]. Based on microtremor measurements, the basin is composed of seven separate layers with different shear wave velocities. The layer with a shear wave velocity greater than 800 m/s was considered as seismic bedrock. The depth of seismic bedrock was estimated by the method conducted by Kudo et. al.(2002) [24]. In Fig. 2 the proposed Duzce basin stratification and the shear wave velocity profile of the basin edge is presented.

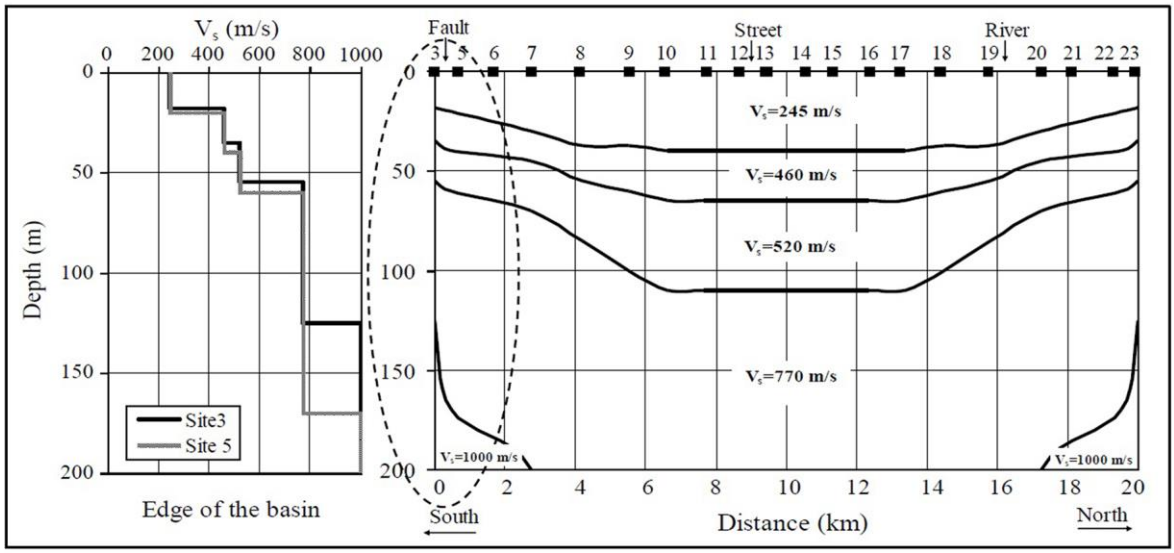

Figure 2: The proposed Duzce basin stratification and the shear wave velocity profile of the basin edge.

2.2 Idealized basin geometry and geotechnical properties

Based on the results of the microtremor measurements, underground explorations and laboratory tests, and with respect to the extracted geologic cross sections of the areas given at Fig. 1 and Fig.2 the idealized geometry of the Dinar and Duzce basins are proposed at Fig. 3.

As can be seen, for Dinar basin which is located between two horsts, the bedrock has got 6° inclination at the east edge until the180m depths. Then, until the depth of 220 m the bedrock angle decreases to 2°. At the west part steeper bedrock with 20° angle continues until the depth of 220 m. At the other parts, horizontal bedrock with the depth of 220 m is modeled. The width of the 2D basin model has been taken 6km.Corresponding soil specifications are presented at Table 1.

For Duzce basin, the findings of the 2D shear wave velocity profile indicate the seismic bedrock inclination of 6° at the basin edge which continues until 2km inside the basin. The soil layers were assumed to extend horizontally within 2.2 km from the basin edge. Also, in order to effectively catch the 2D behavior of the basin, the selected modeling length should exceed the region that is affected by inclined bedrock. Such point is considered as the beginning of the 1D behavior of the basin; the region that the effect of the inclined bedrock is missed. So, the left 2.2km of the basin has been modeled.

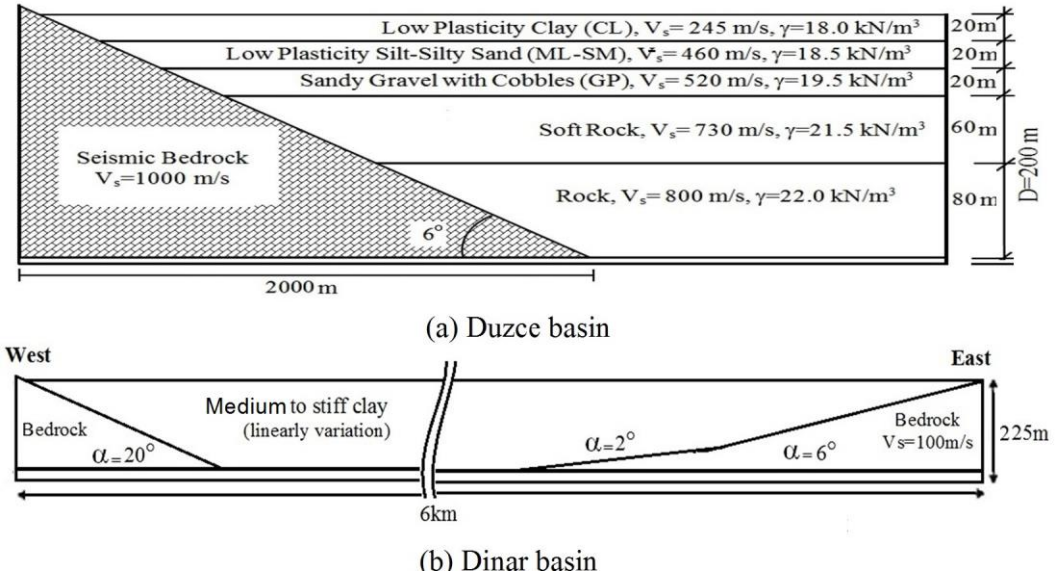

Figure 3: The idealized geometry of the (a) Duzce and (b) Dinar basins.

Regarding geotechnical properties of the basins, the 220 m basin depth of the Dinar basin is divided to two 200 m and 20 m layers on the bedrock in order to model the 20 m transient layer between bedrock and basin (underlying a 5m bedrock layer). A linear variation of the properties over basin depth has been provided for Dinar basin. Duzce basin and its surrounding area consists of alluvium deposits and lake sediments, which are composed of fine grained gravel, sand and silt mixture with clay layers. The geotechnical properties of the idealized Dinar and Duzce basins soils are presented at Table 1.

Table 1: The geotechnical properties of the idealized Dinar and Duzce basins

The idealized 2D model of the Dinar and Duzce basins are subjected to the collection of sixteen strong ground motions with different peak ground accelerations (PGA) level of 0.1, 0.2, 0.3 and 0.4 g, four motions for each PGA level. These records are of different peak ground accelerations, frequency contents and durations. They are baseline corrected and filtered by a 25 Hz low-pass filter. The excitations are applied as SV waves to the model bot-

toms. For missing the effect of soil layers on selected real accelerograms they have been chosen from among those recorded on stiff layers during real earthquakes, or deconvoluted to the corresponding bedrock motion. At Table 2 the specification of the applied earthquakes are presented.

3 ANALYSIS METHOD

To estimate the dynamic behavior of the Dinar and Duzce basins a fully nonlinear analysis using FLAC3D code (Fast Lagrangian Analysis of Continua) based on explicit finite difference scheme which solves the full equations of motion is applied. In this method, both shear and compressional waves are propagated together in a single simulation, and the material responds to the combined effect of both components. This aspect gets more important in the 2D modeling of the basin edge where the waves are trapped at low angle bedrock inclinations. Also, the method follows any prescribed nonlinear constitutive relation and since the strain increments (not tensors) relate to the stress tensors, therefore plastic yielding is modeled appropriately [18]. With respect to the selected soil properties, the corresponding G/Gmax curves have been estimated based on relation proposed by Ishibashi and Zhang (1993) [25] and is presented at Fig. 5.

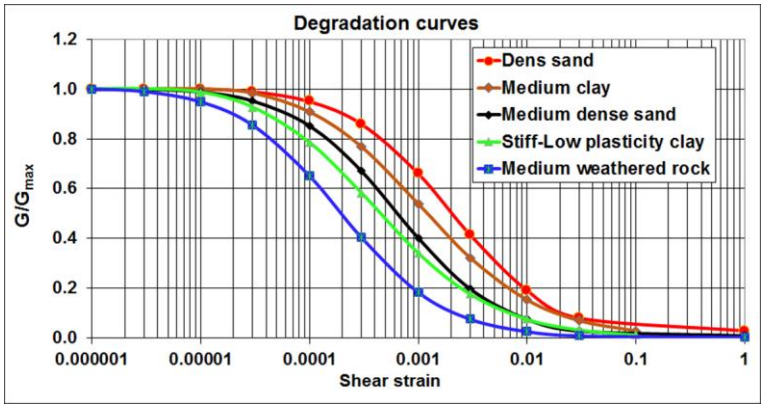

Figure 4: The corresponding G/Gmax degradation curves of the basins' soils.

At the bottom boundary of the model the quiet boundary scheme, which involves dashpots, are attached independently in the normal and shear directions to prevent the reflection of outward propagating waves back into the model as well as allow the necessary energy radiation. For vertical boundaries, the approach used in the continuum finite difference code NESSI [26] are developed via Free-Field boundary condition which involving the execution of free-field calculations in parallel with the main-grid analysis. Also, to provide the accurate transmission of the wave through modeled mesh, based on Kuhlemeyer and Lysmer (1973) [27], with respect to the frequency content of the input waves and the wave speed characteristics of the system, the spatial mesh size was selected smaller than one tenth to one eighth of the wavelength associated with the highest frequency component of the wave.

The verification of this analysis has been done by comparing to the solution of Kawase and Aki (1989) [28], and presented at Iyisan and Khanbabazadeh (2013) [29] and Khanbabazadeh and Iyisan (2014 a,b) [30-31]. The solution of the trapezoidal valley by Kawase and Aki (1989) [28] has been tested by Zahradnik (1995) [32] and Gil-Zepeda et al. (2003) [33], among the others.

4 RESULTS AND DISCUSSION

After the application of the strong ground motions presented at Table 2 from the bottom of the models in time domain, the acceleration of the surface points were recorded. For each surface point, the maximum spectral amplification factor under each earthquake is calculated then the average of resulted spectral amplification for four earthquakes of the same PGA level was estimated and reported. At Fig. 6 and Fig. 7, the maximum spectral amplification variation at the surface of the Dinar and Duzce basins under excitations with four different PGA levels are presented.

4.1 Dinar basin

As seen at the idealized geometry of the Dinar basin, this basin has got an asymmetric geometry with different bedrock angles at its sides. The effect of such geometry can also be seen in the dynamic behavior of Dinar basin at Fig. 6. Two different amplification behaviors are seen at the eastern and western edges of the Dinar basin in terms of amplification amount and influenced distance by the basin edge. Also, the effect of the motion strength on the dynamic behavior of the basin is evident.

The results show that while the highest amplification factor at the western side occurs under the motions with PGA of 0.3g (with the maximum amplification factor of 3.75), it hap-

pens under the motions with PGA of 0.1g at the eastern side (with the maximum amplification factor of 3.82).

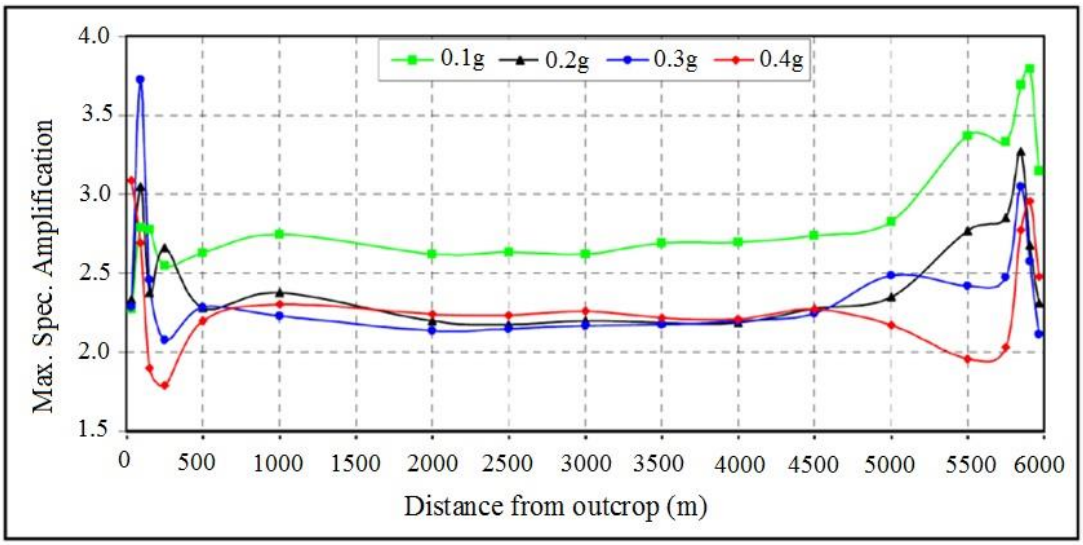

Figure 5: The maximum spectral amplification variation at Dinar basin surface.

There are two different amplification trends at two sides. Because of the enough distance between two edges, no interference of the edges effect is seen. In fact, Dinar basin is divided to three areas, two areas with independent 2D behavior at edges and a middle area with 1D behavior. The point that the amplification curve turns to a flat curve, which continues towards the inner parts of the basin, is usually considered as the beginning of the 1D behavior of the basin; the region that the effect of the inclined bedrock is missed.

It is seen that the milder bedrock inclination at the eastern part of the basin has affected the distance about 1500 m from the outcrop while this distance for the steeper bedrock angle at the western side is about 700 m from outcrop. Between these distances, the effects of the basin edges are cancelled. In this region the basin turns to behave one dimensionally. The highest 1D amplification factor belongs to the motions with PGA of 0.1g. For other PGA levels, relatively close 1D amplification factor is seen. While the sustained spectral amplification of the basin center under the motions of 0.1g PGA is about 2.7, it decreases to about 2.25 for stronger motions with higher PGAs.

4.2 Duzce basin

The amplification curves of the Duzce basin clearly show the influence of the basin edge on the dynamic behavior of Duzce basin. Also, the variation of its effect under excitations with different PGA levels is evident. As can be seen, while the highest amplification factor occurs under the motions with PGA of 0.2g, the lowest amplification factor belongs to the motions with PGA of 0.1g.

Despite the increasing trend of the amplification under the motions with the PGA of 0.1g and 0.2g, it begins to decrease under the motions with higher PGAs. The seen amplification factors under the motions with the PGA of 0.3g and 0.4g reach to 3.4 and 3, respectively.

Also, the maximum amplification curve of the basin surface under the motions with the PGA of 0.3g shows a de-amplification of 0.85 along about 200 meters from the basin edge, unlike the rest of the curves. This shows that the basin edge can sometimes have decreasing effect on amplification. This phenomenon can be the result of the trapping of the waves at the half space between inclined bedrock and surface at the edges.

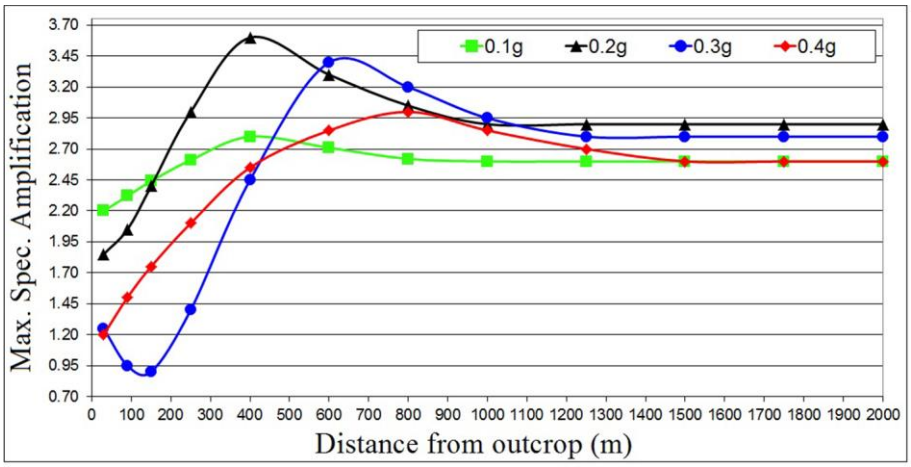

Figure 6: The maximum spectral amplification variation at Duzce basin surface.

As mentioned earlier, from the point that the effect of the inclined bedrock is missed the 1D behavior of the basin begins. For Duzce basin the beginning of 1D behavior under the motions with different strengths is different. While this behavior for motion with the PGA of 0.1g begins at 800m from the outcrop (with the maximum amplification factor of 2.6), it reaches to about 1000m under the motions with the PGA of 0.2g (with the maximum amplification factor of 2.9). Despite the decrease in the maximum amplification factor under the motions with the PGA of 0.3g and 0.4g (with respect to the motions with the PGA of 0.2g), the beginning point of the 1D behavior stretches more. It begins from 1250m and 1500 for the motions with the PGA of 0.3g and 0.4g, respectively. In shorts, inside these areas the effect of the basin edge is dominant.

5 CONCLUSIONS

- In this study, in order to investigate the basin edge effect, at the first, the basin edge model is extracted from the data obtained from extensive microtremor surveys and geotechnical investigations as well as in-situ studies including SPT, CPT, PS logging tests. Using these findings the basin stratification and shear wave velocity profile as well as geotechnical properties of the layers of the basins were obtained. Then, the idealized geometry of the Dinar and Duzce basins edge models were proposed. Afterwards, the basins were subjected to the collection of sixteen strong ground motions with different peak ground accelerations (PGA) levels using a fully nonlinear method which works based on explicit finite difference scheme and solve the full equations of motion using FLAC3D code. Using the recorded acceleration at 12 surface points along the basin edge the variation of the maximum spectral amplification factor was reported.

- The results show that the dynamic behavior of the both Dinar and Duzce basins at their sides is under the effect of basin edge. Comparable amplification amounts with respect to the inner parts of the basins were seen. For asymmetric Dinar basin, two different amplification behaviors were seen at the eastern and western edges of the basin in terms of amplification amount and influenced distance by the basin edge. The higher basin edge effect at the eastern part with lower bedrock inclination with respect to western part was seen. This shows the higher effect of bedrock with lower angles. While the highest amplification factor at the western side occurs under the motions with PGA of 0.3g, it happens under the motions with PGA of 0.1g at the eastern side. Also, it was seen

that at the eastern part of the basin has affected the distance about 1500 m from the outcrop while this distance for the steeper bedrock angle at the western side is about 700 m from outcrop. Between these distances 1D behavior is dominant.

- The results of the dynamic analysis of Duzce basin showed the dominant effect of the inclined bedrock at the basin edge. Also, variation of its effect under excitations with different PGA levels is evident. At this basin the highest amplification factor occurs under the motions with PGA of 0.2g. Also, unlike the rest of the curves, a de-amplification of 0.85 along about 200 meters from the basin edge occurred at Duzce basin edge which shows that the basin edge can sometimes have decreasing effect on amplification. Regarding the influenced distance by the basin edge, while this distance is bout 800m and 1000m for the motions with the PGA of 0.1g and 0.2g, it increases to 1250m and 1500m for the motions with the PGA of 0.3g and 0.4g, respectively.

- By consideration of the all aspects of this study, the results of such investigations can be used as the critical data in land-use planning projects as instrument of earthquake hazard mitigation.

Keywords: Dynamic response, Transient regime, Imperfect interface, Semi-analytical approach, Heterogeneous elastic medium

Abstract. *The two dimensional transient response of a tunnel subjected to an uniform load is described in this paper. The concrete tunnel is embedded in a limestone massif with a heterogeneous chalk layer. The theoretical approach presented here is based on a semi-analytical approach in which the Helmholtz decomposition is used for the separation of wave motion and the solutions of wave equations are written using the Bessel-Fourier serie expansion method in the Laplace domain. The inversion of the Laplace transforms are performed numerically by using the Durbin algorithm. An imperfect contact is used to take into account the discontinuities at the interfaces between the different media. The results of hoop stress and radial displacement on the outer boundary of the tunnel are presented.*

1 INTRODUCTION

Seismic methods have been used for several decades increasingly to asssist in rock mass characterization in many geotechnical engineering applications. The present work concerns the study of mechanical wave propagation in a specific underground environment constituted by a system of cylindrical galleries, some of them presenting a concrete layer, embedded in an elastic full space. The site under study is located at the LSBB (Low Noise Inter-Disciplinary Underground Science and Technology, Rustrel, France). A bibliographical survey has been carried out with a special attention to select articles focusing on configurations close to the LSBB-kind geometry. Fang et al. [1] studied the dynamic response of a non-circular tunnel subjected to longitudinal and transversal waves (P, SV). They used a visco-elastic interface to model the contact between the rock mass and the tunnel. They concluded that the viscosity has a small influence on the dynamic stress in high frequency areas compared to low frequency areas. Fang et al. [2] analyzed the dynamic stress distribution around a circular tunnel subjected to SH waves. Using an elastic slip interface to represent the contact between the alluvial valley and the lined tunnel, they found that the dynamic stress increases when the elastic modulus of the tunnel lining increases, and that the interface effect decreases for larger dimension tunnels. The work described here extends the approach originally proposed by Yi et al. [3] who studied the harmonic response of a cylindrical elastic tunnel, impacted by a plane compressional wave and embedded in an infinite elastic ground. The interface between the rock mass and the linen is considered as an imperfect contact and is modeled with two spring parameters (Achenbach et al. [4]). The extension concerns the heterogeneous aspect around the tunnel called the damaged zone. The heterogeneous description of this area consists in a finite number of isotropic and elastic layers with imperfect contacts at each interface. We propose a cylindrical chalk layer to take into account the heterogeneous area around the tunnel. The main steps of the theoretical approach are: i) applying the Helmholtz decomposition, ii) solving the wave equation based on the separation method and iii) use the Laplace transform and the expansion in Bessel function series in the Laplace domain. We consider a step load that acts on the inner surface of the tunnel, the solutions for each layer are derived and expressed in terms of Bessel-Fourier series. Using the boundary conditions associated with the orthogonality conditions, a global stiffness matrix is constructed and assembled. The Durbin algorithm [5] is used for the inverse transformation in the time domain. The results obtained have been validated by comparison with Zakout et al. [6] and a first set of new results with the configuration under study is proposed.

2 STATEMENT OF PROBLEM

An infinitely long cylindrical tunnel in an infinite limestone massif is subjected to a load acting on the inner surface of the cavity (Figure 1).

The limestone massif is considered to be elastic, homogeneous and we propose a cylindrical layer ($k = 2$) approach to model the heterogeneous area surrounding the concrete tunnel ($k = 3$). We also consider the tunnel and the heterogeneous layer to be elastic and isotropic. Taking into account these hypotheses, the displacement equations of motion in each medium can be written as follows

$$\mu_k \nabla^2 \mathbf{u}_k + (\lambda_k + \mu_k) \nabla \nabla \cdot \mathbf{u}_k = \rho_k \ddot{\mathbf{u}}_k \ , \quad k = \{1, 2, 3\} \tag{1}$$

where the displacement vector $\mathbf{u}$ with subscript k represents motion in a given layer, $\{\lambda_k, \mu_k\}$ are the Lamé constants, ρ_k is the density and the superposed dot denotes time derivative ($\ddot{\mathbf{u}}$ is the second derivative with respect to time).

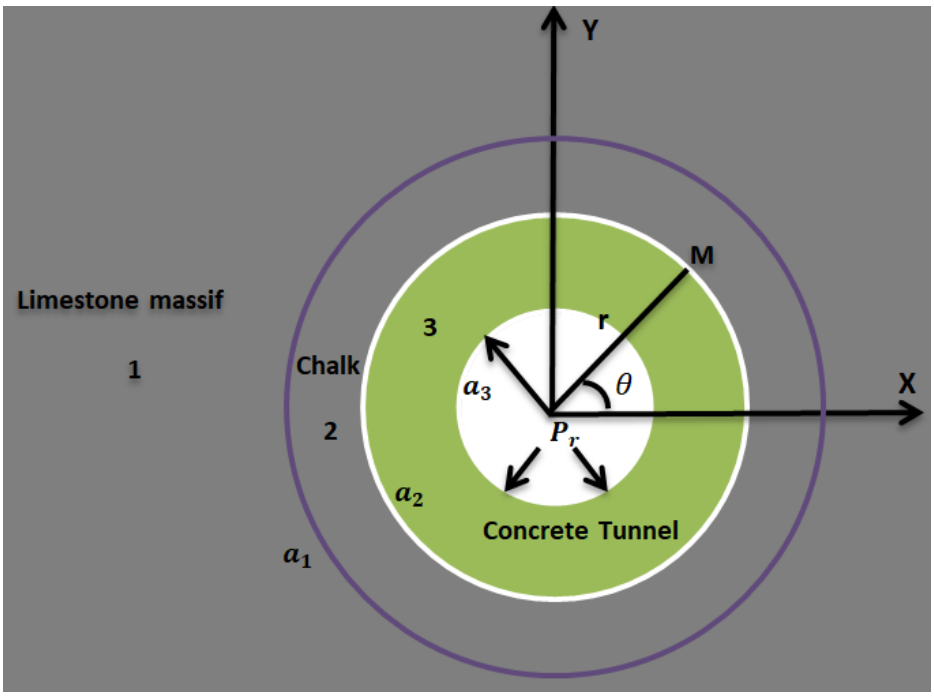

Figure 1: Problem geometry

The displacement field may be separated into scalar ϕ and vector Ψ potentials with the usual Helmholtz decomposition. The problem does not depend on the z-coordinate due to the two dimensional configuration, Ψ has only one single component ψ_z and for the sake of clarity it will be written as ψ. It comes thus

$$\mathbf{u}_k = \nabla\phi_k + \nabla \times \psi_k \tag{2}$$

Substituting equation (2) into (1), two wave equations are obtained

$$\nabla^2\phi_k - \frac{1}{c_{pk}^2}\ddot{\phi}_k = 0 \tag{3}$$

$$\nabla^2\psi_k - \frac{1}{c_{sk}^2}\ddot{\psi}_k = 0 \tag{4}$$

Equations (3) and (4) are relative to P and SV waves, respectively. $c_{pk} = \sqrt{\frac{\lambda_k+2\mu_k}{\rho_k}}$ and $c_{sk} = \sqrt{\frac{\mu_k}{\rho_k}}$ are the P and SV wave velocities in the elastic medium under consideration, ∇^2 is the the Laplace operator in polar coordinates.

The Laplace transforms is defined as

$$\overline{F}(r,\theta,s) = \int_0^\infty F(r,\theta,t)e^{-st}\,\mathrm{d}t \tag{5}$$

Applying the Laplace transform with respect to time to Eqs (3) and (4), we obtain

$$\nabla^2\overline{\phi_k} + \overline{\alpha_k}^2\overline{\phi_k} = 0 \tag{6}$$

$$\nabla^2\overline{\psi_k} + \overline{\beta_k}^2\overline{\psi_k} = 0 \tag{7}$$

where over-bar hereafter denotes the Laplace transform, $\{\overline{\alpha_k} = \dfrac{is}{c_{pk}},\ \overline{\beta_k} = \dfrac{is}{c_{sk}}\}$ are the P and SV wave numbers in the Laplace domain for a given layer and $i^2 = -1$ is the imaginary complex number.

When the step load acts on the inner surface of the tunnel, two incoming cylindrical waves (P, SV) and two outgoing cylindrical ones propagate in the tunnel medium. The same phenomenon is observed in the heterogeneous area, i.e two incoming and two outgoing cylindrical waves (P, SV). The two incoming (P, SV) waves are expressed with Hankel functions of the second kind. The two outgoing (P, SV) are written with Hankel functions of the first kind. The total displacement potentials in the Laplace domain for the heterogeneous area ($k = 2$) and the tunnel ($k = 3$) are

$$\overline{\phi_{kt}} = \sum_{n=0}^{\infty}[L_{nk}H_n^{(2)}(\overline{\alpha_k}r) + P_{nk}H_n^{(1)}(\overline{\alpha_k}r)]cos(n\theta) \tag{8}$$

$$\overline{\psi_{kt}} = \sum_{n=0}^{\infty}[Q_{nk}H_n^{(2)}(\overline{\beta_k}r) + Z_{nk}H_n^{(1)}(\overline{\beta_k}r)]sin(n\theta) \tag{9}$$

where L_{nk}, P_{nk}, Q_{nk}, Z_{nk} are respectively the expansion coefficients per mode of the (P, SV) waves in the tunnel and the heterogenoues area. $\{H_n^{(1)},\ H_n^{(2)}\}$ are the Hankel function of the first and second kind of an integer order n.

Two transmitted waves (P, SV) propage in the limestone massif from the interface $r = a_1$. They are expressed by Hankel functions of the first kind that represent outgoing cylindrical waves.

$$\overline{\phi_{1t}} = \sum_{n=0}^{\infty} E_n H_n^{(1)}(\overline{\alpha_1}r)\cos(n\theta) \tag{10}$$

$$\overline{\psi_{1t}} = \sum_{n=0}^{\infty} F_n H_n^{(1)}(\overline{\beta_1}r)\sin(n\theta) \tag{11}$$

where E_n and F_n are respectively the expansion coefficients per mode of the two transmitted waves (P, SV).

Based on the Helmholtz potential-displacement (11), displacement-strain relations (12) and stress-strain relations generalized by Hooke's law for a linear isotropic material (13), stress and displacement components for the different media $\{k = 1, 2, 3\}$ in the Laplace domain in polar coordinates can be expressed as

$$\overline{u_{r,k}} = \frac{\partial\overline{\phi_{kt}}}{\partial r} + \frac{1}{r}\frac{\partial\overline{\psi_{kt}}}{\partial\theta} \qquad \overline{u_{\theta,k}} = \frac{1}{r}\frac{\partial\overline{\phi_{kt}}}{\partial\theta} - \frac{\partial\overline{\psi_{kt}}}{\partial r} \tag{12}$$

$$\overline{\varepsilon_{rr,k}} = \frac{\partial\overline{u_{r,k}}}{\partial r} \qquad \overline{\varepsilon_{\theta\theta,k}} = \frac{1}{r}\frac{\partial\overline{u_{\theta,k}}}{\partial\theta} + \frac{\overline{u_{r,k}}}{r} \qquad \overline{\varepsilon_{r\theta,k}} = \frac{1}{2}(\frac{\partial\overline{u_{\theta,k}}}{\partial r} - \frac{\overline{u_{\theta,k}}}{r} + \frac{1}{r}\frac{\partial\overline{u_{r,k}}}{\partial\theta}) \tag{13}$$

$$\overline{\sigma_{rr,k}} = \lambda_k(\overline{\varepsilon_{rr,k}}+\overline{\varepsilon_{\theta\theta,k}})+2\mu_k\overline{\varepsilon_{rr,k}} \quad \overline{\sigma_{\theta\theta,k}} = \lambda_k(\overline{\varepsilon_{rr,k}}+\overline{\varepsilon_{\theta\theta,k}})+2\mu_k\overline{\varepsilon_{\theta\theta,k}} \quad \overline{\sigma_{r\theta,k}} = 2\mu_k\overline{\varepsilon_{r\theta,k}} \tag{14}$$

3 BOUNDARY CONDITIONS

The heterogeneous area chalk surrounding the tunnel contains fractures which can modify the mechanical parameters of the materials. We propose an interface model developed by Achenbach et al. [4] to take into account the discontinuities at the interfaces located at $r = a_1$ and $r = a_2$. The basis of the model is that a fracture represents a displacement discontinuity whereas the stresses are continuous. It is applicable to cases for which the fractures are large in extent but small in thickness compared to the wavelength of the mechanical waves. We consider that a fracture of circular shape separates two successive layers. Two stiffness ($k_{r,k}$, $k_{\theta,k}$) constants are useful for modeling the fracture in the radial and angular directions at the interface between two successive layers. The constant $k_{r,k}$ models the fracture in the radial direction and the constant $k_{\theta,k}$ in the circumferential direction. Physically, the contact is assumed to be perfect between two successive layers for largest values of $k_{r,k}$ and $k_{\theta,k}$. For very low values of $k_{r,k}$, $k_{\theta,k}$ two successive layers are detached but present identical traction conditions. The interface conditions at $r = \{a_1,\ a_2\}$ are thus written as

$$\begin{cases} \overline{\sigma_{rr,1}} = \overline{\sigma_{rr,2}} \\ \overline{\sigma_{r\theta,1}} = \overline{\sigma_{r\theta,2}} \\ \overline{u_{r,1}} - \dfrac{1}{k_{r,1}}\overline{\sigma_{rr,1}} = \overline{u_{r,2}} \\ \overline{u_{\theta,1}} - \dfrac{1}{k_{\theta,1}}\overline{\sigma_{r\theta,1}} = \overline{u_{\theta,2}} \\ \overline{\sigma_{rr,2}} = \overline{\sigma_{rr,3}} \\ \overline{\sigma_{r\theta,2}} = \overline{\sigma_{r\theta,3}} \\ \overline{u_{r,2}} - \dfrac{1}{k_{r,2}}\overline{\sigma_{rr,2}} = \overline{u_{r,3}} \\ \overline{u_{\theta,2}} - \dfrac{1}{k_{\theta,2}}\overline{\sigma_{r\theta,2}} = \overline{u_{\theta,3}} \end{cases} \tag{15}$$

We consider a step load which acts on the inner boundary of the tunnel at ($r = a_3$). The relative equations are

$$\begin{cases} \overline{\sigma_{rr,3}} = \dfrac{P_r}{s} \\ \overline{\sigma_{r\theta,3}} = 0 \end{cases} \tag{16}$$

We choose to expand term $\dfrac{P_r}{s}$ of Eq (15) into Fourier cosine series so that the Fourier series appears on each side

$$\frac{P_r}{s} = \sum_{n=0}^{\infty} \kappa_n cos(n\theta) \tag{17}$$

where $\kappa_n = \dfrac{P_r}{s}$ for $n = 0$ and $\kappa_n = 0$ for $n \geq 1$.

Substituting Eqs (11-13) into Eqs (14-15), and applying the orthogonality conditions, n sets of linear algebraic equations are obtained in the Laplace domain

$$[X]_{n,\{10,10\}}\{C\}_{n,10} = \{Y\}_{n,10} \tag{18}$$

$$X = \begin{pmatrix} \times & \times & \times & \times & \times & \times & 0 & 0 & 0 & 0 \\ \times & \times & \times & \times & \times & \times & 0 & 0 & 0 & 0 \\ \times & \times & \times & \times & \times & \times & 0 & 0 & 0 & 0 \\ \times & \times & \times & \times & \times & \times & 0 & 0 & 0 & 0 \\ 0 & 0 & \times & \times & \times & \times & \times & \times & \times & \times \\ 0 & 0 & \times & \times & \times & \times & \times & \times & \times & \times \\ 0 & 0 & \times & \times & \times & \times & \times & \times & \times & \times \\ 0 & 0 & \times & \times & \times & \times & \times & \times & \times & \times \\ 0 & 0 & 0 & 0 & 0 & 0 & \times & \times & \times & \times \\ 0 & 0 & 0 & 0 & 0 & 0 & \times & \times & \times & \times \end{pmatrix}$$

$$\{C\} = \begin{pmatrix} E_n & F_n & L_{n2} & P_{n2} & Q_{n2} & Z_{n2} & L_{n3} & P_{n3} & Q_{n3} & Z_{n3} \end{pmatrix}^T$$

$$\{Y\} = \begin{pmatrix} 0 & 0 & .. & .. & .. & .. & .. & .. & \frac{P_r}{s} & 0 \end{pmatrix}^T$$

The symbol $\times$ denotes non-zero terms.

The inversion of the Laplace transforms are performed numerically by using the following Durbin's formula [5] on the interval $[0, T_0]$

$$F(t) = \frac{e^{at}}{T_0}\{\frac{1}{2}Re[\overline{F}(a)] + \sum_{\varsigma=0}^{M}[Re[\overline{F}(a + \frac{i\pi\varsigma}{T_0})]\cos(\frac{\pi\varsigma t}{T_0}) - Im[\overline{F}(a + \frac{i\pi\varsigma}{T_0})\sin(\frac{\pi\varsigma t}{T_0})]] \quad (19)$$

where M is the truncation parameter, a is an arbitrary real number and $\overline{F}(a)$ can be any of $\overline{u_{r_k}}$, $\overline{u_{\theta_k}}$, $\overline{\sigma_{rr_k}}$.....

4 NUMERICAL RESULTS

The phenomenon of dynamic stress concentration, namely the sharp increase in the stress over some normal value in a localized region of a structural body due to geometric discontinuities such as cavities, corners or notches, is related to the propagation of elastic waves. Structures embedded in a medium act as discontinuities resulting in an amplification of the dynamic signal. Baron et al. [7, 8] have analysed the dynamic stress and displacement fields produced around a circular cylindrical cavity in an infinitely extending elastic medium due to the passage of harmonic or transient waves.

For numerical inversion with the Durbin method [5], the numerical parameters are as follows:

$$aT_0 = 5, \;\; T_0 = 200, \;\; M = 2000$$

At first, we are interested in the validation of our numerical code. Zakout et al. [6] study the transient response of a circular cavity with and without a bonded shell in an infinite elastic medium. We consider the same configuration for the case of the circular cavity unlined by assuming that media 2 and 3 are identical to medium 1. We also consider perfect contacts at interfaces $r = a_1$ and $r = a_2$. Using the same mechanical parameters as Zakout et al. [6], in Figure 2 we compare the nondimensional radial displacement and a good agreement is obtained.

Parameters	Limestone massif	Chalk	Concrete tunnel
$\rho\ (kg/m^3)$	2700	3100	2500
$c_p\ (m/s)$	6000	2600	4216
$c_s\ (m/s)$	3300	1300	2582

Table 1: Mechanical parameters of the media

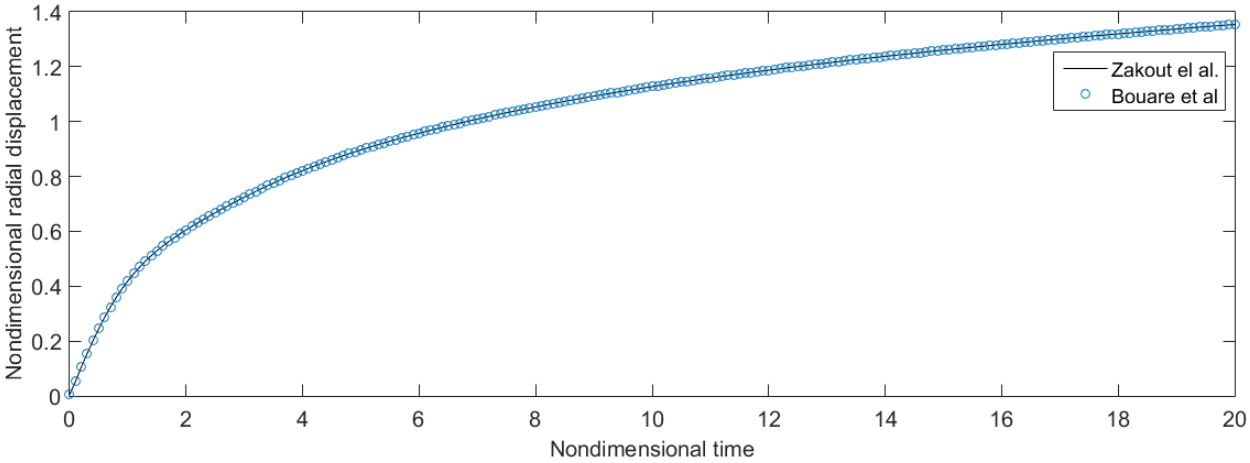

Figure 2: Nondimensional radial displacement for mode ($n = 1$) at the inner surface of the tunnel $r = a_3$ and $\theta = 0$, comparision with Zakout et al. [6].

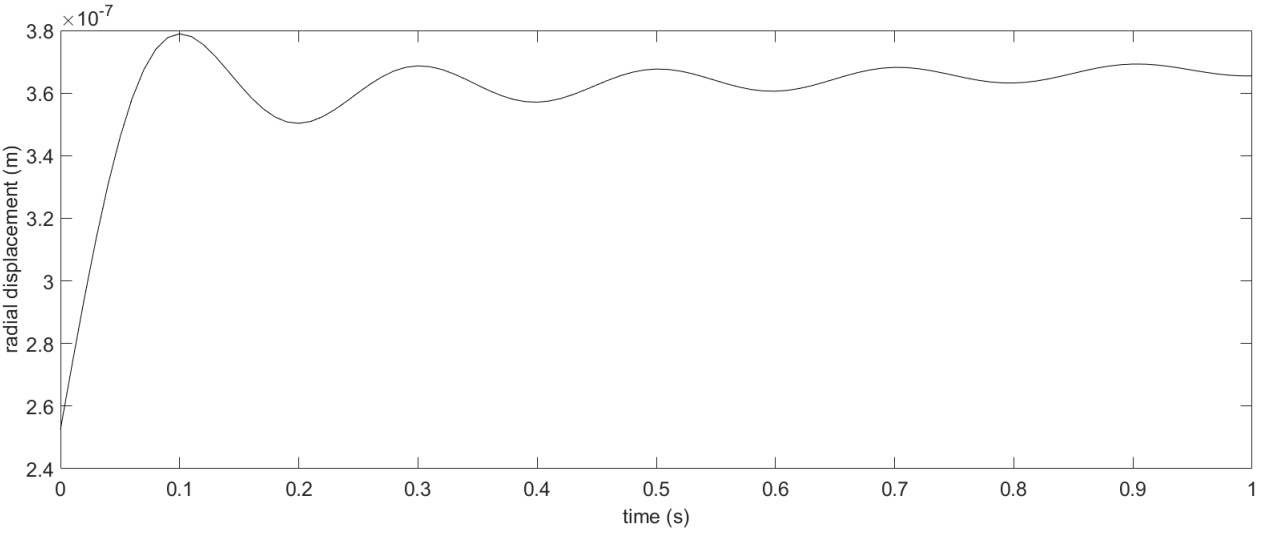

Figure 3: Radial displacement for mode ($n = 0$) at the outer surface of the tunnel $r = a_2$ and $\theta = 0$

The numerical parameters for the geometric points in Figure 1 are $a_1 = 2.2\ m,\ a_2 = 1.2\ m,\ a_3 = 1\ m$.

We consider imperfect contacts, the stiffness constants have the values $k_{r1} = k_{r2} = k_{\theta 1} = k_{\theta 2} = 86.42\ \ Pa/m$ and the charge Pr is equal to $\pi\ Pa$. The mechanical parameters of the media are shown in table 1. The results presented are obtained only for the first mode (n = 0) and at the angle $\theta = 0$. Figures 3 and 4 show the radial displacement and the hoop stress on the outer surface of the tunnel at $r = a_2$. We observed a fast increase in the amplitudes of the

radial displacement and the hoop stress followed by a progressive attenuation over the time. The attenuation is certainly impacted by the quality of the contact at the interfaces which has a considerable effect on the seismic wave signals. Figures 3 and 4 are the first sets of results, other complementary results will be investigated in the near future.

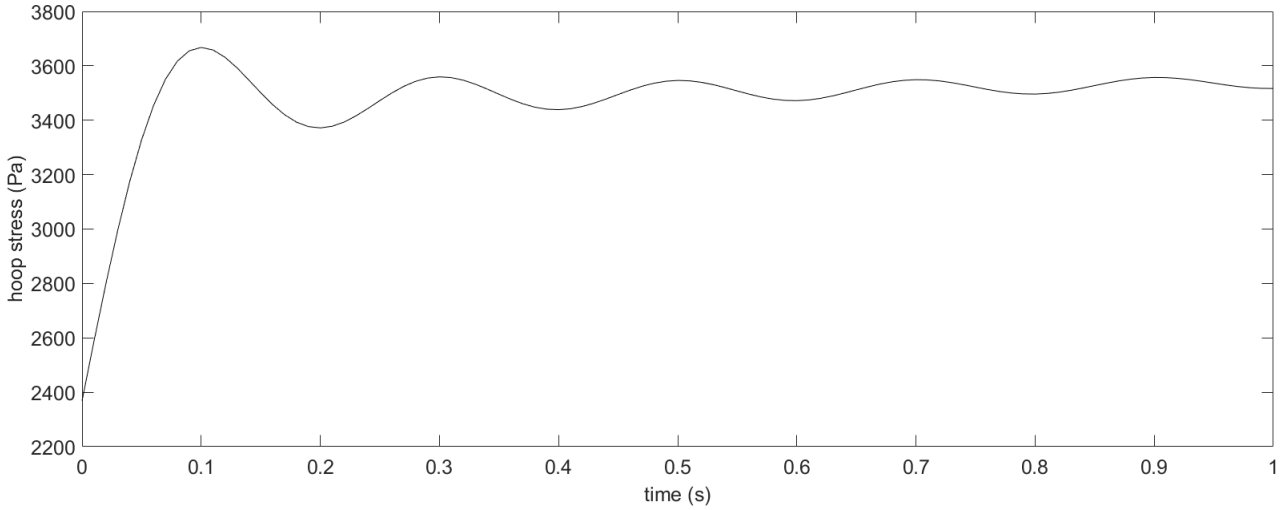

Figure 4: Hoop stress for mode ($n = 0$) at the outer surface of the tunnel $r = a_2$ and $\theta = 0$

5 CONCLUSIONS

We have proposed a transient analysis of an elastic model describing the dynamic response of a circular tunnel lined embedded in a limestone massif with a heterogeneous chalk layer. An imperfect contact model is used to take into account the heterogeneous chalk area surrounding the concrete tunnel. The numerical results are validated with those of Zakout et al. [6] and a first set of results relating to the hoop stress and the radial displacement on the outer surface of the tunnel is presented. Other results will be examined in the near future and we also hope an experimental validation of the numerical results in some distant future.

CONSEQUENCE OF SPATIALLY VARYING GROUND MOTIONS FOR THE RESPONSE OF A BRIDGE STRUCTURE

Z. Yang, C. Kun, and N. Chouw

Abstract

In earthquakes propagating seismic waves will arrive at adjacent bridge piers at different instants. Consequently, the ground motion will not excite all bridge piers at the same time, but with a time delay. Since the soil development along the bridge is never uniform, the spreading waves will be altered by the unequal soil properties along the wave path. The bridge will therefore experience spatially non-uniform ground excitation. The research focuses on the consequence of this non-uniform ground excitation for the response of a bridge structure. The left-hand abutment, bridge pier and right-hand abutment were excited by three separate large-scale shake tables, respectively. The influence of the spatial variation of ground motions on the seismic response is discussed.

Keywords: Spatial variation; Seismic response; Bridge; Shake tables; Earthquake; Pounding

1 INTRODUCTION

Major earthquakes, e.g. the 1995 Kobe earthquake [1], the 1999 Chi-Chi earthquake [2], the 2008 Wenchuan earthquake [3], the 2010 Chile earthquake [4] and the 2011 Canterbury earthquake [5] have shown the seismic vulnerability of bridges. Previous research found that for long bridges, the non-uniform ground motions at adjacent bridge supports is one of the main reasons of the relative movements between bridge structures. This is because the ground motions at adjacent bridges will never be the same due to the finite speed of propagating waves and heterogeneous properties of soil medium along the bridge. Many studies have been conducted to investigate the influence of spatially varying ground motions. Some earlier research [6-8] revealed that a time delay of ground motions has a considerable influence on the response of bridges. After the installation of the Strong Motion Array (SMART-1 array) in Taiwan [9], Chouw and Hao [10] found that for adjacent bridge segments with similar natural frequencies, the ground motion variation is one of the dominant factors for causing the out-of-phase movements between the bridge structures. The work showed the significant influence of wave passage, incoherence and site-response effects on the bridge response during earthquakes.

During strong earthquakes the collisions between adjacent bridge structures are normally impossible to avoid because of a relatively small expansion gap. Research has shown that poundings could reduce bending moments of the piers due to the dissipation of the energy as well as the restriction of the girder movements. However, poundings might also cause the damage at the contact location and increase the unseating probability of the bridge girder own to the transfer of the momentum [11]. Pounding response of bridges subjected to spatially varying excitations has been studied by many researchers. Hao et al. [12], for instance, revealed that the spatially varying ground motions could increase the accelerations and impact forces of adjacent bridge segments, which in turn resulted in an increasing number of collisions. Sextos et al. [13] found in their numerical study that when considering pounding, ignoring ground motion variation could on average result in a 25% underestimation on the ductility demand of bridge piers. Bi et al. [14] showed that the spatially varying ground motions with weak correlation could increase the pounding responses of bridges in both transverse and vertical directions.

Experimental research on the topic is limited. Crewe and Norman [15] were among the few that using the experimental method to investigate the spatial variation effects of ground motions. In their study, a 1:50 scale bridge model was fabricated to evaluate the pounding response of short-span bridges under non-uniform ground motions. The result showed that even for the same input ground motions with only a small time delay the girder displacements was significantly increased. Li and Chouw [16] constructed a two-span bridge model to study the influence of the plastic deformation of the bridge piers when subjected to non-uniform excitations. In a later study [17], a three-span bridge model was chosen to investigate the influence of the size of gap at the expansion joints with considering two-side poundings. The result of their studies indicated that neglecting the spatial variation of ground motions can underestimate the seismic responses of bridges, e.g. the pounding forces and the relative displacements between the neighbouring bridge girders. Shrestha et al. [18] carried out a shake table testing for a large-scale reinforced concrete bridge model subjected to non-uniform ground motions. The authors reported that spatially varying ground motions would increase the longitudinal peak accelerations of the girder.

The moveable abutment is, however, not considered in the studies mentioned above. Because of the significantly dissimilar structural characteristic, the abutments will inevitable influence the seismic responses of the bridge girder, which has been confirmed by many former

researcher [19-22].

To the authors' knowledge the experimental study on the pounding behaviour of bridge structures subjected to the spatially varying ground motions is scarce. To narrow the knowledge gap, in this research a series of shake table tests have been performed on a bridge-abutment model. The effects of spatially varying ground motions and pounding was physically investigated by fixing the left-hand abutment, bridge pier and right-hand abutment on three separate large-scale shake tables, respectively. The ground motions were stochastically simulated based on the target design spectrum specified in the New Zealand standard [23] for soft soil (Class D) condition with low correlation.

2 METHODOLOGY

2.1 Prototype structure and scaled model

The prototype structure is a segment of the Newmarket Viaduct Bridge located in Auckland, New Zealand. The bridge segment is 100 m long and 15.5 m high. The pier-to-pier distance is 50 m. The longitudinal fundamental frequency of the prototype is 0.98 Hz.

The experimental model has been constructed using steel with a dimensional scale of 1:20. The similitude approach followed in this study has been proposed by Chen et al. [24] and Qin et al. [25]. Details of the model are summarised in Table 1. Two abutments were simulated using steel frames, which are significantly stiffer compared to the bridge model in terms of having a much higher fundamental frequency of 330 Hz. The abutment, bridge and adjacent abutment were fixed on a shake table array located in the National Engineering Laboratory for Construction Technology of High-Speed Railway at Central South University, China. The shake table array consists of three 4 m × 4 m independent shake tables with an edge-to-edge distance of 2 m. The bridge-abutment system with shake tables is shown in Figure 1.

Parameter	Model dimension
Bridge span	5000 mm
Pier height	775 mm
Pier-to-pier distance	2500 mm
Pier width	100 mm
Pier thickness	6 mm
Second moment of area of the pier	1.8×10^{3} mm^4
Bending stiffness	1.86×10^{4} N/m
Effective mass	488 kg
Longitudinal frequency	0.98 Hz

Table 1 Parameters of model

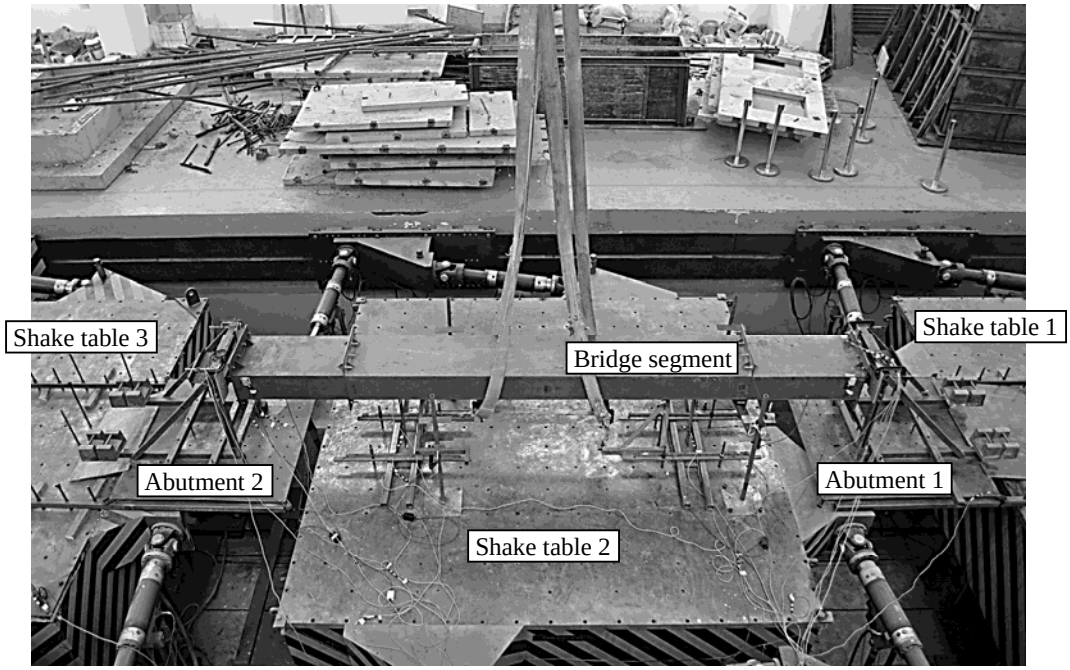

Figure 1 Bridge-abutment model on shake tables

2.2 Experimental set-up

The pounding response of bridges was investigated using pounding heads attached at each girder end. The pounding head has a contact block with a dimension of 310 mm × 56 mm. Since pounding occurs via a contact area, the actual state of impact behaviour of bridges, i.e. surface-to-surface contact, can be simulated effectively. For the case of pounding, the bridge span and adjacent abutments were fixed 5 mm apart from each other. When pounding was not considered, they were sufficiently far apart.

The MEAS 4000A accelerometers with a capacity of ± 2g were used to capture the girder accelerations. Laser displacement transducers were fixed at girder ends to measure the opening and closing displacements of the girder relative to the abutments. The pounding forces developed at the bridge-abutment interface were calculated using the force sensors. The strain gauges were placed near the top and support of each pier for measuring the strains for calculating the bending moments.

2.3 Ground motions

Spatially non-uniform ground motions were simulated stochastically based on the target design spectrum specified in the New Zealand seismic codes [22] for soft soil conditions. Details of the simulation can be found in Chouw and Hao [26]. Two sets of ground motions are considered for each of uniform and non-uniform ground motions, hereafter referred to as Set 1 and Set 2, respectively. The ground displacements at different supports of are presented in Figure 2.

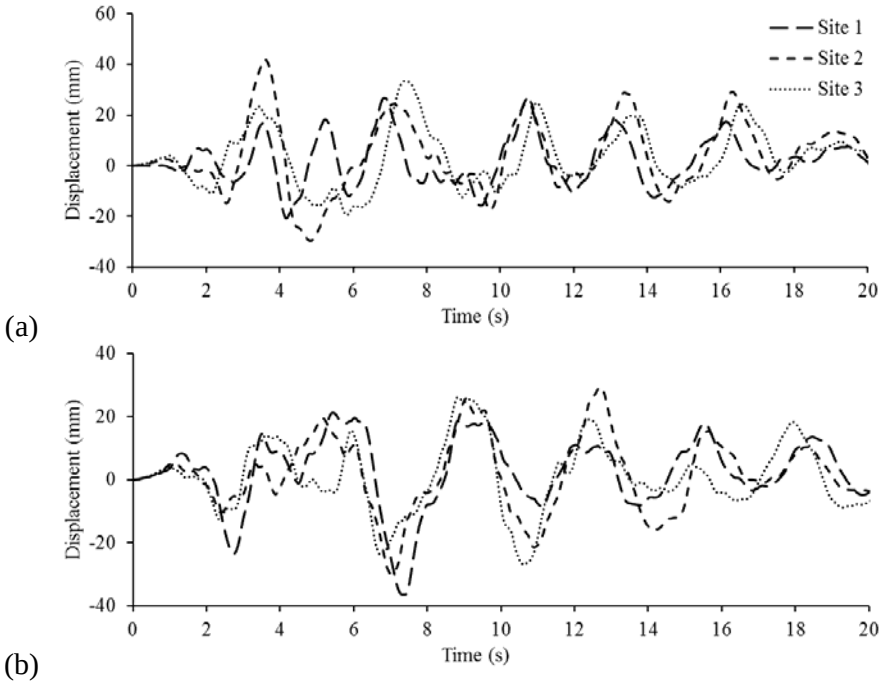

Figure 2 Ground displacements of (a) Set 1 and (b) Set 2

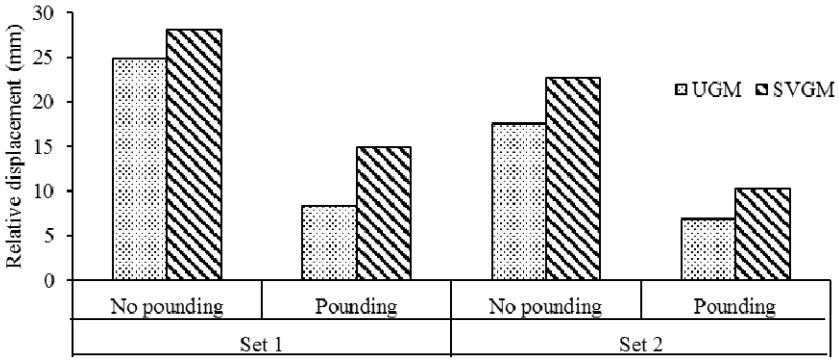
3 RESULTS AND DISCUSSION

To investigate the influence of spatially non-uniform ground excitations, the relative displacements obtained in the case of spatially varying ground excitations (SVGM) are compared to those obtained from an assumption of uniform excitations (UGM). The maximum displacements in both no pounding and pounding cases are present in Figure 3. Fig. 3(a) shows the effect of spatially non-uniform ground motions. It increases the maximum opening displacements of the girder in all considered cases. Fig. 3(b) shows that in the case without considering pounding, non-uniform ground motions increase the maximum displacements by 20%, whereas in the pounding case a significant larger amplification factor of 64% can be observed compared to that of the no pounding case. This result shows that an assumption of uniform ground motions could underestimate the relative movements of the girder whether or not pounding was considering. In the case of considering the spatially varying ground motion the amplitude of the relative displacement increases significantly due to poundings.



(b)

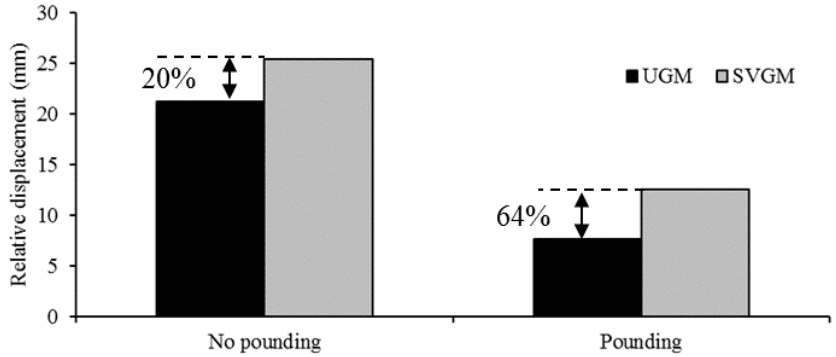


Figure 3: Effects of spatially varying ground motions and pounding on the (a) maximum and (b) average maximum longitudinal relative displacements of the bridge girders due to ground motions Sets 1 and 2.

Figure 4 shows the influence of the spatially varying ground motions on the bending moment developed at the base of piers when pounding was considered. The spatially varying ground motions increase the maximum bending moment by 18% and 27% due to the ground motions Sets 1 and 2, respectively. The results show that with considering pounding the non-uniform ground motions increases the maximum bending moments of piers. However, the influence of the effect on the bending moments is smaller than that of on the relative displacements of the girder (see Fig. (3).

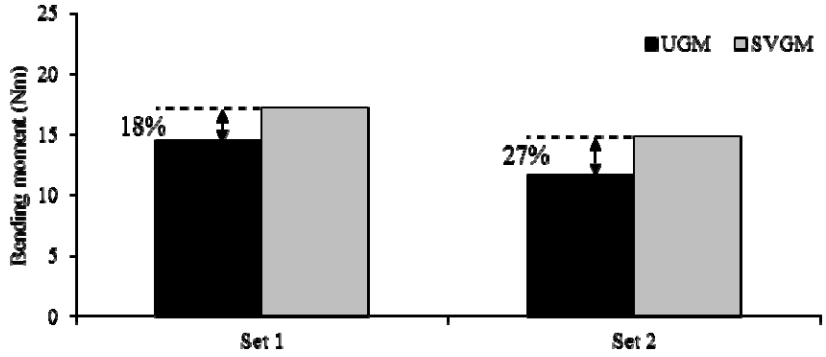

Figure 4: Simultaneous effects of spatially varying ground motions and pounding on the maximum bending moments of the bridge girders due to ground motions Sets 1 and 2.

To investigate the influence of ground motion variations on the pounding response, the pounding forces developed at girder-abutment interface due to ground motions Sets 1 and 2 are plotted in Figure 5. The result shows that the effect of spatially non-uniform ground motions increases the maximum pounding force from 194.43 N to 275.27 N due to ground motions Set 1, whereas the maximum pounding force is increased from 108 N to 240 N due to ground motions Set 2.

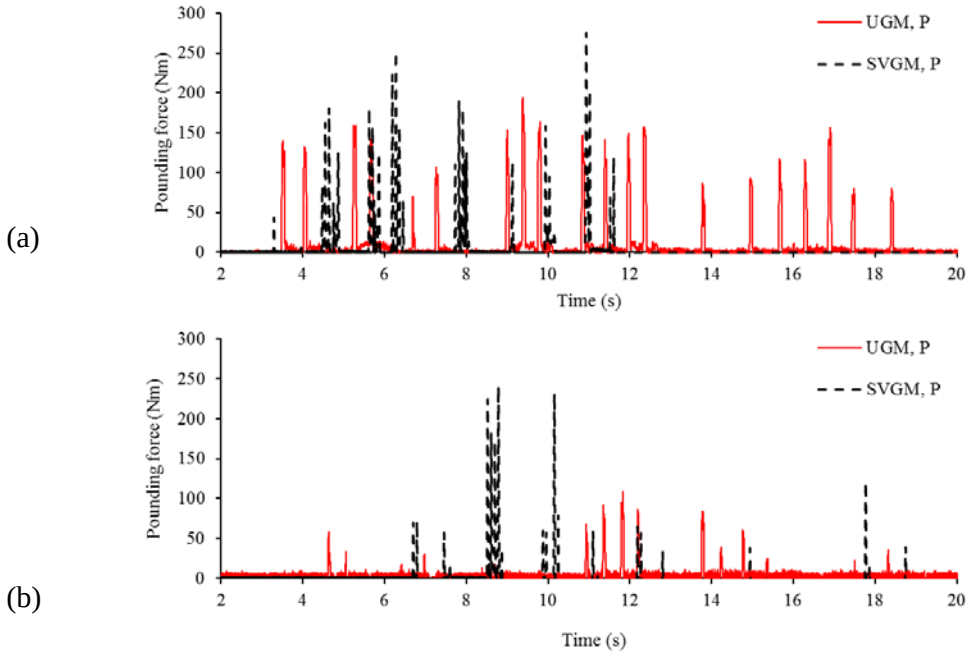

Figure 5: Effects of spatially varying ground motions on the pounding force due to (a) Set 1 and (b) Set 2 ground motions

4 CONCLUSIONS

This paper discussed the simultaneous influence of spatially varying ground motions and pounding on the seismic response of bridges. The following conclusions are drawn:

- The effect of spatially varying ground motions could aggravate the seismic response of bridges whether or not pounding was considered.
- In the case with considering pounding the effect of spatially varying ground motions causes a larger amplification on the relative displacements than the no pounding case.
- Poundings and the spatially varying ground motions have more influence on the relative displacements of the girder than on the bending moments at the bridge pier supports.

Abstract

A simple reduced-order discrete model is used to investigate the problem of dynamic through soil structure to structure interaction via an analytical 2-D formulation that is solved in the time domain. This new model includes sufficient degrees of freedom (DOF) for each of the buildings to analyses the structure-soil-structure interaction between tall and short buildings. This extends the parametric scope of previous studies. Additionally, we employ real ground motion, that are classified into three groups: Near-Field Pulse-Like (NFPL), Near-Field Without Pulse (NFWP) and Far-Field (FF). These records have differences in amplitude, duration, envelope shape, and power spectral content. Over 3 million different structural cases are analysed in Matlab for this extensive parametric study. Interaction between mode one of the short building and mode 2 of the tall building is considered. These mode 1-to-2 interactions along with the mode 1-to-1 interaction suggests that adverse/beneficial structure-soil-structure behaviour occurs for may more buildings than previous studies suggest.

Keywords: Structure-Soil-Structure Interaction (SSSI), Time History, Seismic Analysis, Dynamics.

1 INTRODUCTION

Conventionally, buildings in urban areas are designed by considering the response of structures in isolation, i.e. without any neighbouring structures. However, the high density of buildings in cities inevitably results in the possibility of seismic interaction of adjacent buildings through the underlying or surrounding soil. This phenomenon is widely known as structure-soil-structure interaction (SSSI) and has been reported in the pioneering works of Luco and Contesse [1], Kobori et al. [2], Lee and Wesley [3], Murukami and Luco [4] and Wong and Trifunac [5].

The complexity of the multi-structural interaction problem has also been emphasized in more recent investigations based on numerical two or three-dimensional Finite Element Method (FEM), Boundary Elements Method (BEM) or a combination of these two FEM/BEM procedures. For example the works of Qian and Beskos [6], Karabalis and Mohammadi [7], Lehmann and Antes [8], Qian et al. [9], Yahyai et al. [10], Padron et al. [11], among others. These studies have identified important factors that control the seismic interaction behaviour such as: (i) the separation building distance, (ii) the direction of the orientation between foundations, (iii) the height ratio and dynamic characteristics of adjacent buildings, (iv) the aspect ratio (the building height to width ratio), and (v) the soil type beneath the buildings. One advantage of using such methods is the possibility of modelling complex geometries and considering nonlinearities in the elements. However, those models have a large number of degrees of freedom involved, producing computationally costly and time-consuming analyses.

Another approach is physical modelling, which has been implemented in the last years for the SSSI phenomenon. Trombetta et al. [12] and Mason et al. [13], model the nonlinear behaviour of soil and structure. Knapett et al. [14] analysed similar and highly dissimilar building on shallow foundations using centrifuge modelling. Aldaikh [15] has indicated that the presence of neighbouring buildings could produce favourable/detrimental changes in seismic response. These represent important validation points for numerical models and provide preliminary estimates of the effects of complex interaction problems. However, these experiments are technically challenging because of the problem of scaling and represent a statistically small sample. Thus, a large-scale parametric exploration of this problem requires a different method.

The alternative is to use system models, with a relatively limited number of degrees of freedom, for a parametric study. These low-order models (i) capture the most important dynamic behaviour, (ii) have a relatively small amount of system parameters and (iii) are computationally simple for exploring a vast number of generic cases. These parametric studies should be viewed as a preliminary investigation of the problem. They are not meant to substitute advanced computational models and experimental work of specific cases. Mulliken and Karabalis [16] calculated the interaction between adjacent two and three identical rigid surface foundations supported by a homogeneous half-space soil, and subjected to impulsive, moment, sinusoidal and random loads. Most recently, Alexander et al. [17] proposed a set of frequency-independent rotational coupling spring coefficient that is used to modelling the interaction between adjacent closely spaced buildings. Additionally, Aldaikh et al. [18] proposed an alternative closed-form analytical expression for these interaction springs based on a Boussinesq formulation of the surficial displacement and rotation fields. On the other hand, Vicencio and Alexander [19] extended these previous analyses further by allowing nonlinear hysteretic behaviour in the soil. Results indicate that SSSI effects can increase with soil nonlinearity. Vicencio and Alexander [20] suggest that there are significant interactions between different structures, employed a large database of real records.

Based on the previous discussion, this paper aims to introduce a mathematical formulation of the problem of SSSI, where the model enables an extra mode for each structure, and it is

included the case of a low-rise structure next to a neighbouring much taller structure. We explore over 3 million different systems/ground motion cases. This computationally challenging study required the High-Performance Computing (HPC) machine, BlueCrystal, at the University of Bristol. The objective of this research is to answer the following two questions: (i) does the taller buildings can affect the size of adverse/beneficial SSSI behaviour? and (ii) Is there evidence to suggest that different types of earthquakes can affect the SSSI behaviour?

2 THEORY

Considering the following system shown in Figure 1. It is a pair of building described in terms of six DOFs and coupled by a rotational ground spring κ. The soil/foundation system of each building has one rotational DOF at the foundation level θ_j. The building super-structures have two translational DOFs relative to the ground (x_{2j-1} and x_{2j}). Thus, the three DOFs of each building can be viewed as a projection, onto a three modes vector basis, of a generalised multi-storey building. In the same way, this extended simplified low-order model allows SSSI between the 'second sway mode' of a tall building, and the 'first sway mode' of a shorter building. A known ground displacement field is applied at both foundations, i.e. wave passage effects and spatially heterogeneous ground displacement are neglected in the present work. The kinetic energy and potential energy for this system are given by the equations (1) and (2) respectively.

$$T_E = \frac{1}{2}\sum_{j=1}^{2}\left(\frac{1}{2}m_{bj}\left(\dot{x}_{2j-1} + \dot{x}_g - \frac{1}{2}h_j\dot{\theta}_j\right)^2 + \frac{1}{2}m_{bj}\left(\dot{x}_{2j} + \dot{x}_g - h_j\dot{\theta}_j\right)^2 + m_{sj}r_j^2\theta_j^2\right) \quad \textbf{(1)}$$

$$U_E = \frac{1}{2}\sum_{j=1}^{2}\left(k_{bj}x_{2j-1}^2 + k_{bj}\left(x_{2j} - x_{2j-1}\right)^2 + k_{sj}\theta_j^2\right) + \frac{1}{2}\kappa(\theta_2 - \theta_1)^2 \quad \textbf{(2)}$$

where h_j is the total height of the structures and m_{bj} is the total mass of the buildings. m_{sj} are the foundation/soil masses underneath building 1 and 2, r_j are the soil/foundation masses radius of gyration, $m_{sj}r_j^2$ are the foundation/soil mass polar second moments of area (moments of inertia). k_{bj} are the building lateral stiffnesses, κ is the stiffness of the inter-building soil rotational spring and b_j are the width of the buildings' foundation. The equation of motion of the complete dynamic system can be derived using the Euler-Lagrange as follows.

$$\mathbf{M\ddot{u}} + \mathbf{C\dot{u}} + \mathbf{Ku} = \mathbf{p}\ddot{u}_g \quad \textbf{(3)}$$

The system's linear viscous damping matrix $\mathbf{C}$ defined in equation (3) assumes that each natural mode $n \in [1,6]$ is damped at $\xi_n = 0.05$ of critical damping. $\boldsymbol{\phi}_n$ is the eigenvector for mode n, ω_n are the natural frequencies of the systems. Thus, the Caughey orthogonal damping matrix $\mathbf{C}$ can be calculated as [21]:

$$\mathbf{C} = \mathbf{M}\left(\sum_{n=1}^{6}\frac{2\xi_n\omega_n}{\boldsymbol{\phi}_n^T\mathbf{M}\boldsymbol{\phi}_n}\boldsymbol{\phi}_n\boldsymbol{\phi}_n^T\right)\mathbf{M} \quad \textbf{(4)}$$

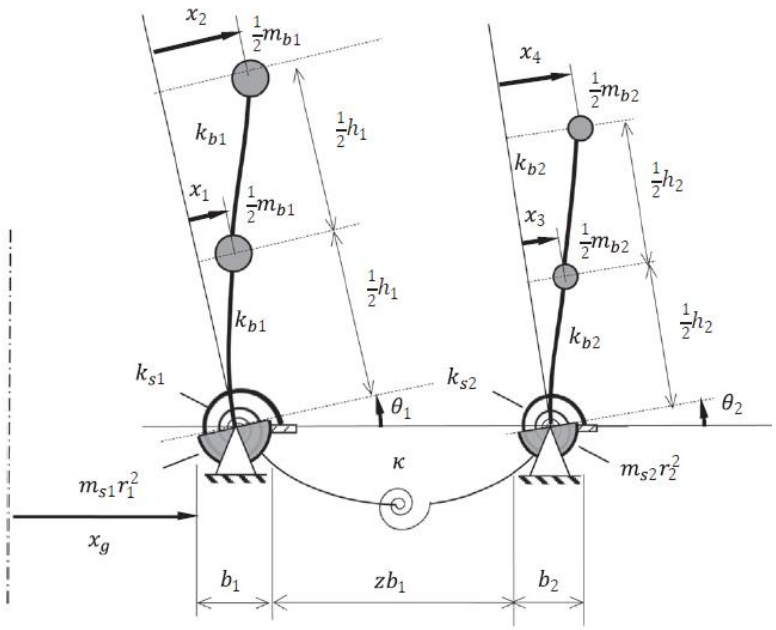

Figure 1: Two buildings discrete model.

The scope of this analysis is restricted to a special case, by assuming the following.

- The same soil profile (loose sand with an average soil density of $\rho_s = 1300kg/m^3$) exists under both buildings.
- Both buildings have a similar square plan area of $b = b_1 = b_2$.
- The buildings can be of different heights h_j, where the first building frequency is estimated using the approximation of the SEAOC Blue Book [22] for the natural period of a structure on a rigid foundation equal to $T = h_1/32$.
- The buildings are spaced at some arbitrary distance from each other zb.
- Building pounding is not permitted as inter-building spacing is assumed large enough to avoid pounding.

Newmark and Rosenblueth [23] proposed that the dynamic mass of soil beneath buildings is equal to $m_s = 0.35b^3\rho_s$. The mass of the buildings can be calculated as $m_{bj} = \rho_b h_j b^2$, where ρ_s and ρ_b are the densities of soil and building respectively. Based on typical spans and floor loading, the average building density is 400-800 kg/m^3. In this research, we used $\rho_b = 600kg/m^3$. Hence, the proportionality constant is equal to $c_1 = 0.76$. The radius of gyration of the soil-cylinder (directly under the rigid foundation) is evaluated using the Newmark's empirical expression $r \approx 0.33b$. We defined the following geometric parameters *Height ratio* ε and *Aspect ratio* s.

$$\varepsilon = \frac{h_2}{h_1}, \quad s = \frac{h_1}{b}, \quad c_1 = 0.35\frac{\rho_s}{\rho_b} \tag{5}$$

Empirical forms for the rotational and inter-building interaction spring defined in Alexander et al. [17] are considered. These springs were validated by (i) finite element models [14], (ii) physical experimental models in shaking table and centrifuge [14, 15] and (iii) closed-form analytical Boussinesq models [18]. Therefore, the values of foundation rotational spring $k_{s1} = k_{s2}$, and the interaction spring stiffness κ are written as an inverse cube power function of non-

dimensional inter-building separation distance z. The rotational stiffness spring coefficient k_s is obtained by using the empirical formulae deducted by Pais and Kausel [24] in the absence of building interaction.

$$k_{s1} = k_{s2} = k_s q_2, \;\; \kappa = k_{s1} q_k, \;\; q_k = -\frac{0.25}{(1+z)^3}, \;\; q_2 = 1 + \frac{0.5}{(1+z)^3}, \;\; k_s = \frac{1}{2}\frac{G_s b^3}{1-\mu} \tag{6}$$

Thus, the Euler-Lagrange equation of motion expressed in matrix form is as follows,

$$\mathbf{M} = \frac{1}{2}\begin{bmatrix} 1 & 0 & -\frac{3}{2}s & 0 & 0 & 0 \\ 0 & 1 & -3s & 0 & 0 & 0 \\ -\frac{3}{2}s & -3s & \frac{45}{4}s^2 + 2c_1 s^{-1} & 0 & 0 & 0 \\ 0 & 0 & 0 & \varepsilon & 0 & -\frac{3}{2}\varepsilon^2 s \\ 0 & 0 & 0 & 0 & \varepsilon & -3\varepsilon^2 s \\ 0 & 0 & 0 & -\frac{3}{2}\varepsilon^2 s & -3\varepsilon^2 s & \frac{45}{4}\varepsilon^3 s^2 + 2c_1 s^{-1} \end{bmatrix} \tag{7}$$

$$\mathbf{K} = \begin{bmatrix} 2 & -1 & 0 & 0 & 0 & 0 \\ -1 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & c_1 c_2 q_2 s \bar{V}_s^2 (1+q_k) & 0 & 0 & -c_1 c_2 q_2 q_k s \bar{V}_s^2 \\ 0 & 0 & 0 & 2\varepsilon^{-1} & -\varepsilon^{-1} & 0 \\ 0 & 0 & 0 & -\varepsilon^{-1} & \varepsilon^{-1} & 0 \\ 0 & 0 & -c_1 c_2 q_2 q_k s \bar{V}_s^2 & 0 & 0 & c_1 c_2 q_2 s \bar{V}_s^2 (1+q_k) \end{bmatrix}, \mathbf{p} = \frac{1}{2}\begin{bmatrix} -1 \\ -1 \\ \frac{9}{2}s \\ -\varepsilon \\ -\varepsilon \\ \frac{9}{2}\varepsilon^2 s \end{bmatrix} \tag{8}$$

Therefore, in this analysis, we need only 3 geometric non-dimensional parameters, (i) Aspect ratio $s = h_1/b$ (for building 1), (ii) The height ratio $\varepsilon = h_2/h_1$ (building 2 to 1) and (iii) the normalised inter-building distance ratio z (ratio of the distance between buildings to building width). The soil parameters are reduced to c_1, c_2, $\bar{V}_s$, ρ_s and μ.

In this paper, we will employ two system performance measures (the following displacement and total acceleration) to calculate the difference between the response of the coupled (SSSI) and uncoupled (SSI) systems.

$$U_{2j} = u_{2j} - 3\frac{h_j}{b}\theta_j, \;\; A_{2j} = \ddot{u}_{2j} + \ddot{u}_g - 3\frac{h_j}{b}\ddot{\theta}_j \tag{9}$$

where A_{2j} are respectively the total (sway + ground + rotational) accelerations for the top of buildings "j" in non-dimensional form. Therefore, we can state the percentage change in power caused by SSSI as follows,

$$\ddot{\chi}_{ii} = 100\frac{[E_s(A_i)]_{SSSI} - [E_s(A_i)]_{SSI}}{[E_s(A_i)]_{SSI}} \tag{10}$$

where subscript i is from 1 to 4 and $E_s(A_i)$ is the total power spectral density (which is based on all data points of response timeseries A_i), which is defined using the Parseval's theorem according to equation (11).

$$E_s(U_i) = \int_{-\infty}^{\infty} |A_i(\tau)|^2 d\tau = \frac{1}{2\pi}\int_{-\infty}^{\infty} |A_i(\omega)|^2 d\omega \tag{11}$$

where $A_i(\omega)$ is the continuous Fourier transform of $A_i(\tau)$. This difference term $\ddot{\chi}_{ii}$ is zero if there is no change between SSSI and SSI analyses or no interaction between the different structures. Using the total power as a comparative variable, produces a statistical estimate of magnitude that is more robust than employing a single peak of the function (displacement and acceleration). To obtain the uncoupled system response (SSI) case, it is possible to calculate the following system (i) increase inter-building distance z to a very large value or (ii) set $q_\kappa = 0$ and $q_2 = 1$.

3 RESULTS AND DISCUSION

3.1 Ground Motion Selection

To calculate the effect of SSSI on the system we consider three types of ground acceleration motion. This includes Far-Field (FF), Near-Field Without Pulse (NFWP) and Near-Field Pulse-Like (NFPL) record sets [25]. The ground motions database is obtained from FEMA P695 [26]. The recorded acceleration series of these ground motions are selected from the Pacific Earthquake Engineering Research (PEER-NGA) West database. The FEMA P695 recommends a set of 22 FF records that are taken from 14 events that occurred between 1971 and 1999. Eight of them occurred in California, and six of them are taken from different places around the world. Each record has two horizontal components. Event magnitudes range from $M_w = 6.5$ to $M_w = 7.6$ with an average magnitude of $M_w = 7.0$. Values of their peak ground accelerations (PGAs) vary from 0.21g to 0.82g with a mean value of 0.43g. The next figure shows the elastic response spectra from all records set used in this research.

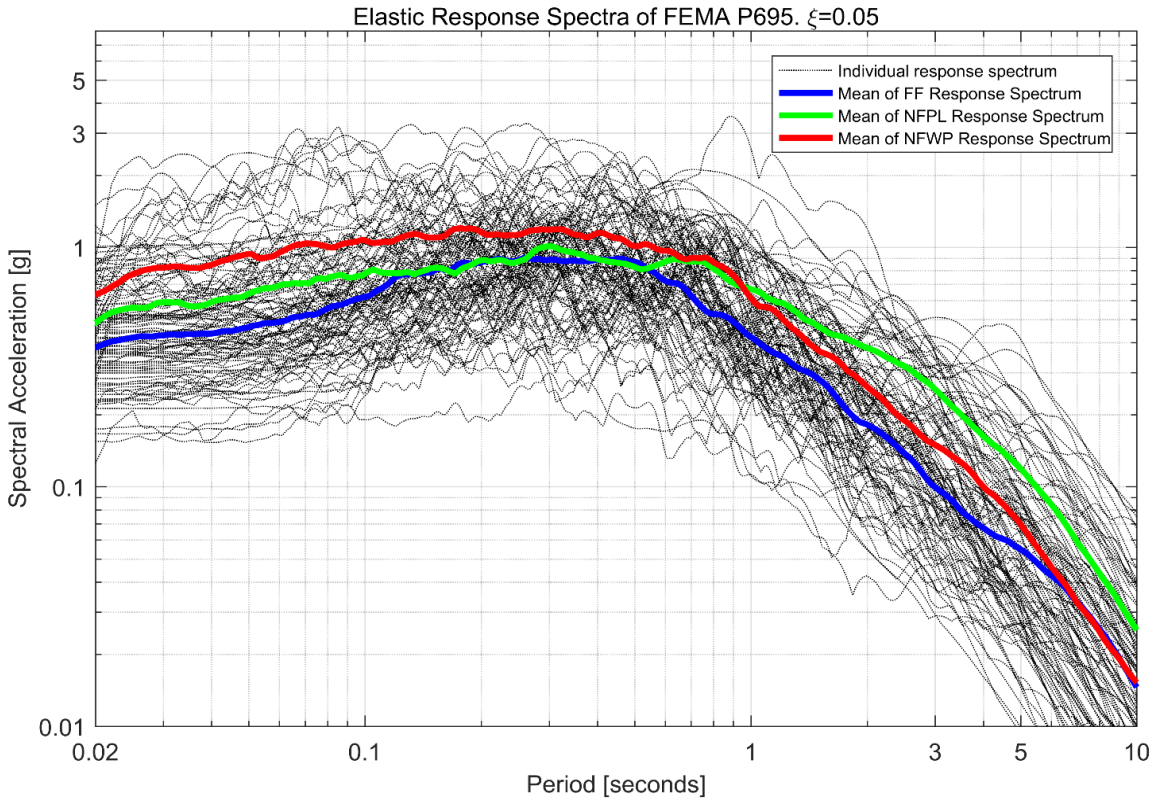

Figure 2: Elastic response spectra of FEMA P695 ground motions.

3.2 Response of the system for a set of parameters

In this section, initial results for the Near-Field Pulse-Like Imperial Valley earthquake is presented. For this, we examine the case when the two buildings are placed in very close proximity to each other, at $z = 0.1$, i.e. at a spacing distance equal to $0.1b$.

Figure 3 displays the response for a system that the second building is 2.6 times the first building, and building one has a height to width ratio equal to 2.6 (aspect ratio $s = h_1/b = 2.6$ and height ratio $\varepsilon = h_2/h_1 = 2.5$). Figure 3(a) shows the uncoupled SSI (blue line) and coupled SSSI (red line) responses for the upper DOFs of building 1, that is the displacement U_2 and the total acceleration A_2. Comparing the uncoupled SSI and coupled SSSI responses, we

observe that the maximum displacement and acceleration of buildings increases for the SSSI case.

Figure 3(b) shows the power spectral density for the displacements and total accelerations of the building 1 (SSI and SSSI cases). We perceive that building 1's total response power increase about $\chi_{22} = 63.7\%$ and $\ddot{\chi}_{22} = 51.3\%$ in the displacement and acceleration respectively. In general, for height ratios greater than 2.0, higher amplifications are observed for displacement than for acceleration.

There is a significant amplification in the displacement power spectral density for a Fourier frequency equal to 0.61Hz. This is mainly due to building 2's first uncoupled natural frequency. An important characteristic of the SSSI system is that the eigenfrequencies for the coupled and uncoupled system are very similar (there is a maximum of 9% variation in natural frequencies). However, the eigenmodes are different for the coupled system as they span the two buildings rather than a single building in the uncoupled system. The resonance at 0.61Hz is not significant for acceleration, mainly because the acceleration response is not as susceptible to low-frequency content by definition. This is a result of the Eulerian relationship $\ddot{\mathbf{v}}(\omega) = (i\omega)^2\mathbf{v}(\omega)$. The second resonance in the displacement and acceleration occurs at a Fourier frequency equal to 2.1Hz (which corresponds to building 1's first uncoupled natural frequency), while the third resonance is due to building's 2 second uncoupled natural frequency.

Figure 3(c) and Figure 3(d) displays the norm of the transfer function for the displacement and acceleration for building 1 and 2 respectively. There is a transfer of earthquake energy between building 2 to building 1, producing a reduction in building 2's responses of $\chi_{44} = -12.3\%$ and $\ddot{\chi}_{44} = -4.1\%$ in the displacement and acceleration respectively. For this parameter setting, the 'first modal frequency' of building 1 (represented by the second peak with a Fourier frequency of 2.1Hz) is close to the natural frequency of the second mode in building 2 (represented by the third peak in Figure 3(d) with a Fourier frequency of 3.4Hz). This produces an additional amplification in the response of building 1. Thus, adding an extra degree of freedom to building 1 and 2 may increase the interaction between the buildings. Nevertheless, incorporating further additional DOF into the buildings (i.e. greater than 3 degree of freedom per buildings) does not significantly influence the SSSI system response. This is because the modal participation factors of additional higher system modes are very small.

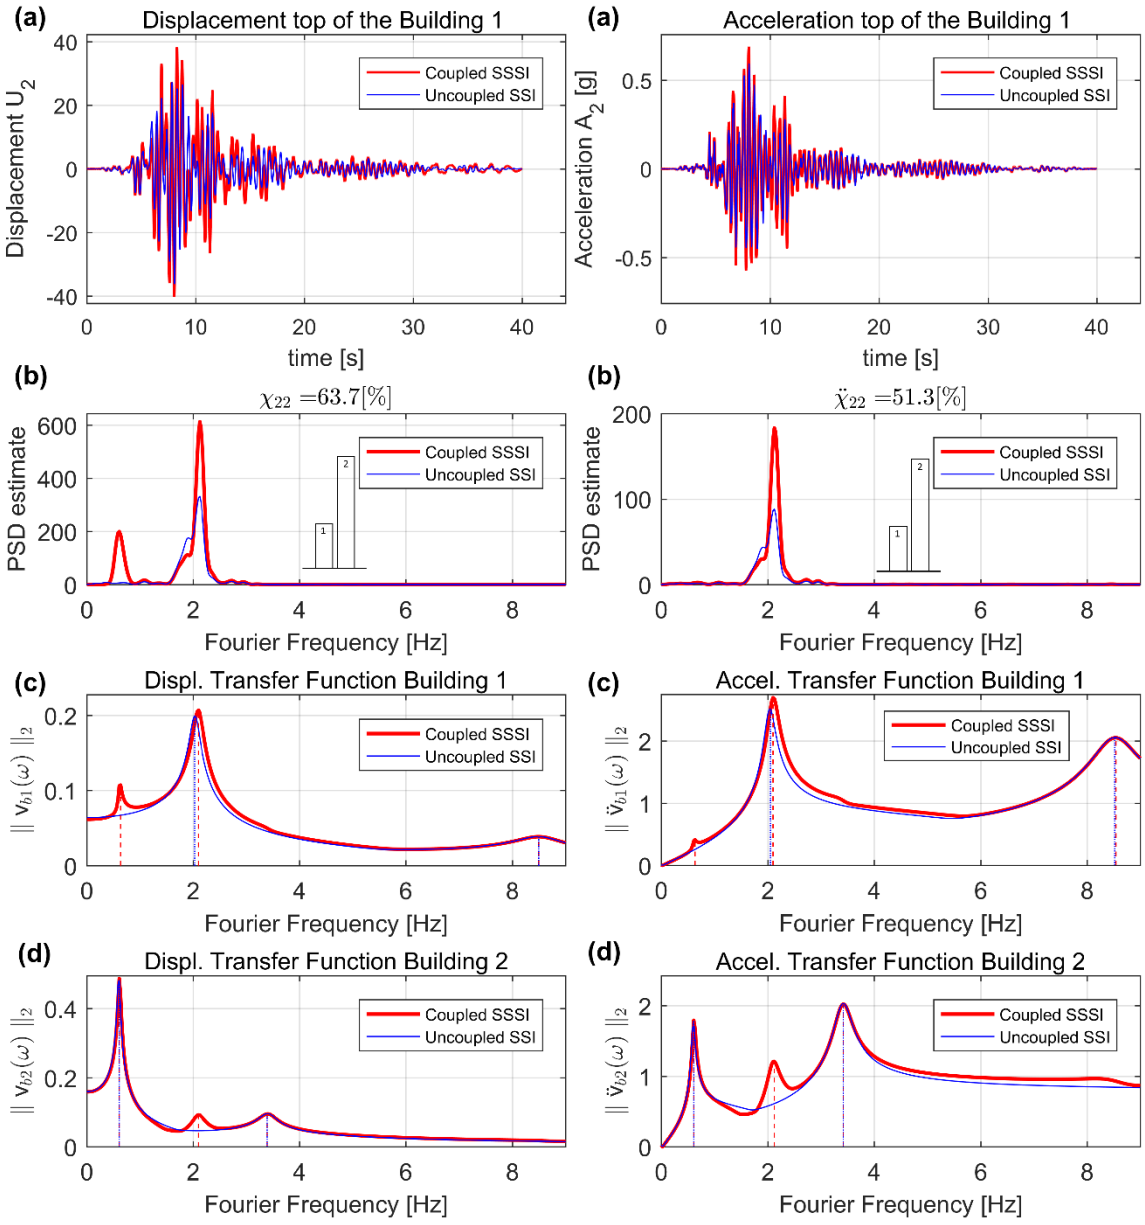

Figure 3: (a) Displacement and acceleration responses of building 1, (b) Power spectral density of displacement and acceleration responses of building 1, (c) Transfer function of displacement and acceleration for building 1 and (d) Transfer function f displacement and acceleration for building 2.

3.3 Change in power with variation in aspect ratio and height ratio

We now take a look at the total change in power of building 1, defined in equation (10) for the acceleration $\ddot{\chi}_{22}(s,\varepsilon)$. This difference term would be zero if there is no difference between the coupled (SSSI) and uncoupled (SSI) analyses.

The variation of error in power, with height $\varepsilon = h_2/h_1$ and aspect ratio $s = h_1/b$ for loose soil and inter-building spacing of $z = 0.1$, is plotted. The system is subjected to all earthquake events, classified by Far-Field (FF), Near-Field Without Pulse (NFWP) and Near-Field Pulse-Like (NFPL) record sets. For each of these record sets, the maximum of maxima error (for this record set), the mean error (for this record set) and the standard deviation of error (for this record set) are presented.

Figure 4 displays the contour plots of variation of error $\ddot{\chi}_{22}(s,\varepsilon)$ for the displacement and acceleration A_2 on top of building 1, for the Far-Field records. Figure 4 contains the results of nearly half million different time-histories analyses. We employed University of Bristol's supercomputer, BlueCrystal, for these simulations. The critical zones in the figure are red, i.e. where the total response power of building 1 is amplified by the presence of building 2. Blue indicates when the response power is reduced.

For the displacement, the worst possible building parametric configuration lies around $\chi_{22}(2.6,1.1) = 110\%$, and when the height ratio is greater than 2. In the case of acceleration, for height ratios greater than 1, i.e. when adjacent buildings are taller, the response of building 1 is amplified. The maximum increase in total acceleration power response occurred when the building parametric configuration lies around $\ddot{\chi}_{22}(2.5,1.1) = 110\%$ and its average is approximately $\ddot{\chi}_{22}(\mathrm{s},1.1) = 40\%$. The dispersion of the values is small, with a maximum of 40%, for the whole range of analysed parameters.

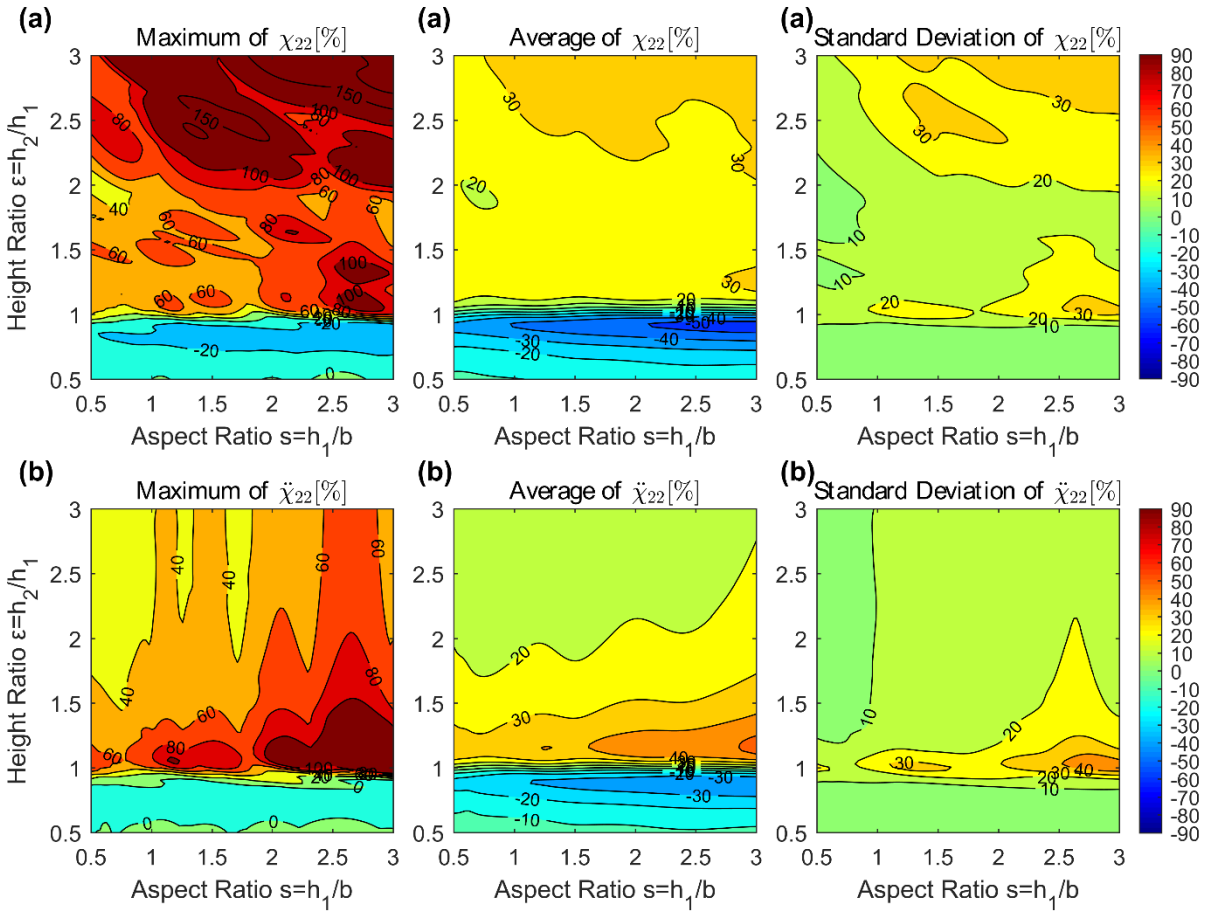

Figure 4: Response for Far-Field records. Maximum value, average and standard deviation for change in (a) displacement and (b) acceleration power.

Figure 5 displays the contour plots of variation of error in power $\ddot{\chi}_{22}(s,\varepsilon)$ for the displacement and acceleration A_2 considering the Near-Field Pulse-Like records. Again, in Figure 5 and Figure 6 over half a million different time-histories analyses are developed. As with the FF records, the maximum increase in total acceleration power response occurred when the structure configuration lies around $\ddot{\chi}_{22}(2.6,1.1) = 110\%$ and reaching values above 400% for the displacement (height ratio greater than 2). The dispersion of the values is small, with a maximum of 32%, for the whole range of analysed parameters.

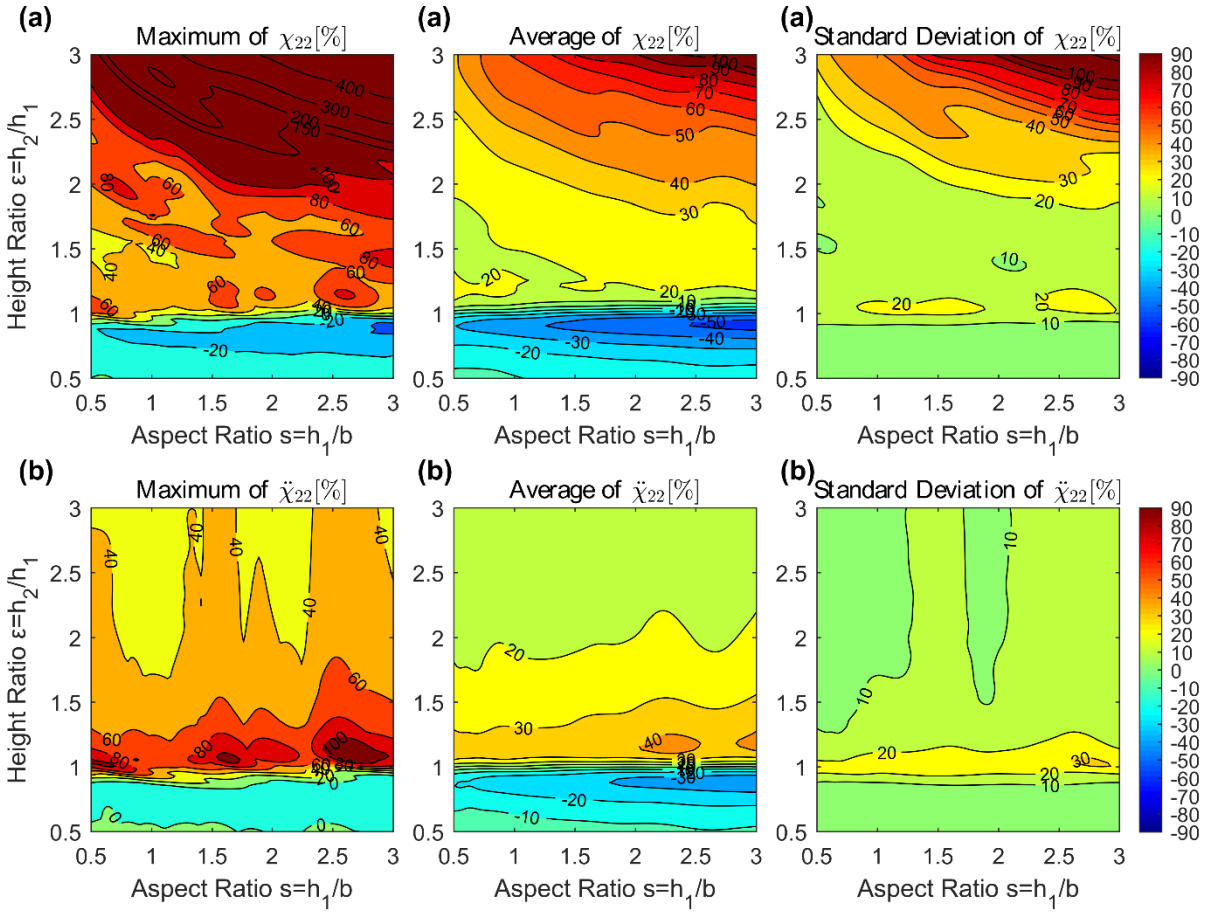

Figure 5: Response for Near-Field Pulse-Like records. Maximum value, average and standard deviation for change in (a) displacement and (b) acceleration power.

Figure 6 shows the variation of change in power for the displacement and acceleration A_2 considering Near-Field Without Pulse records. In general, the behaviour of NFPL and NFWP earthquakes follows a similar pattern for maximum values, averages and standard deviation. Comparing the FF and NF earthquakes, the contour plots suggest that the low-frequency content of the earthquake (especially for Near-Field records) can affect the size of adverse SSSI effects, especially for response displacements when the height ratio is greater than 2.0.

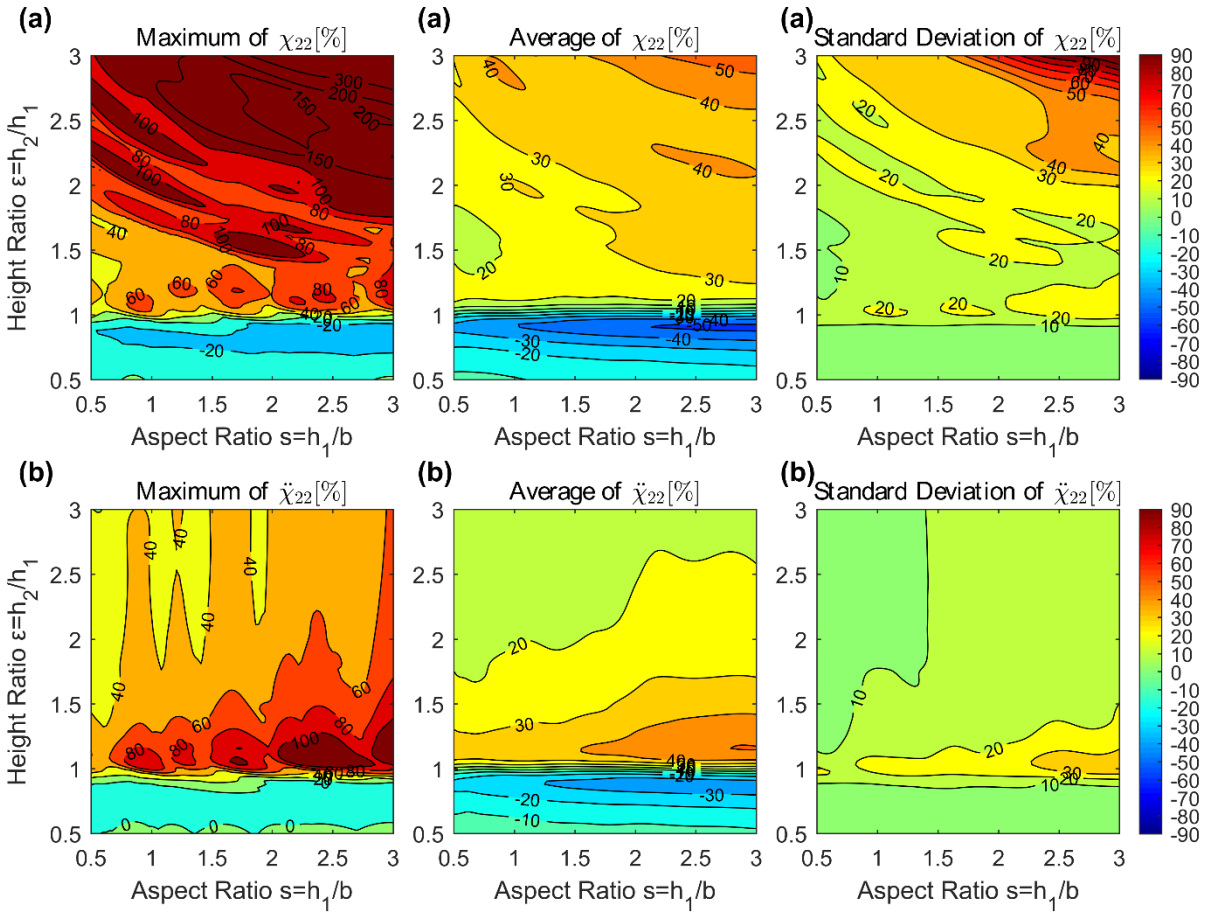

Figure 6: Response for Near-Field Without-Pulse records. Maximum value, average and standard deviation for change in (a) displacement and (b) acceleration power.

4 CONCLUSION

In this paper, we present a theoretical formulation for SSSI between two buildings. These structures are coupled through the underlying soil. Three types of ground motion were considered (Far-Field, Near-Field Without Pulse and Near-Field Pulse-Like records sets), selected from FEMA P695. The analyses have been undertaken for loose soil.

The computational analysis for loose soils showed that there are unfavourable and beneficial configurations for the dynamic characteristics of buildings. Regardless of the seismic event, it is found that the effect of interaction is adverse for building 1 when building 2 is taller: i.e. the power of the earthquake passed from the taller building to the smaller building. For the displacement responses, there is an increase in the response of up to 400%, when there is a large difference of height (height ratio $\varepsilon = h_2/h_1 > 2.0$) between the buildings. This result was not observed in previous studies [15,17]. The taller building imposes a low-frequency 'rigid body rocking mode' on the smaller building. If this behaviour is combined with ground motions that have a larger low-frequency content (i.e. the near field records), then there is significant error in using SSI analyses rather than SSSI analyses for these cases. This behaviour is observed in displacement responses alone because acceleration responses are, by definition, much less susceptible to low-frequency excitation. For the acceleration responses, the greatest amplifications, of up to 120%, are observed for buildings of 10% difference in height. This finding confirms the results of previous studies [17].

This research also indicated that there is a favourable geometric configuration ($\varepsilon = h_2/h_1 < 1.0$) where the seismic risk is reduced in building 1 by the presence of a smaller structure. The most beneficial configuration produces a reduction of the change in power in -45% for displacement and acceleration.

Results obtained from this 6dof model suggest that the introduction of two additional degree of freedoms can affect the size of interaction between the structures. Therefore, the 6dof model allows the interaction of the second sway mode of a much taller structure with the first sway mode of a shorter structure of less than half its height. This suggests that modal coupling between the buildings is possible between more than just the primary modes of each structure and therefore indicates a significant interaction between a taller building 1 and much shorter building 2.

Keywords: Building Vibrations, Building Adjacency Effects, Ground Vibrations, Coupled FEM, Frequency Domain, Parametric Study

Abstract. *Urban densification, despite the economic and social opportunities it offers, brings with it challenges to the well-being of citizens. A direct effect of densification is the rise in noise- and vibration-producing sources, which can lead to both health and comfort issues. In determining the risk associated with excessive vibration levels, the distance between the source and the receiver or target building, the ground properties, and the building type, are all important factors. In this paper, we are concerned with the effect that adjacent buildings have on the prediction of the vibration levels in a residential building, caused by external ground surface loads. The parametric studies were conducted using a coupled finite element model of the ground and the buildings. The analyses were conducted in the frequency domain, and vibrational velocity levels were computed at the receiver building in order to assess how building adjacency affects the receiving building's vibrational response.*

1 INTRODUCTION

The densification of urban areas, driven mostly by economic forces, continues unabated. Urban densification, despite the economic and social opportunities it offers, brings with it challenges to the well-being of citizens. A direct effect of densification is the rise in noise- and vibration-producing sources, which can lead to vibrations that exceed human-tolerable levels. Current construction trends, which tend to favor the use of lighter materials (e.g., timber), promote higher levels of human-perceivable vibrations. In addition, in dense urban settings, the proliferation of vibration-producing sources has an effect on vibration-sensitive equipment, whether in hospitals, research laboratories, or industrial facilities, that cannot be ignored.

Of the many different vibration sources, of interest herein is the analysis of traffic-induced building vibrations, since it remains one of the dominant sources of vibrations in urban environments, further aggravated by densification. The traffic-induced vibration analysis is demanding, since the problem involves a large number of difficult-to-estimate parameters. In broad strokes, the problem can be divided into the three different parts illustrated in Fig. 1: the external source; the medium; and the receiver. The parameters and the properties of each part affect the vibration levels in the receiver building. In devising numerical models to estimate the vibration levels, adjacent buildings are usually not taken into account—it is common practice to only include the receiving building within the model. The effect of adjacent buildings in the response of a receiver building has been primarily studied in the context of earthquake engineering, the so-called structure–soil–structure interaction and/or "site–city effects", where the presence of adjacent buildings can significantly alter the response dynamics (see, for example, [1, 2]). However, the influence of these interaction effects is not a well-studied area for traffic-induced building vibrations. Exceptions include the study of the effect of structural modifications to the receiving building and its surroundings in order to mitigate the vibrational response induced by ground sources [3, 4, 5, 6, 7, 8].

In the present study, we investigate the effect of structural modifications to an adjacent building on the receiving building's vibrational response due to ground surface loading. An example of a suitable and commonly-arising application is the study of traffic-induced building vibrations were residents may be complaining due to increased vibrational levels. In Section 2 we describe modeling of externally induced building vibrations, and in Section 3 we discuss the developed computational model. Section 4 presents the conducted parametric study and the numerical results. In Section 5 we discuss pertinent conclusions of the study.

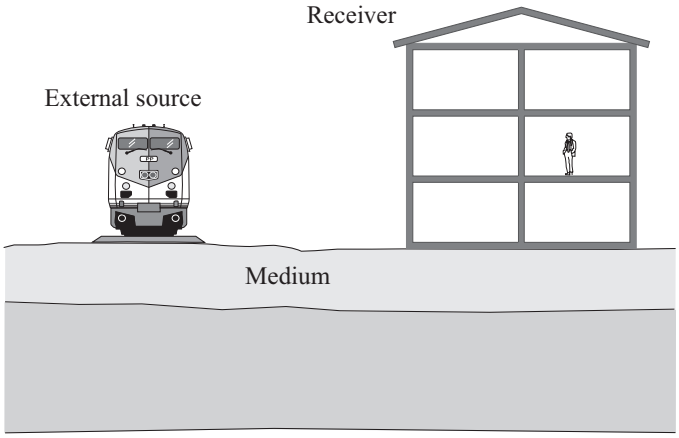

Figure 1: Illustration of typical components of a building vibration problem in the built environment.

2 MODELING OF EXTERNALLY INDUCED BUILDING VIBRATIONS

The modeling procedure used in the present study is based on the assumption of linear elastic behavior, since we consider only low-amplitude vibrations induced by, for example, train and/or road traffic. The analyses of the dynamic loading is performed in the frequency domain and the finite element (FE) method is used to compute velocity levels. Since the spatial variability of the soil and of the building properties occur at scales much smaller than the wavelengths that correspond to the frequency range of interest, in additional to linearity, we assumed homogeneous and isotropic material behavior throughout.

After spatial discretization, the FE model of a linear dynamic system provides a semi-discrete equation of motion in the form of the following system of ordinary differential equations:

$$\mathbf{M}\ddot{\mathbf{u}} + \mathbf{C}\dot{\mathbf{u}} + \mathbf{K}\mathbf{u} = \mathbf{f}, \tag{1}$$

where $\mathbf{M}$, $\mathbf{C}$, and $\mathbf{K}$ denote the mass, damping, and stiffness matrices, respectively, whereas $\mathbf{u}$ denotes the displacements and $\mathbf{f}$ the loads. Dots indicate derivatives with respect to time. In case of steady state displacement response to harmonic excitation, $\mathbf{u}$ and $\mathbf{f}$ can be expressed as complex harmonic functions:

$$\mathbf{f} = \hat{\mathbf{f}}\mathrm{e}^{\mathrm{i}\omega t}, \quad \mathbf{u} = \hat{\mathbf{u}}\mathrm{e}^{\mathrm{i}\omega t}, \tag{2}$$

where $\hat{\mathbf{f}}$ and $\hat{\mathbf{u}}$ denote the complex load amplitude and the displacement amplitude, respectively, i denotes the imaginary unit, ω denotes the angular frequency, and t denotes time. Introducing Eq. (2) in the equation of motion (Eq. 1) yields the equation of motion in the frequency domain:

$$\mathbf{D}(\omega)\hat{\mathbf{u}} = \hat{\mathbf{f}}, \tag{3}$$

where the dynamic stiffness matrix $\mathbf{D}(\omega)$ can be expressed as:

$$\mathbf{D}(\omega) = -\omega^2\mathbf{M} + \mathrm{i}\omega\mathbf{C} + \mathbf{K}. \tag{4}$$

We used a rate-independent (hysteretic) damping model, and thus, the damping can be described by a loss factor [9], as in:

$$\mathbf{K}\eta = \omega\mathbf{C}. \tag{5}$$

Inserting Eq. (5) into Eq. (4), we arrive at:

$$\mathbf{D}(\omega) = -\omega^2\mathbf{M} + (1 + \mathrm{i}\eta)\mathbf{K}. \tag{6}$$

The imaginary part of the stiffness matrix is often referred to as the structural damping matrix. Equation (6) was used to model both the structures and the soil. We note that for the soil, the linear elastic model accounts for the bulk compressional and shear waves, as well as for any interface waves (Rayleigh on the free surface, and Stoneley along any interfaces between soil layers). As is often the case, the FE model occupies a finite computational domain, which is truncated via the introduction of suitable absorbing boundaries. Here, to reduce the computational effort, we used dashpots [10], which are effective when waves impinge at normal incidence.

3 COMPUTATIONAL MODEL

The coupled FE model comprises both the soil and the building structures, which are fully coupled. See Fig. 2 for a schematic of the model. Plane strain conditions were applied, thus a line load as well as an elongated building exposed to planar waves were assumed.

The soil in the example case consists of a stiff 10 m deep soil layer resting on top of bedrock—conditions common in the south of Sweden; see Fig. 3 for the Youngs modulus E, Poissons ratio ν, mass density ρ, and the loss factor η for the soil materials. Treating the bedrock as a linear elastic material rather than a rigid foundation is an important parameter in this study. The dimensions of the building are shown in Fig. 2. The building structure consists of 200 mm thick concrete walls and 300 mm thick concrete slabs. The reinforcing bars are assumed to not influence the response; the isotropic material properties used for the concrete are given in Table 1. The model is excited by a vertical harmonic unit load applied on the ground surface 50 m from the receiver building; the load frequency was varied between 1 and 80 Hz in steps of 0.5 Hz. The frequency range was set to relate to human response, on the basis of the ISO standard [12].

Abaqus 6.13 [11] was used to compute the coupled response. To ensure that the FE analyses provide results of adequate accuracy, the influence of various parameters such as the aspect ratio of the finite elements, the size of the computational domain, and the reflection of waves at artificial boundaries have been studied, while the mesh density was adjusted to account for typical minimum number of nodes per wavelength criteria. The soil, as well as the buildings, were modeled with eight-node (serendipity) plane strain elements. Given the materials and fre-

quency range of interest, the mesh convergence study resulted in an element size of 0.5×0.5 m^2 for the soil layer and 0.5×10 m^2 for the bedrock. Generally, an element size of 0.3×0.3 m^2 was used for the slabs, and 0.2×0.3 m^2 for the walls. The FE mesh of the soil is shown in Fig. 4.

4 PARAMETRIC STUDY

In order to investigate the effects that various parameters of the adjacent building have on the receiving building's vibration response, a single parameter at a time was varied while the others were kept constant. In total, five different parameters related to the adjacent building were varied, and the results are presented in the following five subsections 4.1–4.5. Specifically, we report on the effect of:

1. Distance between the buildings
2. Size of adjacent building footprint
3. Adjacent building cellar depth
4. Adjacent building mass
5. Adjacent building damping

In computing one value representing the vibration response we want to use a metric that is sensitive to the peaks in the response spectra. We are therefore using a Root Mean Quad value (RMQ), calculated as follows:

$$\text{RMQ} = \frac{1}{n}\left(\sum |V|_j^4\right)^{1/4}, \tag{7}$$

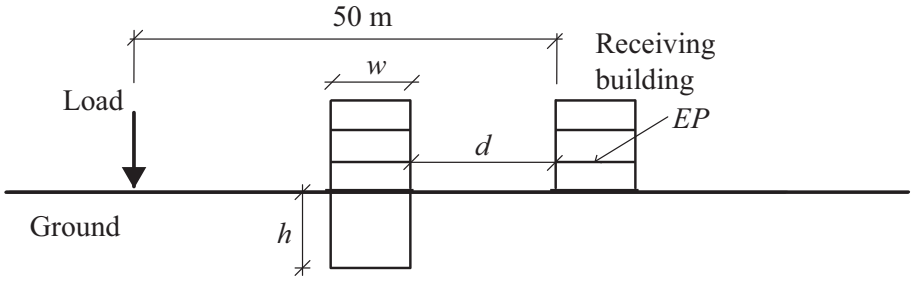

Figure 5: Setup with adjacent building in front of receiving building.

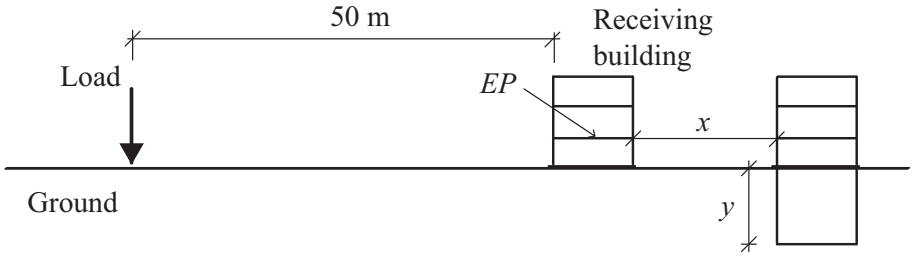

Figure 6: Setup with adjacent building behind receiving building.

where j denotes each discrete frequency, and n is the total number of frequencies. The vertical velocities, $|V|$, were evaluated as complex magnitudes at the mid-point of the first floor level; the specific locations are indicated in Figs. 5 and 6 as *EP* (Evaluation Point).

4.1 Distance between the buildings

In this subsection we evaluate to what extent the distance between the buildings affects the vibrations in the receiving building.

First we consider the case when the adjacent building ($h = 0$, $w = 8$ m) is located in front of the receiving building as seen in Fig. 5. Figure 7 shows that having an adjacent building between the vibration source and the receiving building affects the response significantly. It also shows that the gap-distance d has a minor effect on the response, and that no clear trend can be seen.

Secondly, we consider the case of having an adjacent building without a cellar ($h = 0$) located behind the receiving building. The calculations showed that the response was not affected to any appreciable extent, independently of the distance x between the buildings (cf. Fig. 6). Therefore, we do not show the corresponding frequency response. However, if an 8 m-deep cellar is considered, i.e. $y = 8$ m, the response in the receiving building is affected. The effect of various distances, x, between the buildings for this case is presented in Fig. 8. As seen in the figure, there is an effect on the response depending on the distance to the adjacent building. The effect on the spectrum is rather small but since it affects the large frequency peaks, it still results in a considerable change in the evaluated metric of the response. However, no apparent general trends can be seen other than that the distance between the buildings is of importance.

A setup with no adjacent building represents the reference case. In the left subfigure, the solid black line represents the reference case and the gray vertical lines show the receiving building's eigenfrequencies.

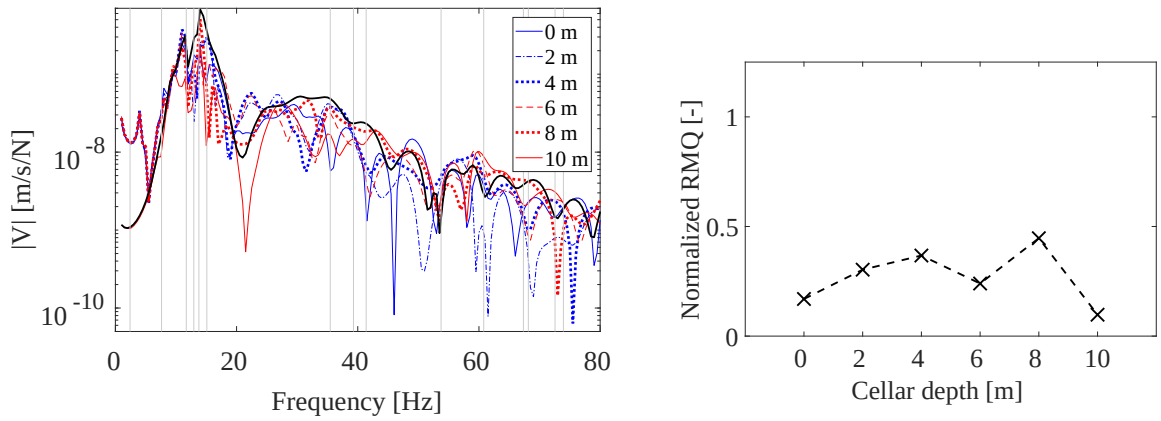
4.2 Size of building footprint

In this subsection we investigate the effects of the footprint size of the adjacent building, when located in front of the receiving building, on the receiving building's response. The model can be seen in Fig. 5, where the footprint size is varied by changing of the width w of the adjacent building. As seen in Fig. 9, the footprint size can have a marked influence on the response. The most significant effect is seen when the adjacent building has the same footprint as the receiving building ($w = 8$ m), where a large reduction in the vibration response is evident. In this setup, the adjacent and receiving buildings have the same modal properties.

4.3 Cellar depth

The influence of the cellar depth for two different locations of the adjacent building is investigated in this subsection. In the first case, the adjacent building is located in front of the receiving building as seen in Fig. 5. The distance d is fixed at 15 m, and the width of the adjacent building is 8 m; we vary the cellar depth h. As seen in Fig. 10, there is a large effect of the cellar depth on the vibration response. The largest influence occurs when the cellar goes all the way down to the bedrock, i.e. $h = 10$ m. The reflection of waves from the concrete cellar walls is then significant.

As was noted in Section 4.1, having the adjacent building without cellar located behind the receiving building did not, to any appreciable extent, affect the vibrational response for any of the tested distances between the buildings. However, the distance has an influence when the adjacent building has a cellar. Now we vary the cellar depth y of the adjacent building located behind the receiving building. The distance x is fixed at 15 m and the width of the adjacent building is 8 m; see Fig. 6 for the model. As seen in Fig. 11, there is only a small effect of varying the cellar depth, but a clear trend is shown; with deeper cellar the reflected waves amplify (normalized RMQ value greater than 1) the response in the receiving building.



(a) Frequency spectrum for the tested values of h. (b) RMQ value normalized to the reference case.

Figure 10: Vibration levels computed employing the adjacent building with cellar in front of the receiving building. The cellar depth h being varied. A setup with no adjacent building represents the reference case. In the left subfigure, the solid black line represents the reference case and the gray vertical lines show the receiving building's eigenfrequencies.

(b) RMQ value normalized to the reference case. Note the scale on the horizontal axis.

Figure 12: Vibration levels computed with the adjacent building in front of the receiving building. The mass density of the adjacent building being varied. A setup with no adjacent building represents the reference case. In the left subfigure, the solid black line represents the reference case and the gray vertical lines show the receiving building's eigenfrequencies.

4.4 Building mass

In this subsection we vary the mass of the adjacent building by changing the material density of the concrete. The adjacent building is located in front of the receiving building; see Fig. 5 for the model. The distance d is fixed at 15 m, the width of the adjacent building is 8 m, and the building does not have a cellar, i.e. cellar depth $h = 0$.

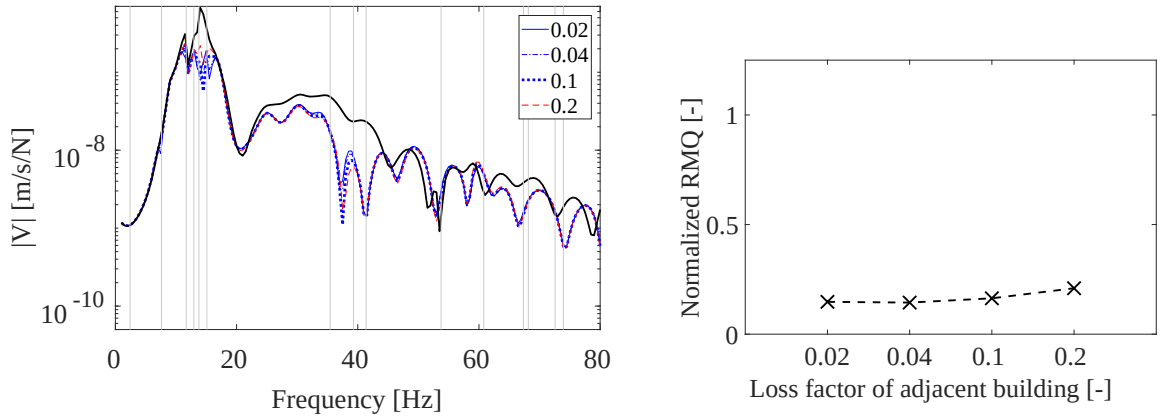
As seen in Fig. 12 the mass of the adjacent building has a significant effect on the response. A heavier adjacent building in front of the receiving building mitigates the vibrations to a larger extent than a lighter building. Note that the lowest as well as the highest tested mass densities are not realistic—however, they indicate that the largest influence occurs for mass densities between 250 and 2500 kg/m^3.

4.5 Building damping

The amount of damping in the adjacent building, which is located in front of the receiving building according to Fig. 5, is varied. The distance d is fixed at 15 m, and the width of the adjacent building is 8 m and it does not have a cellar, i.e. cellar depth $h = 0$. The loss factor was varied between 0.02 and 0.2. It was seen that varying the damping in the adjacent building had a minor effect on the evaluated vibration levels in the receiving building; see Fig. 13 for the response.

5 CONCLUSIONS

The paper presents a conceptual study of the effects of structural parameters of an adjacent building on the vibration response in a receiving building. The FE method was used to create a coupled soil and structure model that was excited by a ground surface load. The analysis was conducted in the frequency domain with plane strain conditions, and the velocity levels were computed in the frequency range of 1–80 Hz and evaluated at the midpoint of the first floor.



(a) Frequency spectrum for the tested damping values of the adjacent building.

(b) RMQ value normalized to the reference case. Note the scale on the horizontal axis.

Figure 13: Vibration levels computed with the adjacent building in front of the receiving building. The amount of damping in the adjacent building being varied by use of the loss factor η. A setup with no adjacent building represents the reference case. In the left subfigure, the solid black line represents the reference case and the gray vertical lines show the receiving building's eigenfrequencies.

Two main general tendencies were observed: (i) to place a building between the vibration source and the receiving building may work as a wave obstacle, thus mitigating the incoming ground vibrations—the benefit is greater when the intervening building is heavier; (ii) having building(s) with a cellar behind the receiving building may amplify the response and should therefore be considered in a vibration analysis.

This conceptual study clearly points that there are so-called "site–city effects" in the problem of ground-surface induced building vibrations, and that adjacent buildings must be considered in an analysis aiming at determining vibrations levels in a building.

6 ACKNOWLEDGMENTS

The research presented in this paper was partly funded by several agencies. They being: Swedish Governmental Agency for Innovation Systems, grant ref.no. 2018-04159; The city of Helsingborg through Plattformen; and The Swedish Foundation for International Cooperation in Research and Higher Education (STINT). The financial supports are gratefully acknowledged. The former Master's student Johansson [13] is gratefully acknowledged for his contribution to the research presented in the paper.

Abstract

The present study refers to the interaction between two adjacent strip foundations that have different depths of embedment. In particular, one foundation is characterized as deep and is embedded in an elastic isotropic soil layer which is resting on a rigid substratum, while the other foundation is characterized as surface and is resting on the soil layer's surface. The two foundations have an equal value of half-width, B and the embedment depth, D of the deep foundation is equal to B. The distance ratio S/L, where S is the distance between the foundations and L is the width of each foundation receives the values of 0.5,3,5 and 10. In order to investigate the effect of the soil layer's depth H, the distance ratio is kept constant and equal to 0.5 while the H/B ratio receives the values of 2, 4, 8 and 32.

The main target is the calculation of the impedance matrix of the two interacting foundations and is achieved by the use of the finite element method. The accuracy of the finite element model is verified by comparison studies with the rigorous results from the boundary element method, concerning a single strip foundation, embedded or surface.

Each strip foundation has three degrees of freedom; the vertical translation, the horizontal translation and the rotational one. Therefore, harmonic type of loading is applied at each foundation for each degree of freedom and the flexibility matrix is calculated for a normalized frequency range of $0.1<\alpha o<2$, where $\alpha o=\omega B/Vs$; ω is the loading frequency and Vs is the shear wave velocity. The final flexibility matrix is a 6x6 symmetric matrix, which consists of terms referring to the deep or surface foundation response and the coupled response between them. The flexibility functions are presented for typical values of S/L and H.

The main conclusions are focused on the comparison between the response of each foundation which belongs to the system of the two and the response of a single foundation, deep or surface. Additional comments refer to the effect of the soil layer's depth on the coupling terms of the flexibility matrix of the two adjacent foundations.

Structure-soil-structure interaction, Strip footings, Finite Element Method.

1 INTRODUCTION

The assumption of fixed base boundary conditions for a structure can be considered appropriate only in very limited cases of a hard substratum time. Consequently, the soil-structure interaction (SSI) phenomenon must be taken into account, especially during dynamic structural design analysis. Furthermore, in dense populated areas, of closely spaced structures or structures on relatively close supports, the cross interaction through the soil between adjacent foundations might also be important [1]. Therefore, in order to evaluate the dynamic characteristics or the response of adjacent structures, it is necessary not only to investigate the classical interaction between the foundation and the soil medium, but also the interaction between the adjacent foundations through the soil [2]. Each foundation which diffracts the incident wave field can be regarded as a disturbance producing a secondary wave field affecting its neighboring [3]. This phenomenon is known as dynamic cross interaction (DCI) problem [2], structure-soil-structure interaction (SSSI, 3SI) problem [4] or foundation-soil-foundation interaction (FSFI) problem [5].

The interaction of soil medium and a surface strip foundation was investigated by many researchers. Some researches refer to the coupling between horizontal and rocking response. Luco and Westmann (1972) studied the coupling under the assumption of welded soil contact. Horizontal-rocking coupling arises during the application of lateral forces (e.g. wind), earthquake loading or machine vibrations [7]. The coupled and uncoupled horizontal-rocking response of a surface foundation under the assumption of relaxed and welded as well boundary conditions was studies by Karasudhi et al. (1968). The dynamic response of a surface strip foundation without accounting for horizontal-rocking coupling was investigated by Hryniewicz (1981). Furthermore, some additional researches focus on the properties of the soil medium. Wickham's study (1977) referred to a rigid strip foundation in smooth contact with a semi-infinite elastic solid. A semi-analytical technique was applied by Gazetas and Roesset (1976) in order to estimate the dynamic compliances of a rigid strip foundation resting on an elastic, linearly hysteretic, layered half-space. Von Estorff and Schmid (1984) analyzed the dynamic behavior of a strip foundation resting on a soil layer using the BEM. A frequency domain BEM formulation has been used by Dominguez and Abascal (1989) in a 2-D analysis of a strip footing on zoned viscoelastic soils. Jendoubi et al. (2008) studied the response of a strip footing resting on a half-space with constant or variable shear wave velocity.

The first studies concerning the through-the-soil coupling of adjacent surface foundations referred to the two-dimensional space. Cruze and Rizzo (1968) applied a frequency domain BEM formulation in order to study two and three dimensional elastodynamic problems, between two rigid surface foundations. The dynamic cross interaction of adjacent infinitely long shear walls, supported on semi-cylindrical foundations under the prism of two-dimensional anti-plane shear problem, was studied by Luco and Contesse (1973) for the case of two structures, by Wong (1975) and Wong and Trifunac (1975) for the case of several structures and by Murakami and Luco (1977) for the case of an infinite number of equally space structures. The finite element method was applied for the study of two-dimensional plane-strain models by Lysmer et al. (1974, 1975), Liang (1974) and Aydinoglu and Cakiroglu (1977), whereas the boundary integral equation approach was applied by Nakai and Fukuwa (1982), Antes and v. Estorff (1986) and Kokkinos and Spyrakos (1991) for the same problem.

The soil-structure interaction of an embedded foundation was studied by many researchers as well. Karabalis and Beskos (1986) applied the full-space Green's functions in order to investigate the dynamic response of an arbitrarily shaped embedded rigid foundation. The dynamic response under vertical and horizontal loadings of arbitrarily shaped embedded foundation was calculated by Gazetas et al. 1985 and Gazetas et al. 1987. Rajapakse and Shah

(1988) studied also the dynamic response of rigid strip foundations of arbitrary geometry embedded in a homogeneous elastic half-space. Hatzikonstantinou et al. 1989 estimated the static and dynamic stiffness coefficients while Fotopoulou et al. 1989 estimated the radiation damping coefficients of arbitrarily shaped rigid foundations embedded in an elastic homogeneous half-space. The dynamic response of an arbitrary shaped rigid strip foundation embedded in an orthotropic elastic soil under time-harmonic vertical, horizontal and moment loading was studied by Wang and Rajapakse (1991). The impedance functions of rigid massless soil-structure interfaces, embedded in arbitrarily heterogeneous half-spaces were calculated by Esmaeilzadeh Seylabi et al. (2016).

The dynamic performance of an embedded strip foundation was investigated by many researchers. In particular, Kobori et al. (1982) and Nakai et al. (1984) applied the boundary integral equation scheme. Israil and Ahmad (1989) investigated the dynamic response of surface and embedded rigid strip foundation in viscoelastic soils under vertical excitation. The research was continued by Ahmad and Bharadwaj (1991) who investigated in detail the influence on key mechanical and geometrical parameters on the dynamic horizontal stiffness of rigid strip foundations embedded in layered soil, while the research of Bharadwaj and Ahmad (1992) referred to the rocking degree of freedom.

Although, many studies refer to the dynamic behavior of a single, massless, rigid embedded foundation, very few deal with the dynamic cross-interaction problem of two adjacent embedded foundations. It is worth mentioning that Rajapakse and Shah (1988) investigated the effect on impedances due to the presence of an adjacent embedment for various distances between foundations and embedment ratios. Furthermore, Betti (1997) studied the dynamic cross-interaction between two identical rigid square foundations embedded in a homogeneous viscoelastic half-space by the application of the boundary element method.

The present study refers to the dynamic cross interaction between two adjacent strip foundations that have different depths of embedment and is a step further to previous investigations concerning two adjacent surface or embedded foundations [39, 40]. Difference in depth of embedment may appear in cases where there is a basement in one of the adjacent structures. The complete 6x6 impedance matrix of the coupled system is calculated for various values of the distance ratio S/L, while the height of the soil stratum is kept constant. The study is completed by the investigation of the effect of the height of the soil stratum on the foundations coupling for the minimum value of S/L.

2 PROBLEM AND MODEL DESCRIPTION

The problem under study is depicted in Fig.1. The main target of the study is the degree of interaction between two rigid, massless, strip foundations that have different depths of embedment. Therefore, the left foundation is embedded to a depth D, in a soil layer which is resting on a rigid substratum while the right foundation is resting on the free soil surface. The welded contact condition [9] issues at each foundation-soil interface. Consequently, complete continuity of displacements is assumed for the area of contact (perfect bond). The adjacent foundations have the same length, L or half-width, B and their separation distance is denoted as S. Each foundation has three degrees of freedom: horizontal translation, u_i; vertical translation, w_i; and rotation, φ_i. the corresponding loadings that activate the three degrees of freedom are denoted as: H_i, horizontal force; V_i, vertical force; and M_i, moment. In the following figure the positive direction of the external loads and the corresponding displacements are depicted. Subscript 1 refers to the deep foundation while subscript 2 refers to the surface foundation. The soil comprises of a layer of thickness, H which is assumed as elastic, homogeneous and isotropic.

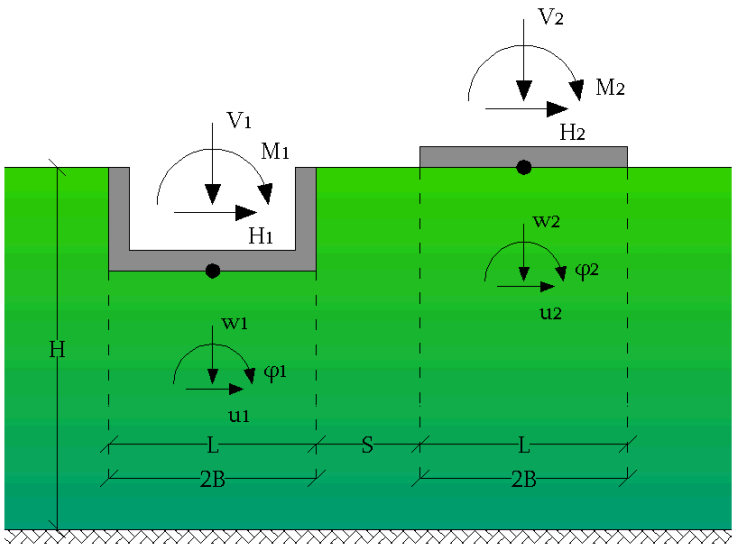

Figure 1: Adjacent strip foundation with different depths of embedment.

The system of the adjacent foundations has six degrees of freedom in total. The loading and displacement vector are related by the impedance matrix, K which takes the following form.

$$\begin{Bmatrix} V_1 \\ H_1 \\ M_1 \\ V_2 \\ H_2 \\ M_2 \end{Bmatrix} = \begin{bmatrix} K_{11} & K_{12} & K_{13} & K_{14} & K_{15} & K_{16} \\ & K_{22} & K_{23} & K_{24} & K_{25} & K_{26} \\ & & K_{33} & K_{34} & K_{35} & K_{36} \\ & & & K_{44} & K_{45} & K_{46} \\ & \text{symm.} & & & K_{55} & K_{56} \\ & & & & & K_{66} \end{bmatrix} \cdot \begin{Bmatrix} w_1 \\ u_1 \\ \varphi_1 \\ w_2 \\ u_2 \\ \varphi_2 \end{Bmatrix} \tag{1}$$

The 6x6 matrix is symmetrical. Each term is a frequency dependent complex number. The real part (in-phase component) represents the true stiffness, the restraining action of the soil and can be taken into account in the form of springs in a discrete model. Moreover, the imaginary part (out-of-phase component) represents the energy dissipation due to radiation and in a discrete model corresponds to dashpots [4, 5].

Therefore, the complete displacement field of the two foundations is needed in case where the external loading is applied at the deep foundation while the displacement field only of the surface foundation itself is needed in case where the external loading is applied at the surface foundation. The reverse issues if the surface foundation is denoted with subscript 1 and the deep with subscript 2.

The main tool used for the estimation of the response of the complex system under different excitation frequencies is the finite element method. In the case of a strip foundation, related to a track, dam or building foundation with a high ratio of length to width, the assumption of plane strain conditions can be considered to be reasonable [2]. Therefore, the finite element model is created in 2D space with the aid of 9-node quadrilateral 2-D solid elements.

The foundation-soil-foundation problem is typically a wave propagation problem. Thus, the minimum finite element size for each excitation frequency is equal to $\lambda_R/10$, where λ_R is the wavelength of minimum wave propagation velocity in the model, which usually corresponds to Rayleigh waves. Furthermore, the wave propagation problem in a model constructed by the used of the finite element method, cannot be simulated perfectly due to the restriction imposed by the model length and the finite element size [41]. In particular, the model must be large enough in order to reduce any reflected waves at its boundaries [42] and

the finite elements' size must be as small as possible in order to accurately describe a wavelength. Therefore, in order to avoid any wave reflections, quiet boundaries suggested by Lysmer and Kuhlemeyer (1969) were used.

The soil characteristics are the following: shear modulus, G equals to 132MPa, Poisson's ratio, v equals to 0.4 and density, ρ equals to 1.75t/m^3. The ratio between the foundation's depth and its half-width, D/B is kept constant and equal to unity. The problem is first studied for H/B equal to 2 and for various values of S/L ratio (0.5, 3, 5, 10). Furthermore, in order to maximize the foundation-soil-foundation interaction effects, the distance ratio, S/L is also kept constant and equals to 0.5. The interaction is studied for various typical values of the soil layer's depth ratio, H/B (2, 4, 8 and 32).

3 FINITE ELEMENT RESULTS

3.1 Validation studies

In order to validate the finite element model two validation studies were performed. The first one refers to the calculation of flexibility matrix of a deep foundation while the second one of a surface foundation.

Huh (1986) calculated the flexibility matrix of a rigid, massless, strip foundation embedded to a depth, D of a soil layer resting on rigid substratum by the use of the boundary element method. Figure 2 depicts the comparison between the researcher's results and the results of the present study by the use of the finite element method. The horizontal axis of the charts represents the normalized frequency α_o, $\alpha_o = (\omega \cdot B)/V_s$, where V_s is the shear wave velocity and the vertical axis is normalized by the parameters π, G and B.

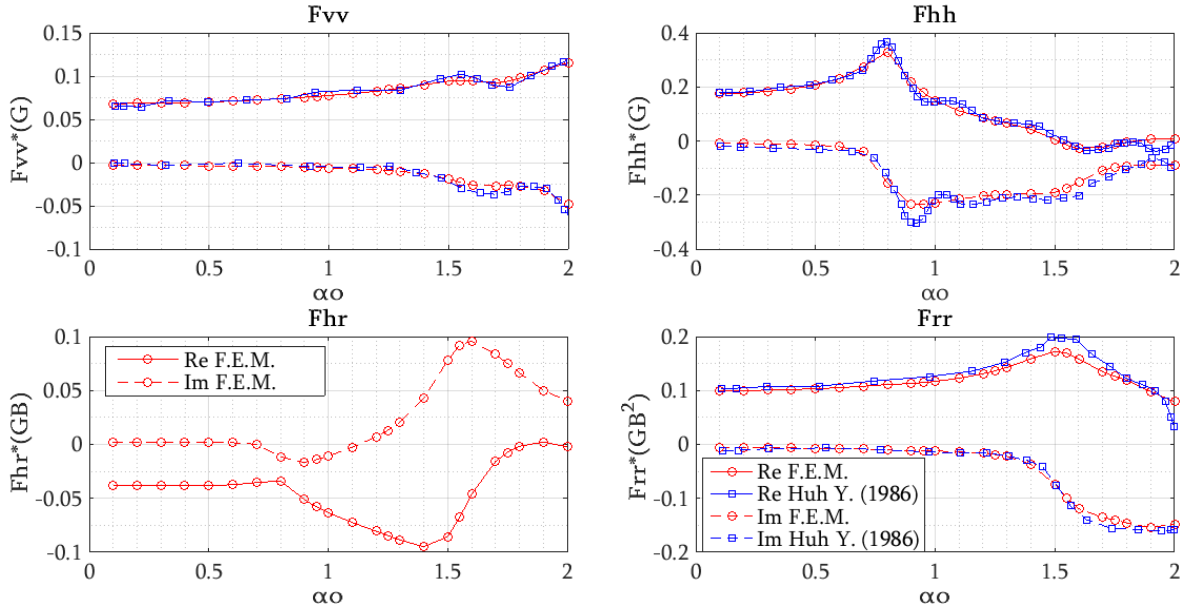

Figure 1: Validation study results for the case of an isolated, rigid, massless strip foundation embedded to a soil layer resting on a rigid substratum.

The vertical loading of an isolated deep foundation does not produce any horizontal or rocking displacement. Therefore, no coupling terms exist for the vertical degree of freedom. On the other hand, the horizontal/moment loading produces rotations/horizontal translations, respectively. Therefore, the coupling terms of motion are presented in Fig.2.c. Unfortunately

no information is given by Huh (1986) regarding the coupled horizontal-rocking degree of freedom. The results of the finite element method are in very good agreement with the result of the boundary element method. Consequently, the validation study referring to the deep foundation can be considered successful.

Luco and Westmann (1972), Hryniewicz (1981) and Wang et al. (2015) calculated the flexibility matrix of a rigid, massless, strip foundation bonded to the free surface of an elastic half-space. Figure 2 depicts the comparison between the researchers' results and the results of the present study by the use of the finite element method.

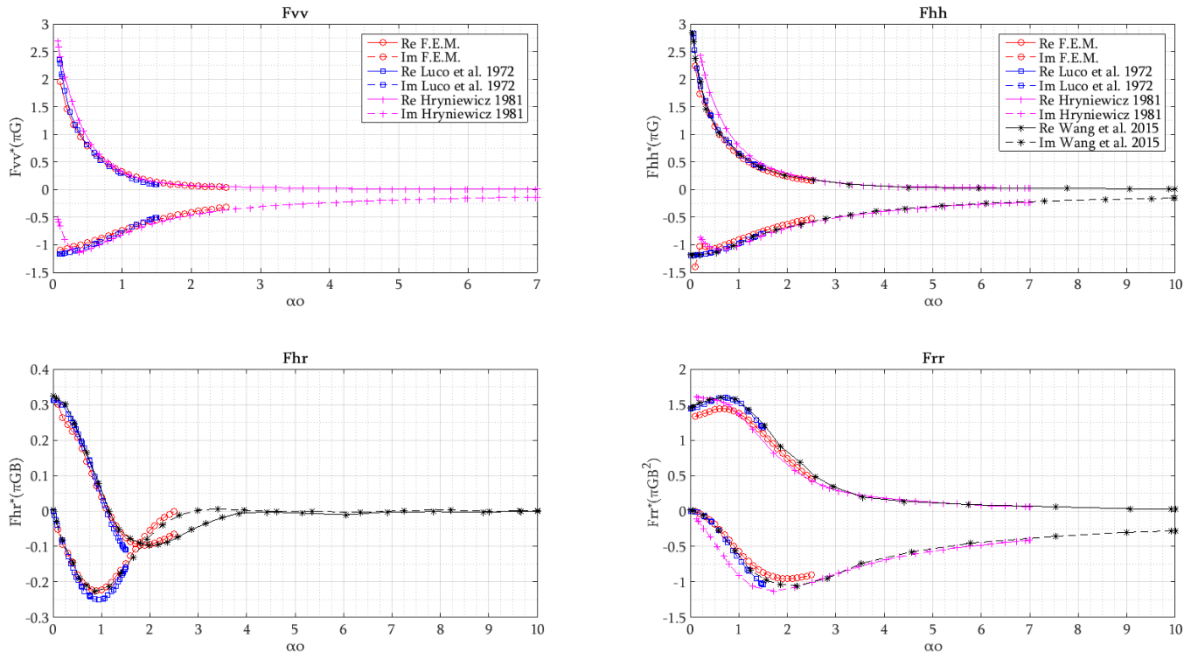

Figure 3. Validation study results for the case of an isolated, rigid, massless strip foundation bonded to an elastic half-space.

Once again, the vertical loading of an isolated surface foundation does not produce any coupling terms with the other degrees of freedom. Taking into account that the researchers' results are produced by the boundary element method, which treats accurately the wave propagation problem in half-space, it can be concluded that the finite element results are in good agreement. Therefore, the second validation study referring to a single surface foundation can also be considered successful.

3.2 Study of coupling between two foundations with different embedment depths

The main core of the present study refers to the estimation of the dynamic cross interaction between two rigid, massless, strip foundations that have different depths of embedment. Therefore, the question that must be answered is the following: How much an external loading imposed on a foundation affects the dynamic behavior of its adjacent one? In order to answer the above question two features must be examined. The first feature refers to the deviation of the behavior of each coupled foundation from the behavior of an isolated one, while the second feature refers to the coupling terms of the 6x6 flexibility matrix. Therefore, additional analyses were performed in order to calculate the flexibility matrices of an isolated deep and an isolated surface foundation as well. The distance ratio, S/L receives the following values: 0.5, 3, 5 and 10 while the soil layer's depth, H/B is constant to 2.

Based on the analyses results, it was found that the displacement field of each foundation is attributed not only on its external loading but on the adjacent foundation's loading as well. The smaller the ratio S/L is the bigger the effects of the foundation-soil-foundation interaction phenomenon are. Therefore, not only there are coupling terms between the horizontal and rocking movement of the foundation itself but coupling terms also appear between the two foundations even for the vertical excitation. In particular, Fig. 4 depicts the foundations movement at a random time frame for the case of S/L=0.5. It can be observed that even the vertical excitation causes a rocking movement not only on the foundation itself but on the adjacent foundation as well. The blue color depicts the initial position of the foundations while the cyan the deformed one.

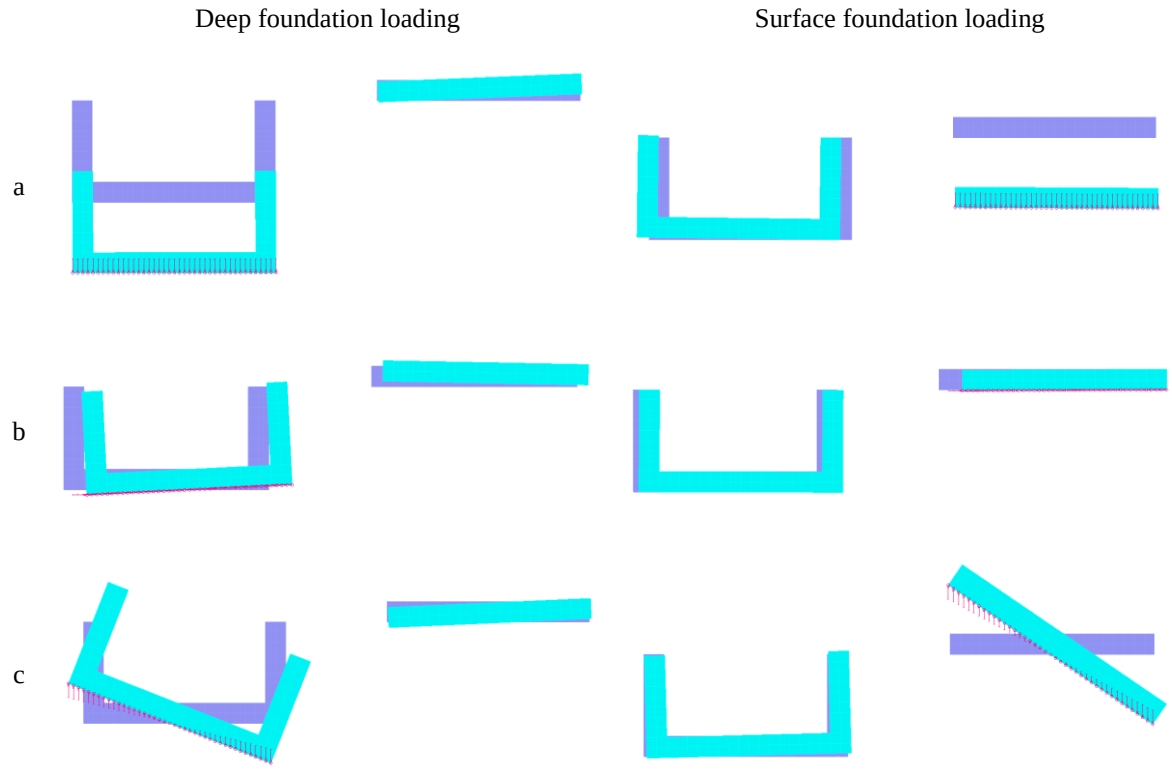

Figure 3. Foundations response at a random time frame for the case of S/L=0.5: a) vertical loading, b) horizontal loading, c) moment loading.

The foundation-soil-foundation interaction is expressed by the flexibility matrix, which is the inverse of the impedance matrix. The necessary terms, real and imaginary parts, for the definition of the impedance matrix, according to equation (1) that are related to the behavior of the deep foundation are depicted in Fig. 4 and Fig.5. The horizontal axis of the charts represents the normalized frequency αo and the vertical axis is normalized by the parameters π, G and B. The deviation from the behavior of an isolated deep foundation is observed at the coupling terms between vertical loading and translational and rocking degrees of freedom. Therefore, in the case of adjacent foundations, the vertical loading produces a complete displacement field on the foundation itself. This phenomenon is intense for small values of distance ratios, such as S/L=0.5 or 3. However, taking into account the small values of the aforementioned coupling terms in comparison to the other terms of the matrix, it can be concluded that they can be ignored, especially in the low frequency range.

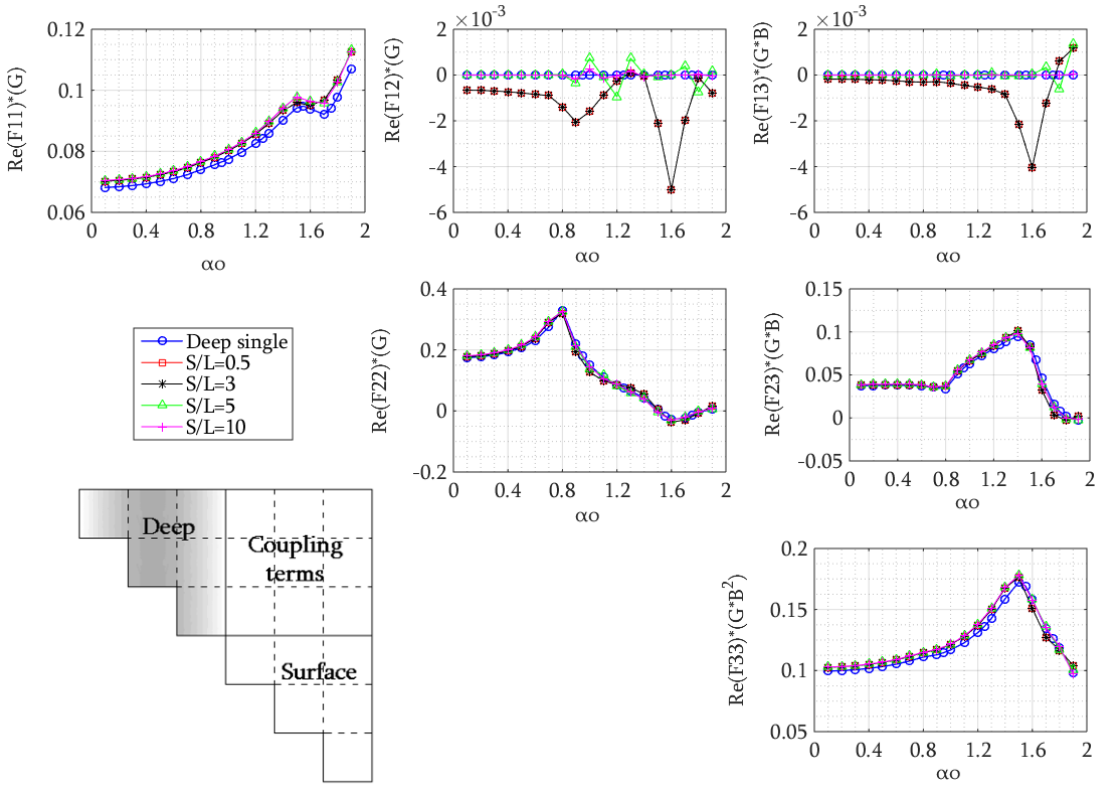

Figure 4. Real parts of the necessary terms for the definition of the flexibility matrix referring to the response of the deep foundation for various values of S/L (H/B=2).

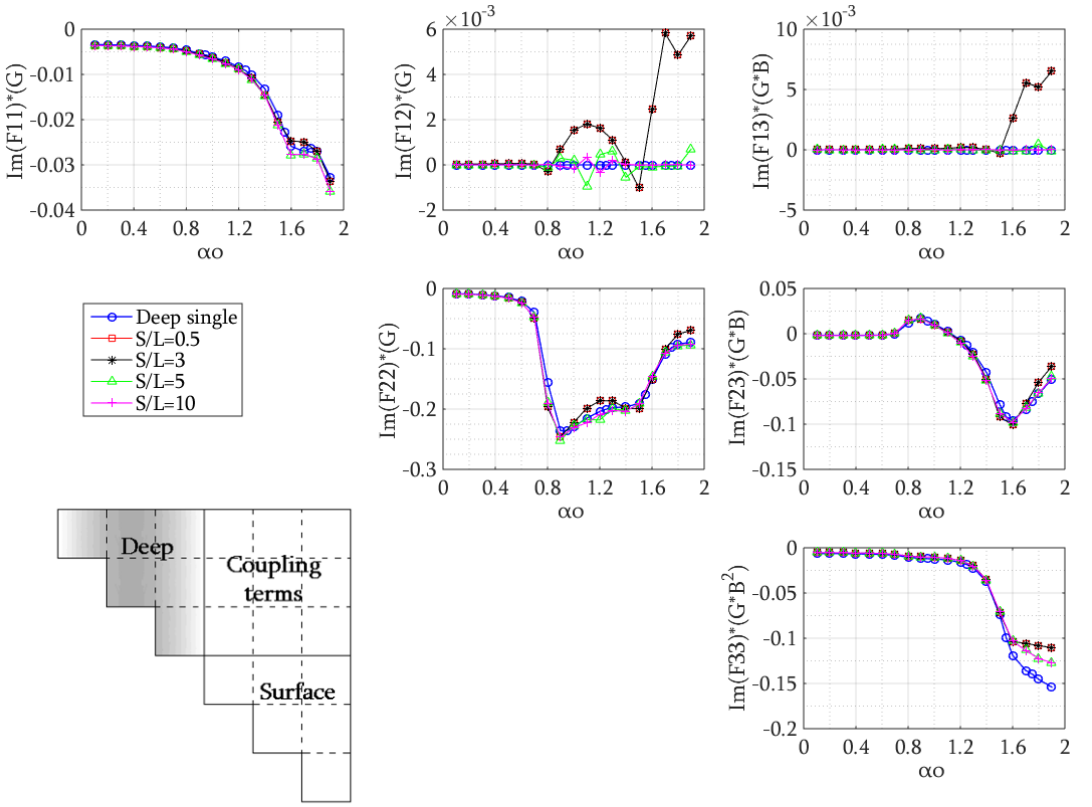

Figure 5. Imaginary parts of the necessary terms for the definition of the flexibility matrix referring to the response of the deep foundation for various values of S/L (H/B=2).

In Fig.6 and Fig.7 the real and imaginary parts of the flexibility matrix that are related to the behavior of the surface foundation are depicted. The deviation from the behavior of an isolated surface foundation is intense, especially in the high frequency range. Furthermore, the coupling terms that relate the vertical loading to the horizontal and rocking degree of freedom receive higher values than in the case of the deep foundation. Therefore, it can be concluded that the surface foundation is affected in a higher level than the deep foundation from the through-the soil- coupling.

In Fig.8 and Fig.9 the real and imaginary parts of the flexibility matrix that are related to the pure coupling between the two foundations are depicted. Their values are a significant portion of the values of the corresponding degrees of freedom of the two foundations. The coupling is intense for small values of distance ratios, S/L=0.5 and 3. Furthermore, the interaction is stronger for horizontal and moment loading than for vertical loading, especially in the high frequency range.

Consequently, for the case of a constant value of H/B=2, the through-the-soil coupling of two rigid, massless, strip foundations with different depths of embedment cannot be ignored for small values of distance ratios and in the high frequency range. Even though, the behavior of each foundation does not decline from the behavior of an isolated one, the coupling terms control the final behavior of the complex system.

Taking into account that the through-the-soil coupling of the adjacent foundations is strongest for the smallest distance ratio, another question that arises is related to the effect of the soil layer's depth ratio, H/B. Therefore, the 6x6 flexibility matrix is calculated for typical values of H/B: 2, 4, 8 and 32.

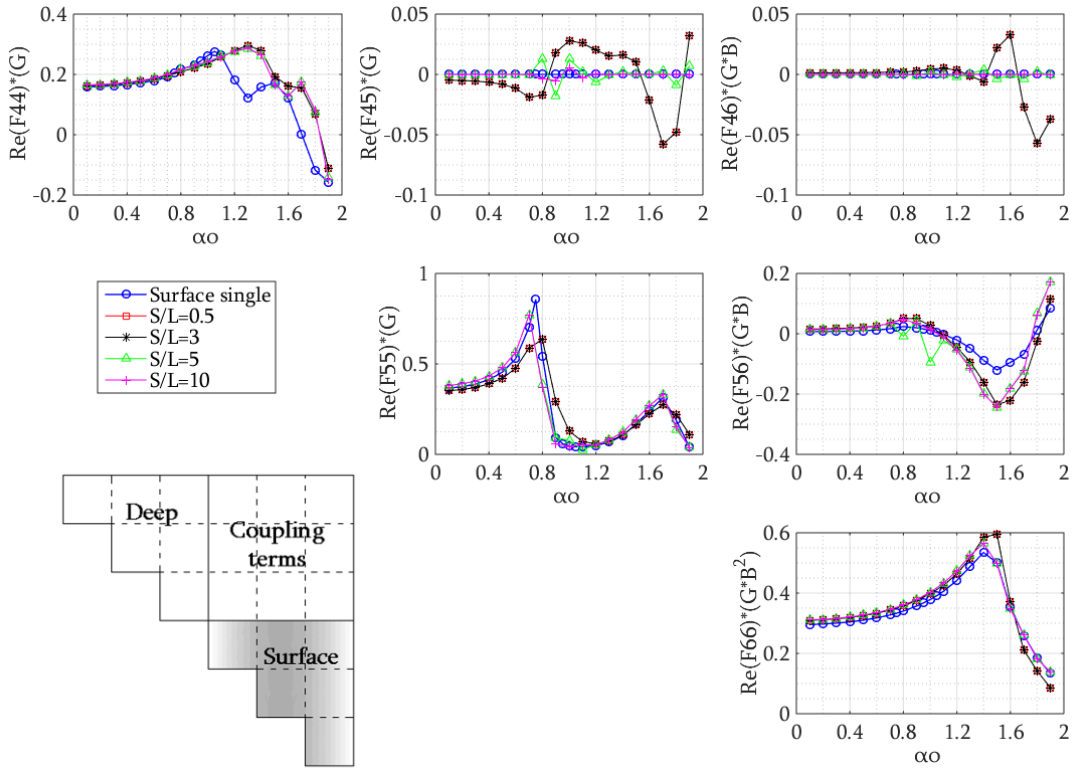

Figure 6. Real parts of the necessary terms for the definition of the flexibility matrix referring to the response of the surface foundation for various values of S/L (H/B=2).

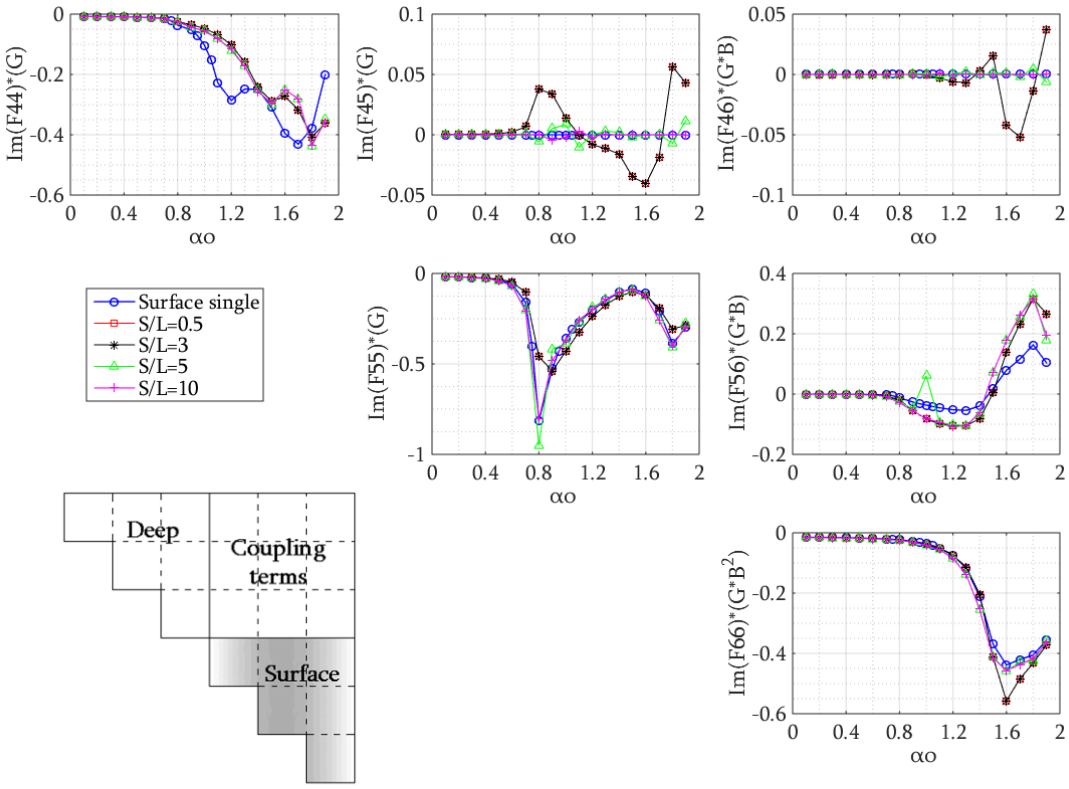

Figure 7. Imaginary parts of the necessary terms for the definition of the flexibility matrix referring to the response of the surface foundation for various values of S/L (H/B=2).

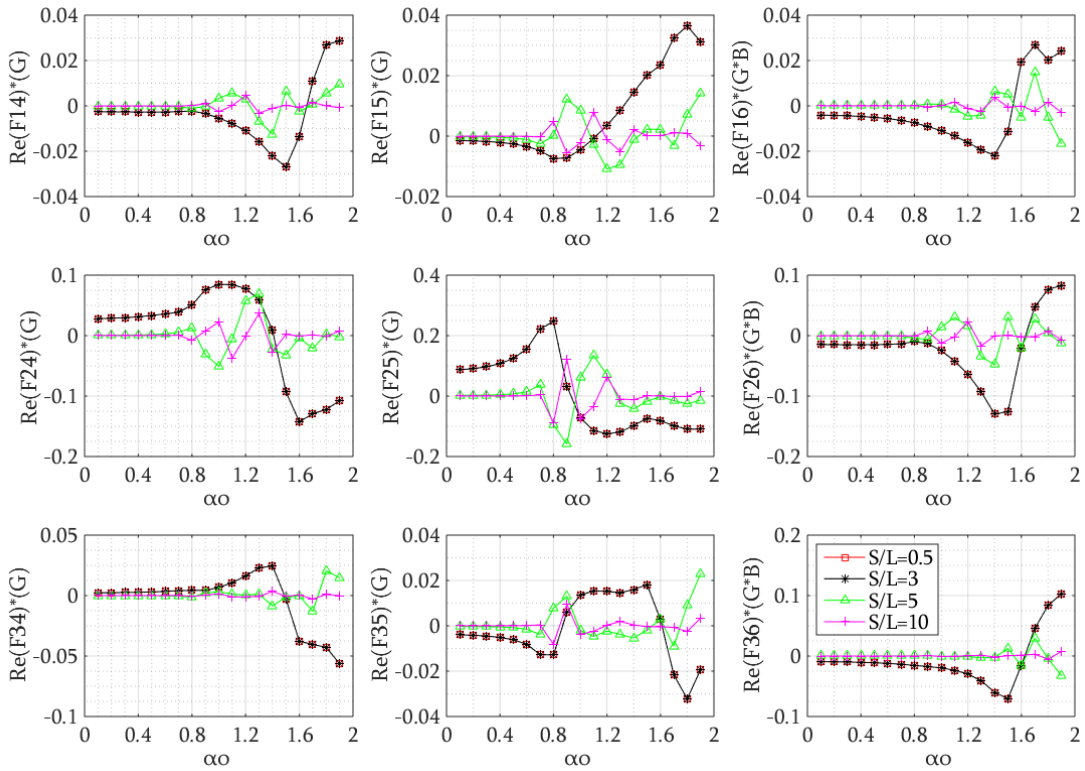

Figure 8. Real parts of the necessary terms for the definition of the flexibility matrix referring to the coupling terms between the deep and the surface foundation for various values of S/L (H/B=2).

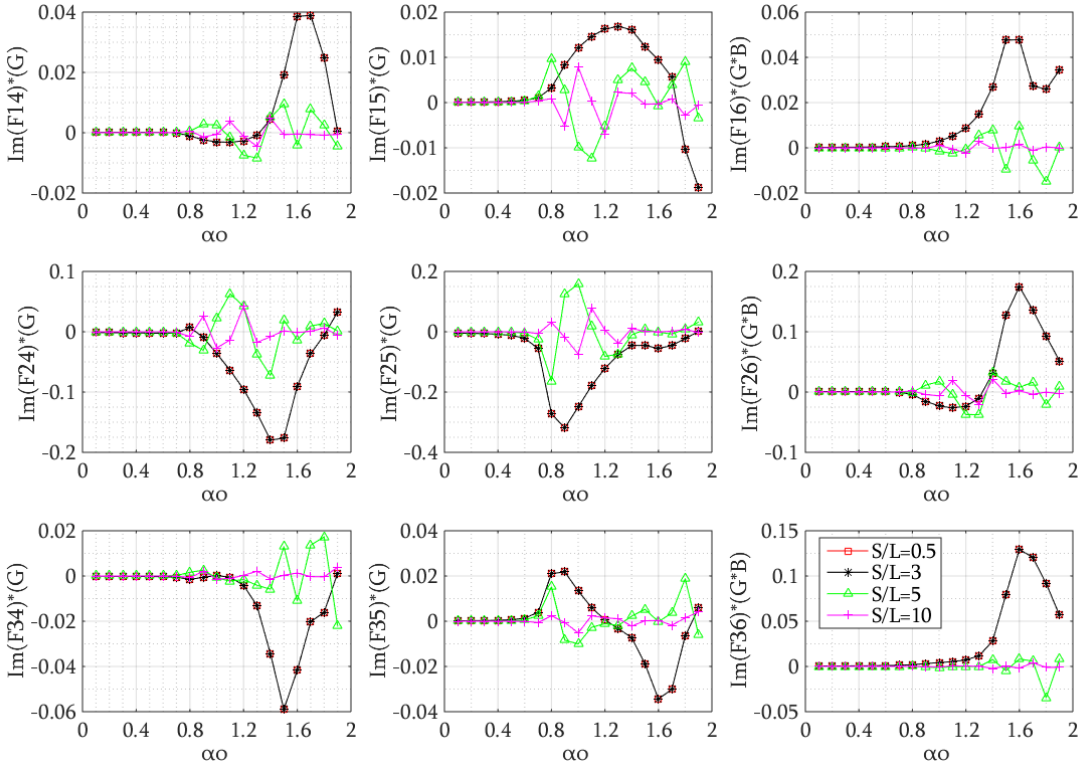

Figure 9. Imaginary parts of the necessary terms for the definition of the flexibility matrix referring to the coupling terms between the deep and the surface foundation for various values of S/L (H/B=2).

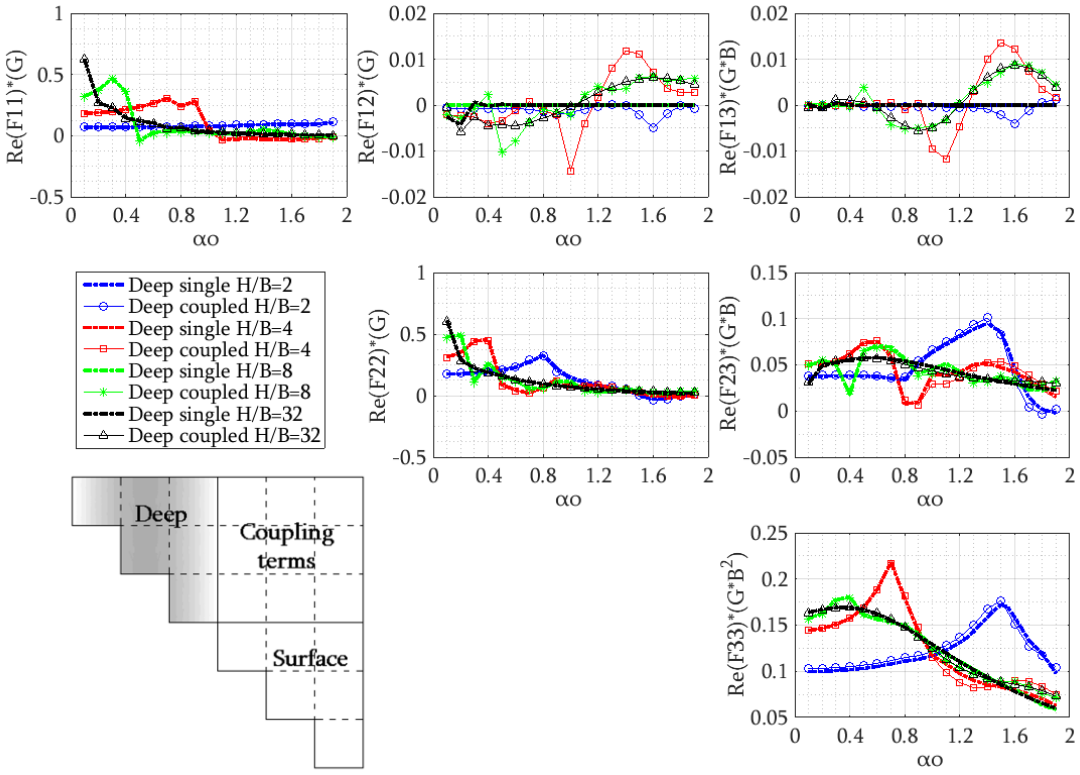

Figure 10. Real parts of the necessary terms for the definition of the flexibility matrix referring to the response of the deep foundation for various values of H/B (S/L=0.5).

In Fig.10 and Fig.11 the real and imaginary parts of the flexibility matrix related to the response of the deep foundation are depicted. The thick lines represent the behavior of an isolated deep foundation at various values of H/B. The behavior of the coupled foundations does not deviate substantially from the behavior of the isolated one, except for the coupling terms between the vertical loading and the horizontal/rotational degrees of freedom. The coupled effect cannot be ignored especially in the high frequency range for the real parts and for total frequency range for the imaginary parts. Moreover, the coupling effect does not weaken with the increase of H/B ratio.

In Fig.12 and Fig.13 the real and imaginary parts of the flexibility matrix related to the response of the deep foundation are depicted. The response of the coupled surface foundation deviates substantially from the response of the isolated foundation according to the degree of freedom excited and to the H/B ratio. In particular, the largest degree of deviation is presented for the rocking motion, while the smallest one for the vertical motion. Furthermore, the deviation is strongest for H/B=2, while it still remains significant for larger values of H/B. The coupling terms between the vertical excitation and the horizontal/rocking degree of freedom receive the highest values for small values of H/B and only in the high frequency range. The aforementioned behavior is expected for a surface foundation.

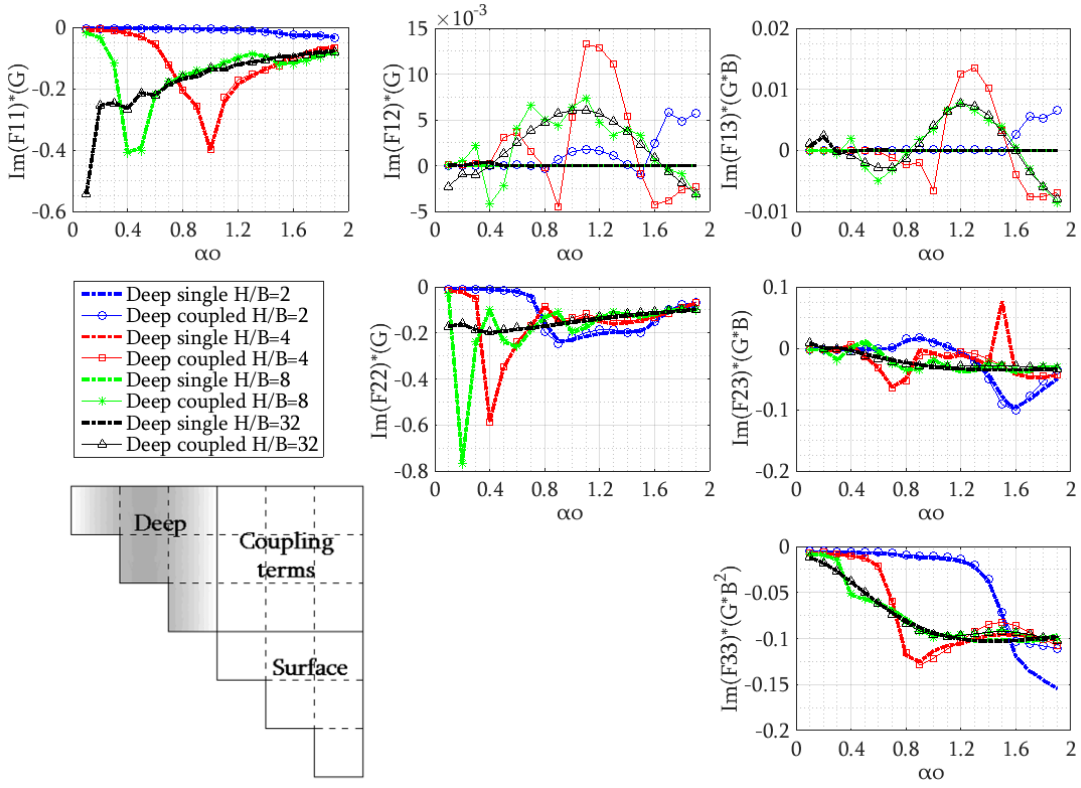

Figure 11. Imaginary parts of the necessary terms for the definition of the flexibility matrix referring to the response of the deep foundation for various values of H/B (S/L=0.5).

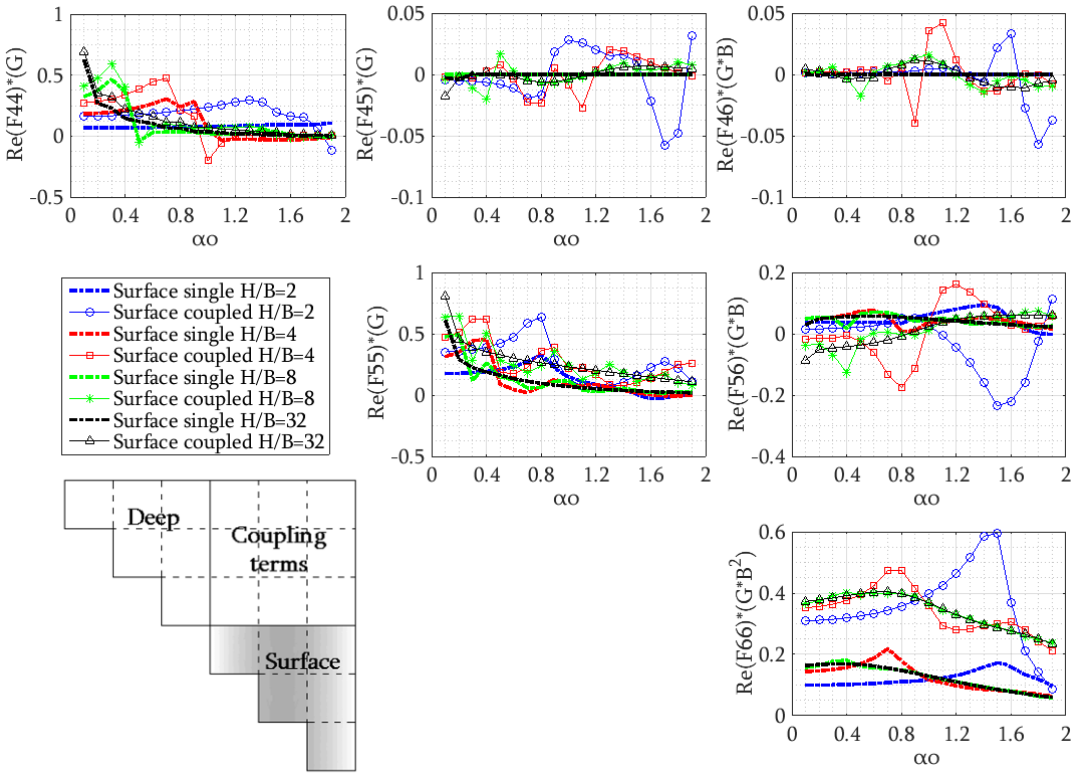

Figure 12. Real parts of the necessary terms for the definition of the flexibility matrix referring to the response of the surface foundation for various values of H/B (S/L=0.5).

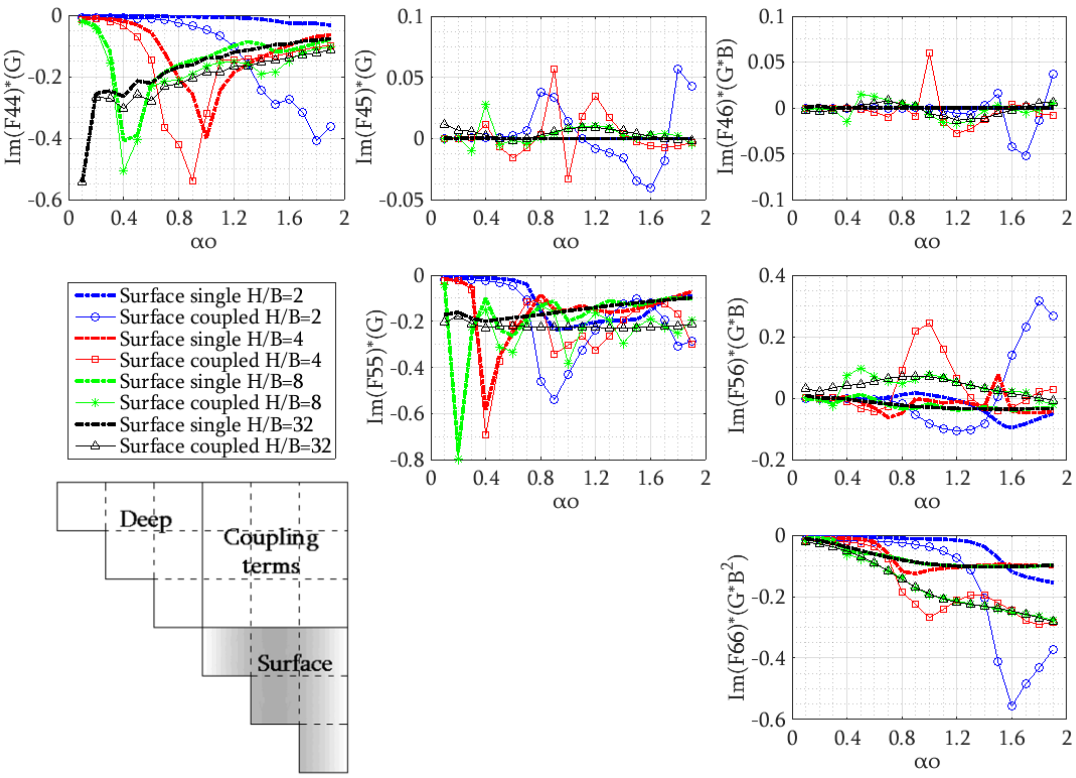

Figure 13. Imaginary parts of the necessary terms for the definition of the flexibility matrix referring to the response of the surface foundation for various values of H/B (S/L=0.5).

In Fig.14 and Fig.15 the real and imaginary parts of the flexibility matrix related to the coupling terms between the two foundations are depicted. Comparing the maximum normalized values of the coupling terms with the values of the corresponding degrees of freedom of the two foundations, it is obvious that the through-the soil coupling cannot be ignored. For the vertical loading, the coupling terms receive their smallest values for H/B=2. As the ratio H/B increases, the coupling due to vertical excitation covers the total frequency range with larger values. For horizontal loading, the coupling terms receive higher values for small ratios of H/B. Furthermore, for moment loading the interaction of the two foundations for small values of H/B dominates in the high frequency range but as H/B increases the phenomenon covers the total frequency range.

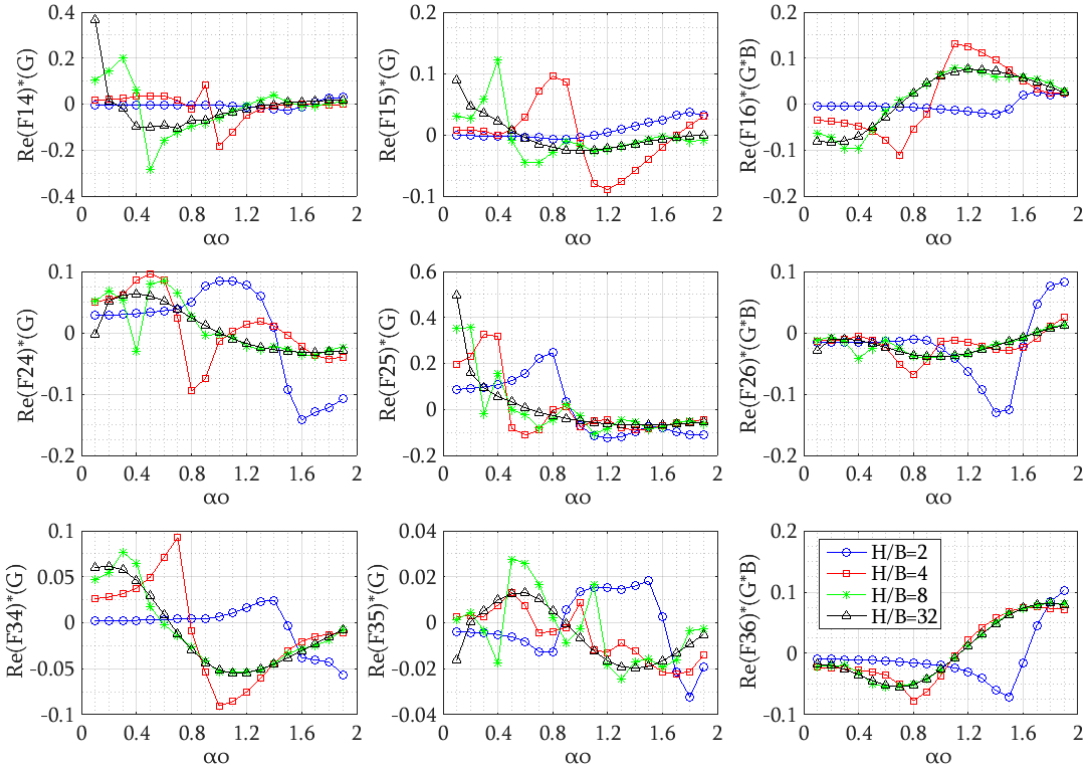

Figure 14. Real parts of the necessary terms for the definition of the flexibility matrix referring to the coupling terms between the deep and the surface foundation for various values of H/B (S/L=0.5).

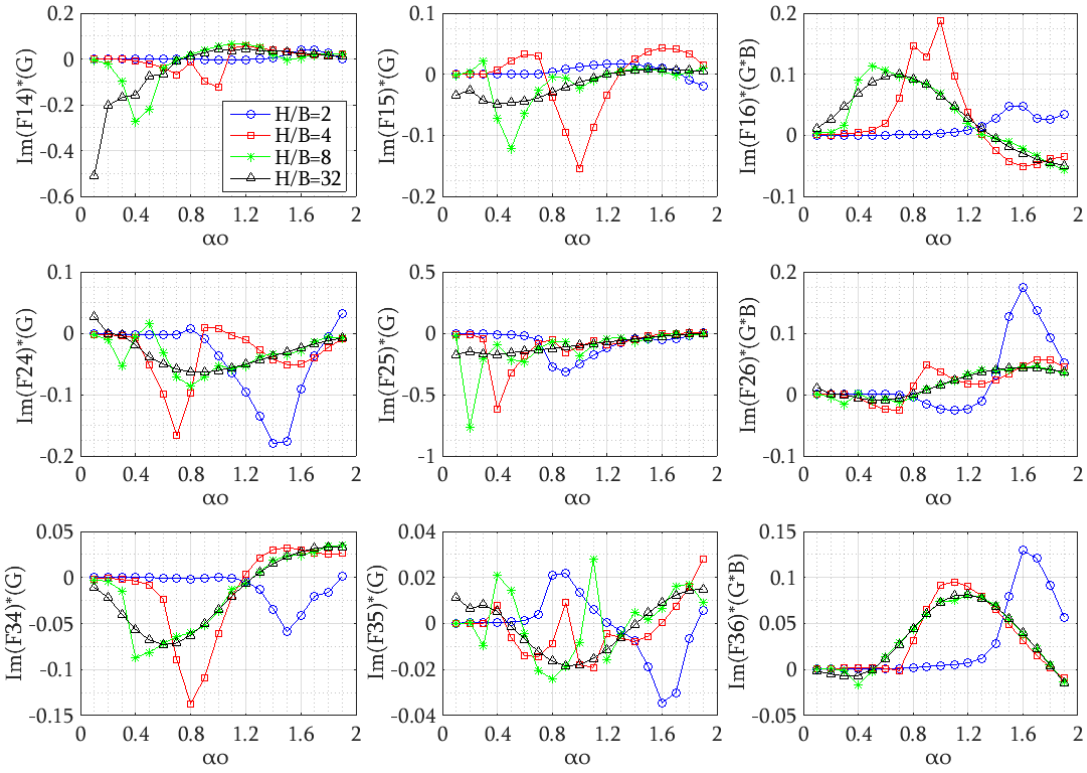

Figure 15. Imaginary parts of the necessary terms for the definition of the flexibility matrix referring to the coupling terms between the deep and the surface foundation for various values of H/B (S/L=0.5).

4 CONLCUSIONS

The through the soil coupling of two rigid, massless strip foundations with different depths of embedment has been studied by the use of the finite element method. The accuracy of the finite element model was verified by the comparison studies referring to an isolated surface and an isolated deep strip foundation. The foundation-soil-foundation is expressed by the impedance or flexibility matrix of the coupled system.

In the case of H/B=2, the response of the deep foundation deviates from the behavior of an isolated one only at the coupling terms of horizontal and rocking motion, caused by a vertical loading, especially for small values of S/L (0.5 and 3) and in the high frequency range. On the other hand, the surface foundation is more susceptible to the dynamic cross interaction. In particular, not only the aforementioned coupling terms are affected but also the terms due to horizontal and moment loading. Finally, the coupling terms between the two foundations receive important values at small distances and in the high frequency range, especially for horizontal and moment loading. Therefore, the through-the-soil coupling between the two foundations cannot be ignored for small values of distances at shallow bedrocks.

In the case of S/L=0.5, the response of the deep foundation deviates from the behavior of an isolated one only at the coupling terms of horizontal and rocking motion, caused by a vertical loading. The aforementioned deviation is obvious for all values of H/B. On the contrary, the response of the surface foundation deviates substantially for all degrees of freedom and for all values of H/B. Finally, the coupling terms between the two foundations receive high values only in the high frequency range for small values of H/B. On the contrary, as the H/B ratio increases, the coupling becomes stronger in the whole frequency range. Therefore, the

through-the-soil coupling between two closely spaced foundations cannot be ignored even for high values of H/B.

The charts of real and imaginary parts of the impedances can be used in a simplified model of springs and dashpots of the two foundations.

IMPACT OF SEISMIC UPLIFT AND SOIL SUPPORT ON THE ACCELERATION OF A LIQUID STORAGE TANK

Abstract

A rigid base is assumed in most seismic studies of liquid storage tanks. Additionally, recent studies have shown that permitting uplift can significantly reduce the damage to tanks. Uplift is the transient partial separation of the tank base from the supporting foundation. However, uplift of storage tanks is still not well studied and a rigid base is assumed in numerical studies. In this work, the simultaneous effect of uplift and a soil foundation are utilised to evaluate experimentally the effect of these two factors on the acceleration in the tank wall. A low-density polyethylene tank and a shake table were employed. Stochastically generated seismic excitation is employed based on the New Zealand design standard, NZS 1170.5, for medium soil, classification B. Three base conditions were considered: 1) fixed-base tank on a rigid support, 2) free-base tank on a rigid support and 3) free-base tank on a flexible support.

To simulate the rigid support condition, the tank is resting on a steel plate rigidly attached to the shake table. A laminar box infilled with sand is utilised to represent a flexible soil condition. Results revealed that the highest acceleration at the tank top occurred when the tank is resting freely on a rigid supporting base. Furthermore, for this case the maximum uplift occurred at the same time as the maximum acceleration. However, for the case of a flexible support, the maximum acceleration occurred at the tank base and did not coincide with the time of maximum uplift. The maximum uplift occurred for a flexible supporting base and is not related to the maximum acceleration at the tank top. Thus, the distribution of the maximum acceleration, and hence uplift, depends significantly on the support condition.

1 INTRODUCTION

Liquid storage tanks are required to supply and regulate water, petrol or other chemicals following damaging seismic events. Hence, their integrity after emergencies is essential, especially for the fast recovery of the affected area. Experiences with strong earthquakes have repeatedly shown the vulnerability of tanks under dynamic loads. The vulnerability lies from the complex uncertainties originating from the interaction between the liquid, the tank wall and the supporting soil. However, these complications are usually incorporated by simplifications in the design analysis and may not represent adequately the real behaviour of the tank under seismic loads.

Damage to a tank wall is generally associated with high concentration of both hoop and axial stress. Hoop stress is related to the hydrodynamic pressure due to the liquid. Axial stress is associated with uplift, which is the transient separation of a part of the tank base from the supporting foundation. Uplift in liquid storage tanks depends on several parameters that include the dimensions of the tank, the ratio of the tank radius to the liquid height (aspect ratio *h/r*), the stiffness of the base plate and supporting foundation. Another factor that may amplify the risk of failure is soil-structure interaction (SSI).

SSI involves factors that are not generally addressed in a holistic design. The majority of studies in this topic have been numerical, but opinions differ on some of the key parameters of SSI. On the one hand, a flexible support condition is beneficial to the tank response, i.e. the magnitude of acceleration and stresses are reduced [1–3]. According to Larkin [4], on the other hand, the tank response depends on the soil and tank properties. Additionally, the changes in the fixed base natural frequencies that may occur produce significant changes in the system response. If the natural frequency of the tank is close enough to the predominant frequency of the soil site, amplification in the response may occur [5–7]. Hence, during the design phase, assuming a rigid support condition does not always guarantee conservative results [8].

Limited experimental studies have been conducted considering SSI [9-14]. Ormeño et al. [10] utilised an aluminium tank on a shake table, focusing on the development of the acceleration of the tank and associated uplift. To simulate a flexible base support, a rigid box with sand was utilised. It was concluded that the maximum acceleration for aspect ratios $h/r = 1$ and 2.5, when SSI is considered, presented similar magnitude. However, the maximum acceleration is less than that of the case when the tank is resting on a rigid base.

The present paper evaluates, through an experimental study using a laminar box, the combined effects of uplift and a flexible support foundation (sand) on the earthquake-induced acceleration of a storage tank.

2 EXPERIMENTAL SET-UP

2.1 Tank model

A low-density polyethene (LDPE) tank, 750 mm in height and 450 mm in diameter, is used to model a prototype steel tank. Neglecting the influence of oscillations at the fluid free surface, i.e. the convective mode of response, the model can be analysed as a Single-Degree-of-Freedom (SDOF) system based only on the impulsive inertia forces on the tank wall [3]. Thus, the similitude conditions may be defined using the Buckingham π theorem, along with the Cauchy number for a SDOF system [15]. The model and prototype properties are shown in Table 1, and the scale factors are shown in Table 2. The fundamental periods were estimated according to the work reported in NZSEE [16], for an anchored-roofless tank on a rigid support condition.

	Model	Prototype
Material	LDPE	Steel
Elastic Modulus E (GPa)	1.12	210
Radius r (m)	0.225	4.5
Liquid Height H (m)	0.675	13.5
Maximum liquid Mass (kg)	107	858 833
Fundamental period (s)	0.034	0.14

Table 1. Properties of the model and prototype

Dimension	Scale factor
Length	20
Mass	8000
Time	4.2
Acceleration	1.16

Table 2. Scale factors

Two support conditions for the tank were utilised, i.e. 1) a rigid steel plate fixed to the shake table, representing a rigid support condition, i.e. rock, Figure 1(a); 2) sand contained in a laminar box (described in Section 2.3) i.e. a flexible support condition representing a soil site, **Error! Reference source not found.**(b). All tests were performed with a liquid height of 675 mm, which corresponds to an aspect ratio of three. Three tank base conditions are utilised: 1) The tank is fixed to the rigid steel plate, 2) the tank is unanchored and is placed directly on the rigid steel plate, and 3) the tank is resting freely on sand in the laminar box.

Two columns of three accelerometers, i.e. at 0° and 180°, see Figure 1(c), at heights of 30 mm, 375 mm and 700 mm, were attached to the external face of the LDPE tank, see Figure 1(c). All the accelerometers were oriented at the same direction, i.e. positive in the direction from 180° to 0 °. In both support cases (rigid and flexible), an accelerometer was attached to the shake table.

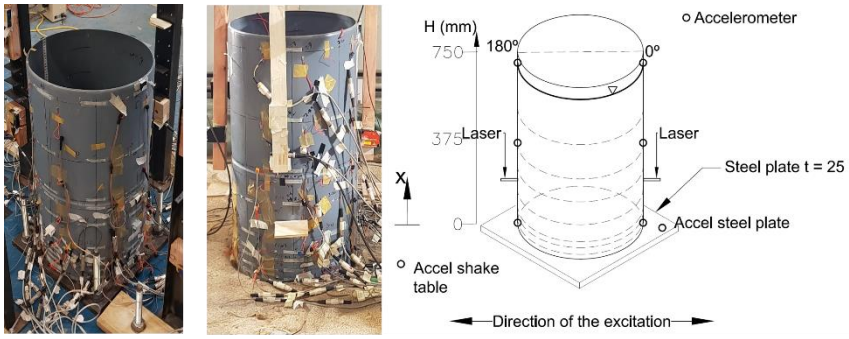

Figure 1. LDPE tank (a) fixed and free-rigid base, (b) free-flexible base, and (c) measurements locations.

2.2 Anchorage

The LDPE tank was fixed to a rigid steel plate of $t = 25\ mm$ thickness through eight M8 bolts. A round steel plate of 3 mm thickness was placed inside the tank to avoid stress concentration on the base plate due to the pressure from the bolts, as shown in Figure 2. Hence, modifications to the tank wall stiffness were avoided. An extra accelerometer was placed on the steel plate to record the acceleration of the tank base (see Figure 1(c)).

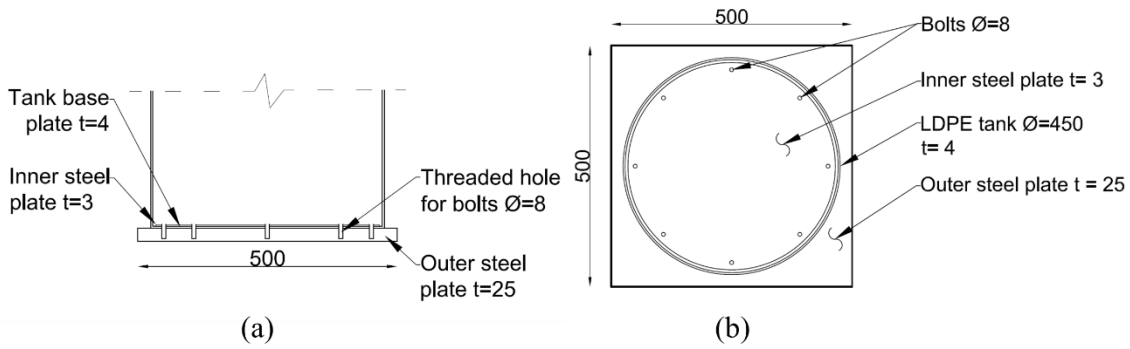

Figure 2. Fixing of LDPE tank base (a) Front view, and (b) top view (units in mm).

2.3 Laminar box

A 2 m cubic laminar box is used to simulate the earthquake-induced shear deformation of the sand that results from seismic motion (Fig. 3). The maximum permitted displacement of each layer of the laminar box is 175 mm in the direction of the shake table motion. More information regarding the characteristics of the box can be found in [17]. The box is filled to a height of 1.43 m with sand with an average density of 1.58 $\mathrm{t/m^3}$. One accelerometer was placed on the sand surface, next to the tank base.

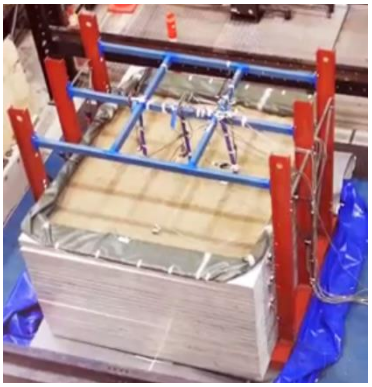

Figure 3. Cubic laminar box filled with sand.

The shear wave velocity was measured at the beginning of the experiment by creating an impulse, to ascertain the shear stiffness of the sand. The experimental set-up and the recorded accelerations are shown in Figure 4. A circular steel plate was placed on the sand surface. A horizontal impact from a hammer on the steel plate produces a downward travelling shear wave that was recorded by two accelerometers a distance of $700\ mm$ apart. The average shear wave velocity v_{s_m} may be estimated by dividing the travel distance ΔL by the travel time Δt. From Figure 4, the travel time is $\Delta t = 1.1554 - 1.1514 = 0.004\ s$. The estimated mean velocity is $v_{s_m} = 175\ m/s$. An empirical method to estimate the shear wave velocity is by Equation (1) [18]:

$$v_s = \sqrt{\frac{D_r + 25}{100}} \sqrt{\frac{0.422 \times 10^6\ (\sigma'_m)^{\frac{1}{2}}}{\rho}} \tag{1}$$

where v_s is the shear wave velocity in m/s, D_r is the sand relative density, $\mathrm{D_r} = 56\%$; ρ is the sand mass density, 1580 $\mathrm{kg/m^3}$; σ'_m is the mean effective stress at the respective depth, estimated as $\sigma'_\mathrm{m} = (\sigma'_\mathrm{v} + 2\sigma'_\mathrm{h})/3$; σ'_v is the effective vertical stress and σ'_h is the horizontal effective stress.

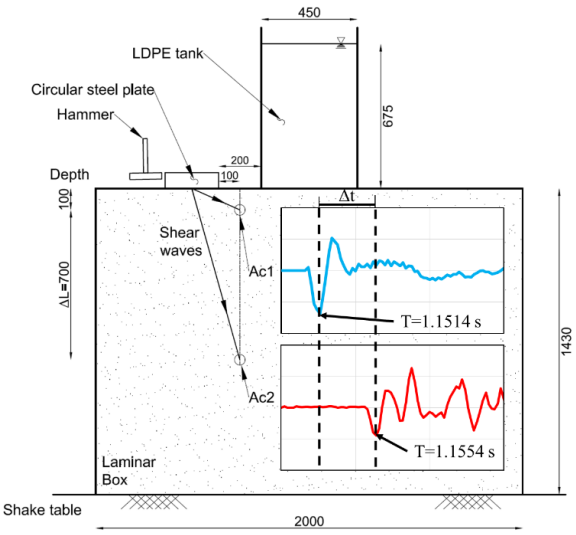

Figure 4. Configuration of impulse test and shear waves recorded by both accelerometers (units in mm).

The stresses may be estimated by elastic solutions for a uniform surface stress over a circular area, in this case, $675\ kPa$. The mean stress is $\sigma'_{m_{100}} = 405\ Pa$ and $\sigma'_{m_{800}} = 135\ Pa$. Hence, the shear wave velocity is $v_{s_{100}} = 222\ m/s$, $v_{s_{800}} = 169\ m/s$, and $v_{s_m} = 196\ m/s$. The subscript indicates the depth from the ground surface and the "m" indicates the mean value. The estimated mean shear wave velocity is similar to the result obtained experimentally.

2.4 Excitation applied

The shake table excitation was stochastically simulated based on the target spectrum for a medium fine grained soil, i.e. classification C of the design standard NZS 1170.5, Figure 5(a). The target spectrum was calculated utilising the NZSEE recommendations for time domain analysis of liquid storage tanks [16], [19]. However, the NZ 1170.5 code specifies the lower limit of the frequency range of interest $T_{min} > 0.4\ s$, and Ormeño, et al. [20] found application of this lower limit of period underestimates the response of some tanks. The $0.4\ s$ limit was established for structures, not specifically tanks, because periods below this figure are difficult to determine and hence have relatively high uncertainty, especially when structures present complex geometries and diverse materials. For tanks, which usually have a regular geometry and are made of a single material, this restriction may lead to an underestimate of the response. Thus, the lower limit of frequency given by NZS 1170.5 was not applied in this work. The lower limit applied was $0.4T_{pro} = 0.057\ s$ and the upper limit was $1.3T_{pro} = 0.186\ s$, as specified in the recommendations of NZSEE [14]. The response spectrum of the simulated excitation and the target spectrum are shown in Figure 5(b). The range of frequencies of interest for matching the response and the natural period of vibration of the tank with an assumed fixed base are shown.

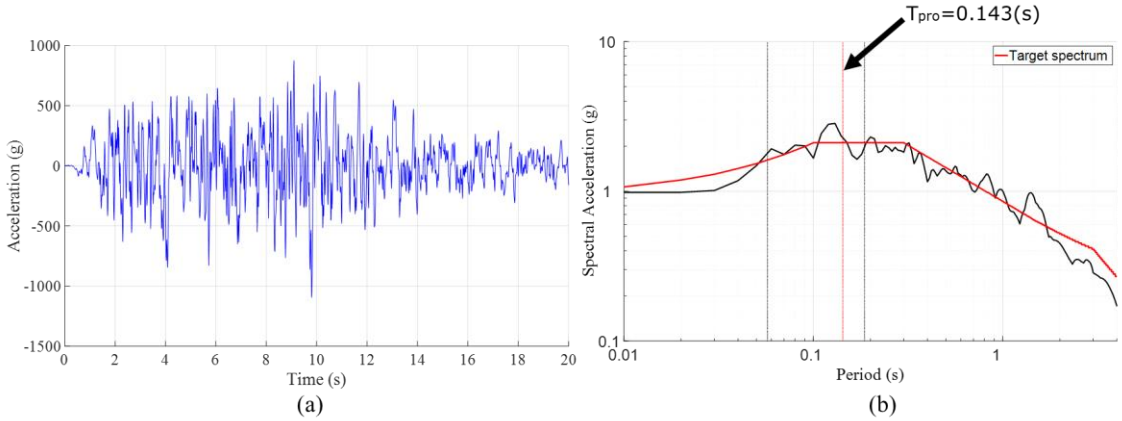

Figure 5. Base excitation. (a) Simulated motion for a medium soil condition defined by NZS 1170.5 and (b) response spectrum of the simulated ground motion and target spectrum of the NZS 1170.5.

3 RESULTS

Table 3 shows the maximum acceleration recorded at the tank base. For the rigid base conditions, the maximum acceleration is given by the accelerometer on the steel plate; for the flexible base condition, by the accelerometer on the sand surface. The results hereafter have been normalised by the maximum base acceleration to remove minor fluctuations in the applied motion.

	Base case		
	Fixed rigid	Free rigid	Flexible
Maximum acceleration (g)	0.14	0.13	0.17

Table 3. Maximum acceleration at the base of the tank

Table 4 shows the normalised absolute maximum accelerations for the bottom, middle and top of the tank, for the three base conditions. For the fixed base condition, the amplification of acceleration at the tank top is 25% referred to the acceleration at the tank base. For the free-base case, on a rigid foundation, the tank top experienced the highest amplification of 260% with respect to the acceleration at the tank base. Thus, if the tank is resting on a rigid foundation, fixed or free to uplift, the design of the tank wall should recognise the acceleration is not constant over the height of the tank.

The normalised acceleration of the tank resting on sand has two main differences compared with the results of the tank on a rigid foundation. Firstly, the highest acceleration of the tank on sand occurred at the bottom of the tank, i.e. 30 mm from the supporting base, that is 81% higher than the acceleration of the sand surface, adjacent to the tank base. This result is perhaps counter intuitive, i.e. the maximum acceleration may be expected to occur at the top of the tank. Based on the experiment results, the interaction of the supporting soil and the tank base resulted in differences in the development of the acceleration along the tank height.

Secondly, the maximum amplification of the base acceleration on a rigid base (3.6) is almost three times the maximum acceleration experienced when the tank is supported by a flexible foundation (1.3). These results suggest that the maximum acceleration that should be considered for design of the tank wall is given by the case when the tank is resting freely on a rigid foundation (may be interpreted as a rock site), and occurs at the top of the tank.

Hence, the design of an anchored tank on a hard rock site would results in high tie-down forces and lower wall stresses than the same tank free to uplift.

	Base case		
	Fixed rigid	Free rigid	Flexible
Top	1.25	3.60	0.91
Middle	1.08	1.64	0.90
Bottom	0.98	0.93	1.34

Table 4. Variation of maximum normalised acceleration in the tank wall

Figure 6 shows the time-histories of the angle of rotation α for the time $t = [8,12]\ s$, being the time interval containing the time of the maximum of acceleration. The rotation angle α is the angle formed between the supporting soil and the tank base when uplift occurs at one side of the tank (see Figure 7). It is assumed that the base plate is rigid, hence it did not experienced any deformation. The angle α is calculated using the time-history of uplift. It is worth noting that in the cases of the rigid and flexible base the maximum uplift for each side of the tank occurred at the same instant of time. Those results suggest that in the considered case the occurrence of uplift depends more on the characteristics of the earthquake rather than the supporting soil condition.

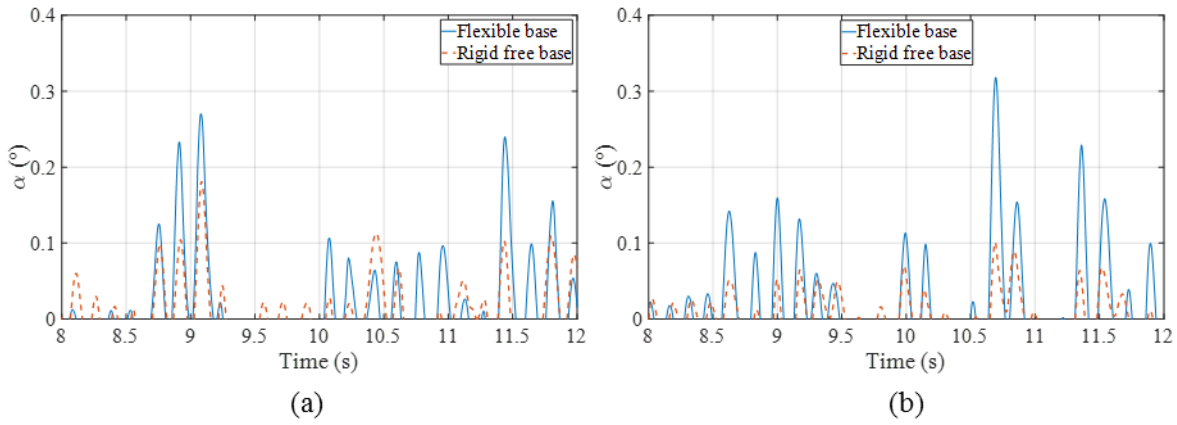

Figure 6. Comparison of angle of rotation α for free rigid and flexible base at (a) 180° and (b) 0°

Table 5 shows the times when the maximum acceleration of the shake table, acceleration of the tank wall and uplift occurred, for both rigid and flexible base cases. These values were extracted from time-history records as shown in Figure 6. Figure 7 shows sketches of the tank configuration when the maximum uplift occurred and the normalised acceleration profiles along the dimensionless height x/H for each supporting case. It is assumed that the acceleration profiles follow a linear distribution along the tank wall. The three accelerometers are indicated by circles.

From Table 5, for the case of a rigid base, at the same side of the tank (180°), the maximum acceleration in the tank wall occurred 10 ms before the maximum uplift. Figure 7(a) shows the acceleration profile at the time at the maximum uplift. The tank top has the maximum acceleration of the profile. Considering the profile at 180°, for a flexible supporting soil the maximum acceleration occurs 10 ms after the maximum uplift, while simultaneously the maximum uplift takes place at the side of 0° (see Figure 7(b)). The lowest accelerometer of the tank recorded the maximum acceleration of the profile of 0°. Even though the tank on a flexible base soil experienced around 30% uplift more than that of the rigid base case, the development of acceleration was almost three times higher when the tank was on a rigid base.

From the observation of the water in the tank, it was generally observed that the water was vibrating out-of-phase with respect to the tank wall, and from time to time changed to being in-phase. This suggests that for both rigid and flexible base cases, the time when the maximum acceleration of the shake table occurred does not coincide with the time of the maximum acceleration of the tank wall and maximum uplift.

	Maximum acceleration shake table		Maximum acceleration tank wall		Maximum Uplift			
					Rigid base		Flexible base	
	Rigid	Flexible	Rigid	Flexible	0°	180°	0°	180°
Time (s)	11.305	11.305	9.075	10.705	10.69	9.085	10.695	9.08

Table 5. Comparison of the time of maximum acceleration of the shake table, tank wall and uplift

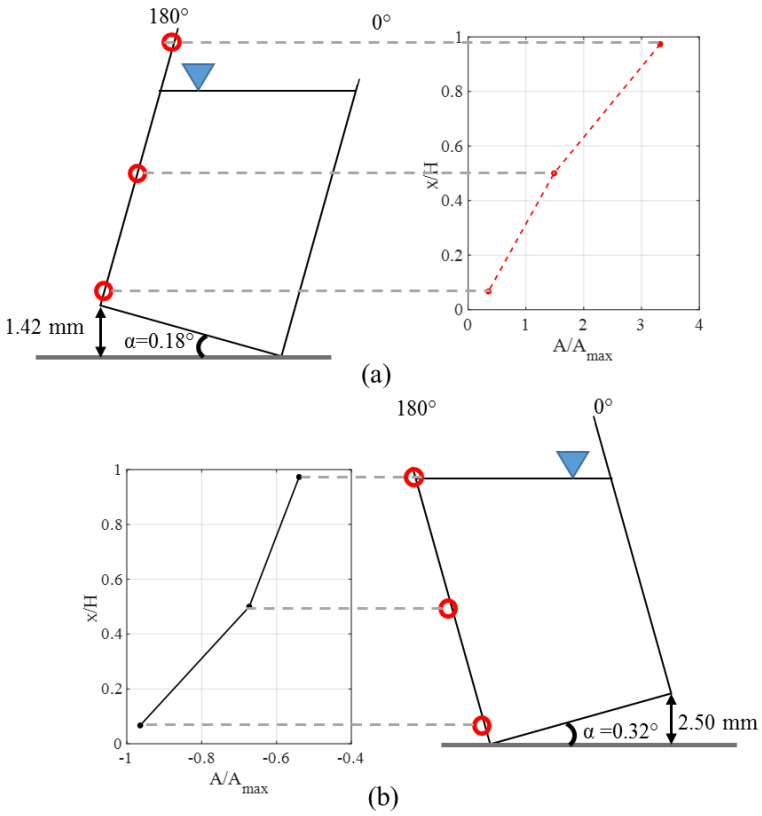

Figure 7. Acceleration profiles in the tank wall when maximum uplift occurred. (a) Rigid supporting case $t = 9.085\ s$ and (b) flexible base case $t = 10.695\ s$

4 CONCLUSIONS

A low-density polyethylene tank was used as a model for a steel tank and tested on a shake table. One stochastically simulated base motion based on the design spectrum of NZS1170.5 for a class C site was used. Two support conditions were utilised, i.e. 1) on a rigid base (steel plate); 2) on a flexible base (sand). Results from three base conditions were compared: i) fixed on a rigid base, ii) free on a rigid base and iii) free on sand. The experiments were performed with an aspect ratio of three. The main aim was to investigate the combined effects of a flexible foundation on uplift and tank acceleration. The results of the experiments reveal:

1) The highest acceleration occurred for a free-rigid base condition, at the top of the tank. It was thrice the maximum acceleration of the case with a fixed-base condition and twice

of the case for the tank on sand. In the cases considered, soil-structure interaction reduces the development of acceleration in the tank wall.

2) The maximum acceleration did not always occur at the top of the tank. For a flexible base, the maximum acceleration occurred at the bottom of the tank. This location of the maximum acceleration may be due to the interaction between the soil and the structure as well as the interaction between the fluid and the tank wall (out-of-phase vibrations).
3) In all cases considered the maximum uplift of occurred for the case of supporting sand, even though the maximum acceleration occurred when the tank was on a rigid base. However, the occurrence of the maximum uplift in both cases of a rigid and flexible base coincided.

Keywords: periodic elevated structures, dynamic soil-structure interaction, wave finite element method

Abstract. *This paper presents a methodology to study wave propagation in periodic elevated structures consisting of a series of identical cells. The wave finite element method is used to determine the dynamic response of the structure while only a single reference cell is modeled. A substructuring approach is used to efficiently compute the condensed dynamic stiffness matrix of the reference cell. To demonstrate the methodology, the receptance of a slab track is computed. The results are validated with the Floquet transform method and the classical wave finite element method.*

*Presently at Wood, Australia

1 INTRODUCTION

Predicting the dynamic response of large-scale structures is computationally expensive, especially when dynamic soil-structure interaction (SSI) is taken into account. For periodic structures, the SSI problem can be solved for a single reference cell using periodic structure theory [1, 2]. A periodic finite element-boundary element (FE-BE) formulation using Green-Floquet functions has been proposed to solve periodic SSI problems [3, 4]. The Floquet transformation is used to transform the equilibrium equations to the wavenumber domain. The wave finite element method (WFEM) avoids this transformation by employing the free wave characteristics of the reference cell [5, 6]. In this paper, a methodology based on the WFEM is presented to study wave propagation in periodic elevated structures. The periodic reference cell is divided in four parts to efficiently compute its condensed dynamic stiffness matrix. Section 2 introduces the WFEM and elaborates the methodology for elevated structures. In Section 3, the methodology is demonstrated by computing the receptance of a floating slab track. The results are validated using the classical WFEM and the Floquet transform method. Section 4 concludes the paper.

2 METHODOLOGY

In this section, the classical WFEM to compute the forced vibration response of one-dimensional waveguides is briefly recapitulated [5]. Next, the method is adapted to efficiently study wave propagation in periodic elevated structures.

2.1 The wave finite element method (WFEM)

Figure 1 shows an infinitely long periodic structure which is divided in periodic cells with length L. The dynamic stiffness matrix $\mathbf{D} = \mathbf{K} + \mathrm{i}\omega\mathbf{C} - \omega^2\mathbf{M}$ of a reference cell k relates the forces $\mathbf{f}_k$ to the displacements $\mathbf{u}_k$:

$$\begin{Bmatrix} \mathbf{f}_{\mathrm{L}k} \\ \mathbf{f}_{\mathrm{I}k} \\ \mathbf{f}_{\mathrm{R}k} \end{Bmatrix} = \begin{bmatrix} \mathbf{D}_{\mathrm{LL}} & \mathbf{D}_{\mathrm{LI}} & \mathbf{D}_{\mathrm{LR}} \\ \mathbf{D}_{\mathrm{IL}} & \mathbf{D}_{\mathrm{II}} & \mathbf{D}_{\mathrm{IR}} \\ \mathbf{D}_{\mathrm{RL}} & \mathbf{D}_{\mathrm{RI}} & \mathbf{D}_{\mathrm{RR}} \end{bmatrix} \begin{Bmatrix} \mathbf{u}_{\mathrm{L}k} \\ \mathbf{u}_{\mathrm{I}k} \\ \mathbf{u}_{\mathrm{R}k} \end{Bmatrix}. \tag{1}$$

The subscripts L, I, and R denote the degrees of freedom (DOFs) on the left interface, the interior DOFs, and the DOFs on the right interface of the reference cell, respectively. If no external forces are applied to cell k ($\mathbf{f}_{\mathrm{I}k} = \mathbf{0}$), the condensed dynamic stiffness matrix $\tilde{\mathbf{D}}$ is

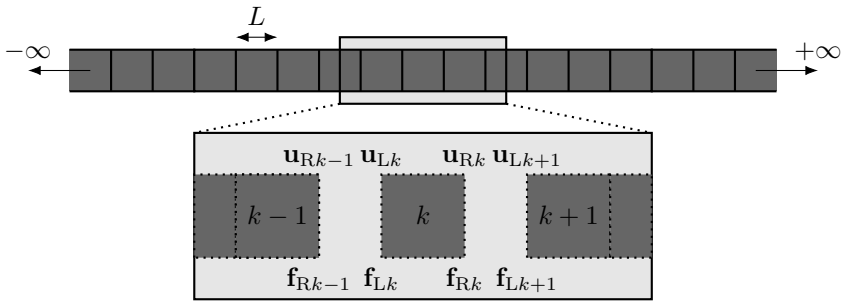

Figure 1: Periodic structure consisting of an infinitely long array of identical cells.

obtained after elimination of the interior DOFs:

$$\begin{Bmatrix} \mathbf{f}_{\mathrm{L}k} \\ \mathbf{f}_{\mathrm{R}k} \end{Bmatrix} = \begin{bmatrix} \tilde{\mathbf{D}}_{\mathrm{LL}} & \tilde{\mathbf{D}}_{\mathrm{LR}} \\ \tilde{\mathbf{D}}_{\mathrm{RL}} & \tilde{\mathbf{D}}_{\mathrm{RR}} \end{bmatrix} \begin{Bmatrix} \mathbf{u}_{\mathrm{L}k} \\ \mathbf{u}_{\mathrm{R}k} \end{Bmatrix} \tag{2}$$

where

$$\begin{bmatrix} \tilde{\mathbf{D}}_{\mathrm{LL}} & \tilde{\mathbf{D}}_{\mathrm{LR}} \\ \tilde{\mathbf{D}}_{\mathrm{RL}} & \tilde{\mathbf{D}}_{\mathrm{RR}} \end{bmatrix} = \begin{bmatrix} \mathbf{D}_{\mathrm{LL}} & \mathbf{D}_{\mathrm{LR}} \\ \mathbf{D}_{\mathrm{RL}} & \mathbf{D}_{\mathrm{RR}} \end{bmatrix} - \begin{bmatrix} \mathbf{D}_{\mathrm{LI}} \\ \mathbf{D}_{\mathrm{RI}} \end{bmatrix} \mathbf{D}_{\mathrm{II}}^{-1} \begin{bmatrix} \mathbf{D}_{\mathrm{IL}} & \mathbf{D}_{\mathrm{IR}} \end{bmatrix}. \tag{3}$$

If the number of interior DOFs is large, this condensation is computationally expensive.

Free wave propagation in periodic media is described by Floquet theory which states that waves propagate from cell to cell with only a change in amplitude and phase [1]. This is represented by the propagation constant μ that relates the displacements and forces at the interfaces of neighboring cells k and $k+1$:

$$\mathbf{u}_{\mathrm{L}k+1} = e^{-\mu}\mathbf{u}_{\mathrm{L}k}, \tag{4}$$

$$\mathbf{f}_{\mathrm{L}k+1} = e^{-\mu}\mathbf{f}_{\mathrm{L}k}. \tag{5}$$

Furthermore, continuity of displacements and equilibrium of forces is imposed at the cell interfaces:

$$\mathbf{u}_{\mathrm{L}k+1} = \mathbf{u}_{\mathrm{R}k}, \tag{6}$$

$$\mathbf{f}_{\mathrm{L}k+1} + \mathbf{f}_{\mathrm{R}k} = \mathbf{0}. \tag{7}$$

The following relation is obtained from equations (4) and (6):

$$\mathbf{u}_{\mathrm{R}k} = e^{-\mu}\mathbf{u}_{\mathrm{L}k}, \tag{8}$$

while combining equations (5) and (7) results in:

$$\mathbf{f}_{\mathrm{R}k} = -e^{-\mu}\mathbf{f}_{\mathrm{L}k}. \tag{9}$$

Equation (9) is further elaborated using equation (2):

$$\tilde{\mathbf{D}}_{\mathrm{RL}}\mathbf{u}_{\mathrm{L}k} + (\tilde{\mathbf{D}}_{\mathrm{LL}} + \tilde{\mathbf{D}}_{\mathrm{RR}})\mathbf{u}_{\mathrm{R}k} = -\tilde{\mathbf{D}}_{\mathrm{LR}}e^{-\mu}\mathbf{u}_{\mathrm{R}k}. \tag{10}$$

Equations (8) and (10) are combined into the following eigenvalue problem from which the free wave characteristics (propagation constants and free wave modes) of the reference cell are obtained [5]:

$$\begin{bmatrix} \mathbf{0} & \mathbf{I} \\ -\tilde{\mathbf{D}}_{\mathrm{LR}}^{-1}\tilde{\mathbf{D}}_{\mathrm{RL}} & -\tilde{\mathbf{D}}_{\mathrm{LR}}^{-1}(\tilde{\mathbf{D}}_{\mathrm{LL}} + \tilde{\mathbf{D}}_{\mathrm{RR}}) \end{bmatrix} \begin{Bmatrix} \mathbf{u}_{\mathrm{L}k} \\ \mathbf{u}_{\mathrm{R}k} \end{Bmatrix} = e^{-\mu} \begin{Bmatrix} \mathbf{u}_{\mathrm{L}k} \\ \mathbf{u}_{\mathrm{R}k} \end{Bmatrix}. \tag{11}$$

Note that this eigenvalue problem can be reformulated to improve the numerical conditioning [7, 8]. It can be shown that the propagation constants μ appear in pairs (μ,$-\mu$) [8]. The real part $\mathrm{Re}(\mu)$ of the propagation constant μ determines the wave attenuation, while the imaginary part $\mathrm{Im}(\mu)$ determines the phase change over the cell length L. A wave is called positive-going if its amplitude decreases towards the right ($\mathrm{Re}(\mu) > 0$) or, if power is flowing towards the right ($\mathrm{Im}(\mu) > 0$), when its amplitude is constant ($\mathrm{Re}(\mu) = 0$). A wave is called negative-going if its amplitude decreases towards the left ($\mathrm{Re}(\mu) < 0$) or, if power is flowing towards the left ($\mathrm{Im}(\mu) < 0$), when its amplitude is constant ($\mathrm{Re}(\mu) = 0$). The number of positive- and

negative-going waves is equal to the number of DOFs n at the interface between two cells. Furthermore, three wave types are observed: (1) non-decaying waves ($\mathrm{Re}(\mu) = 0$), (2) evanescent waves ($\mathrm{Im}(\mu) = 0$), and (3) decaying waves (all other cases).

The propagation constants of positive- and negative-going waves are denoted by μ_p and μ_n, respectively. The corresponding free wave modes $\boldsymbol{\psi}_\mathrm{p}$ and $\boldsymbol{\psi}_\mathrm{n}$ are the eigenvectors in equation (11). Each mode $\boldsymbol{\psi}_\mathrm{p}$ or $\boldsymbol{\psi}_\mathrm{n}$ is associated with a force vector $\boldsymbol{\rho}_\mathrm{p}$ or $\boldsymbol{\rho}_\mathrm{n}$, which is computed as:

$$\boldsymbol{\rho}_\mathrm{p} = \left(\tilde{\mathbf{D}}_\mathrm{LL} + e^{-\mu_\mathrm{p}}\tilde{\mathbf{D}}_\mathrm{LR}\right)\boldsymbol{\psi}_\mathrm{p} \tag{12}$$

for the positive-going waves, and as:

$$\boldsymbol{\rho}_\mathrm{n} = \left(\tilde{\mathbf{D}}_\mathrm{RR} + e^{+\mu_\mathrm{n}}\tilde{\mathbf{D}}_\mathrm{RL}\right)\boldsymbol{\psi}_\mathrm{n} \tag{13}$$

for the negative-going waves. The modes $\boldsymbol{\psi}_\mathrm{p}$ and $\boldsymbol{\psi}_\mathrm{n}$ are collected in the matrices $\boldsymbol{\Psi}_\mathrm{p}$ and $\boldsymbol{\Psi}_\mathrm{n}$, while the force vectors $\boldsymbol{\rho}_\mathrm{p}$ and $\boldsymbol{\rho}_\mathrm{n}$ are collected in the matrices $\mathbf{R}_\mathrm{p}$ and $\mathbf{R}_\mathrm{n}$.

Subsequently, the free wave characteristics are used to construct the condensed dynamic stiffness matrix of a semi-infinite part of the structure. First, consider the semi-infinite part to the left of cell k where only negative-going waves are propagating (figure 1). Hence, the displacements $\mathbf{u}_{\mathrm{R}k-1}$ at the right side of cell $k-1$ are written as a linear combination of the wave modes $\boldsymbol{\Psi}_\mathrm{n}$:

$$\mathbf{u}_{\mathrm{R}k-1} = \boldsymbol{\Psi}_\mathrm{n}\boldsymbol{\alpha}_\mathrm{n} \tag{14}$$

with $\boldsymbol{\alpha}_\mathrm{n}$ the modal coordinates of the negative-going waves. Similarly, the forces $\mathbf{f}_{\mathrm{R}k-1}$ are written as a linear combination of the force vectors $\mathbf{R}_\mathrm{n}$:

$$\mathbf{f}_{\mathrm{R}k-1} = \mathbf{R}_\mathrm{n}\boldsymbol{\alpha}_\mathrm{n}. \tag{15}$$

Eliminating the modal coordinates $\boldsymbol{\alpha}_\mathrm{n}$ results in an expression for the dynamic stiffness matrix $\mathbf{S}_\mathrm{n}$ of the semi-infinite part to the left of cell k:

$$\mathbf{S}_\mathrm{n} = \mathbf{R}_\mathrm{n}\boldsymbol{\Psi}_\mathrm{n}^{-1}. \tag{16}$$

A similar approach is followed to construct the dynamic stiffness matrix $\mathbf{S}_\mathrm{p}$ of the semi-infinite part to the right of cell k where only positive-going waves are propagating, relating the forces $\mathbf{f}_{\mathrm{L}k+1}$ to the displacements $\mathbf{u}_{\mathrm{L}k+1}$:

$$\mathbf{S}_\mathrm{p} = \mathbf{R}_\mathrm{p}\boldsymbol{\Psi}_\mathrm{p}^{-1}. \tag{17}$$

Finally, the condensed dynamic stiffness matrix of a finite part of the structure consisting of N cells is constructed, accounting for both positive- and negative-going waves. The displacements $\mathbf{u}_{\mathrm{L}1}$ at the left side of the first cell and $\mathbf{u}_{\mathrm{R}N}$ at the right side of the Nth cell are written as a linear combination of the wave modes $\boldsymbol{\Psi}_\mathrm{p}$ and $\boldsymbol{\Psi}_\mathrm{n}$:

$$\begin{Bmatrix}\mathbf{u}_{\mathrm{L}1}\\ \mathbf{u}_{\mathrm{R}N}\end{Bmatrix} = \begin{bmatrix}\boldsymbol{\Psi}_\mathrm{n}e^{+N\mu_\mathrm{n}} & \boldsymbol{\Psi}_\mathrm{p}\\ \boldsymbol{\Psi}_\mathrm{n} & \boldsymbol{\Psi}_\mathrm{p}e^{-N\mu_\mathrm{p}}\end{bmatrix}\begin{Bmatrix}\boldsymbol{\alpha}_\mathrm{n}\\ \boldsymbol{\alpha}_\mathrm{p}\end{Bmatrix}. \tag{18}$$

A similar expression is used for the forces $\mathbf{F}_{\mathrm{L}1}$ and $\mathbf{F}_{\mathrm{R}N}$ as a linear combination of the force vectors $\mathbf{R}_\mathrm{p}$ and $\mathbf{R}_\mathrm{n}$, respectively:

$$\begin{Bmatrix}\mathbf{F}_{\mathrm{L}1}\\ \mathbf{F}_{\mathrm{R}N}\end{Bmatrix} = \begin{bmatrix}-\mathbf{R}_\mathrm{n}e^{+N\mu_\mathrm{n}} & \mathbf{R}_\mathrm{p}\\ \mathbf{R}_\mathrm{n} & -\mathbf{R}_\mathrm{p}e^{-N\mu_\mathrm{p}}\end{bmatrix}\begin{Bmatrix}\boldsymbol{\alpha}_\mathrm{n}\\ \boldsymbol{\alpha}_\mathrm{p}\end{Bmatrix}. \tag{19}$$

The modal coordinates $\boldsymbol{\alpha}_{\mathrm{n}}$ and $\boldsymbol{\alpha}_{\mathrm{p}}$ are eliminated from equations (18) and (19), as follows:

$$\begin{Bmatrix} \mathbf{F}_{\mathrm{L}1} \\ \mathbf{F}_{\mathrm{R}N} \end{Bmatrix} = \begin{bmatrix} -\mathbf{R}_{\mathrm{n}} e^{+N\mu_{\mathrm{n}}} & \mathbf{R}_{\mathrm{p}} \\ \mathbf{R}_{\mathrm{n}} & -\mathbf{R}_{\mathrm{p}} e^{-N\mu_{\mathrm{p}}} \end{bmatrix} \begin{bmatrix} \boldsymbol{\Psi}_{\mathrm{n}} e^{+N\mu_{\mathrm{n}}} & \boldsymbol{\Psi}_{\mathrm{p}} \\ \boldsymbol{\Psi}_{\mathrm{n}} & \boldsymbol{\Psi}_{\mathrm{p}} e^{-N\mu_{\mathrm{p}}} \end{bmatrix}^{-1} \begin{Bmatrix} \mathbf{u}_{\mathrm{L}1} \\ \mathbf{u}_{\mathrm{R}N} \end{Bmatrix}$$
$$= \begin{bmatrix} \tilde{\mathbf{S}}_{\mathrm{LL}} & \tilde{\mathbf{S}}_{\mathrm{LR}} \\ \tilde{\mathbf{S}}_{\mathrm{RL}} & \tilde{\mathbf{S}}_{\mathrm{RR}} \end{bmatrix} \begin{Bmatrix} \mathbf{u}_{\mathrm{L}1} \\ \mathbf{u}_{\mathrm{R}N} \end{Bmatrix}. \tag{20}$$

The properties of a block matrix are used to compute the matrix inverse. The condensed dynamic stiffness matrix $\tilde{\mathbf{S}}$ relates the forces to the displacements at both ends of the finite part. Note that the dynamic stiffness matrix is denoted by $\mathbf{S}$ for parts consisting of multiple cells, while $\mathbf{D}$ is used for a single cell. A tilde is used to denote a dynamic stiffness matrix after condensation.

2.2 Periodic elevated structures

In this section, the WFEM is used to compute the forced vibration response of periodic elevated structures such as the bridge shown in figure 2. Waves propagate through both the bridge deck and the soil (one-dimensional waveguides), and interact through the bridge piers. The dynamic response of this structure is computed efficiently by substructuring the reference cell into four parts (figure 2): the bridge pier (part a), the foundation (part b), the bridge deck between two piers (part c), and the soil between two foundations (part d). Instead of constructing an FE model of the entire reference cell, each part is modeled separately. This reduces the computational effort, particularly when the number of interior DOFs in the reference cell is large.

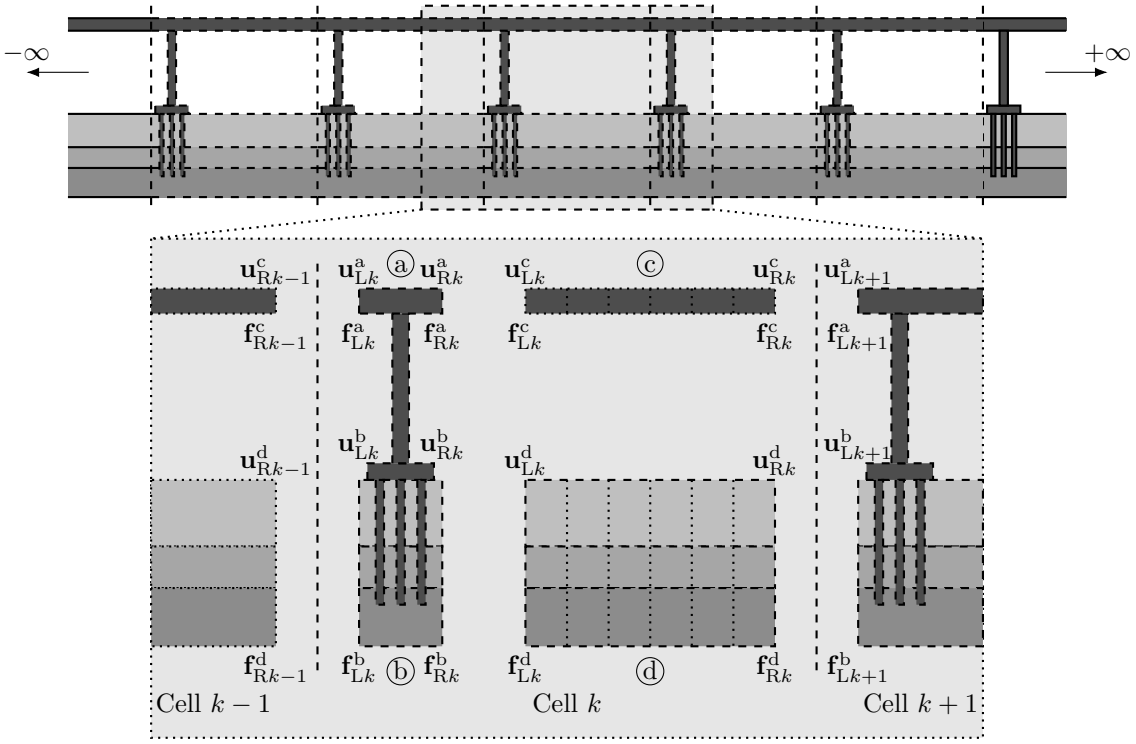

Figure 2: Periodic elevated structure consisting of an infinitely long array of identical cells. The reference cell is divided into four parts a, b, c, and d.

2.2.1 Substructuring of the reference cell

The dynamic stiffness matrix of the coupled parts a and b is denoted by $\mathbf{D}_{\mathrm{ab}}$, where the subscript ab denotes the union of parts a and b:

$$\begin{Bmatrix} \mathbf{f}^{\mathrm{a}}_{\mathrm{L}k} \\ \mathbf{f}^{\mathrm{b}}_{\mathrm{L}k} \\ \mathbf{f}^{\mathrm{a}}_{\mathrm{I}k} \\ \mathbf{f}^{\mathrm{b}}_{\mathrm{I}k} \\ \mathbf{f}^{\mathrm{a}}_{\mathrm{R}k} \\ \mathbf{f}^{\mathrm{b}}_{\mathrm{R}k} \end{Bmatrix} = \begin{bmatrix} \mathbf{D}^{\mathrm{aa}}_{\mathrm{LL}} & \mathbf{D}^{\mathrm{ab}}_{\mathrm{LL}} & \mathbf{D}^{\mathrm{aa}}_{\mathrm{LI}} & \mathbf{D}^{\mathrm{ab}}_{\mathrm{LI}} & \mathbf{D}^{\mathrm{aa}}_{\mathrm{LR}} & \mathbf{D}^{\mathrm{ab}}_{\mathrm{LR}} \\ \mathbf{D}^{\mathrm{ba}}_{\mathrm{LL}} & \mathbf{D}^{\mathrm{bb}}_{\mathrm{LL}} & \mathbf{D}^{\mathrm{ba}}_{\mathrm{LI}} & \mathbf{D}^{\mathrm{bb}}_{\mathrm{LI}} & \mathbf{D}^{\mathrm{ba}}_{\mathrm{LR}} & \mathbf{D}^{\mathrm{bb}}_{\mathrm{LR}} \\ \mathbf{D}^{\mathrm{aa}}_{\mathrm{IL}} & \mathbf{D}^{\mathrm{ab}}_{\mathrm{IL}} & \mathbf{D}^{\mathrm{aa}}_{\mathrm{II}} & \mathbf{D}^{\mathrm{ab}}_{\mathrm{II}} & \mathbf{D}^{\mathrm{aa}}_{\mathrm{IR}} & \mathbf{D}^{\mathrm{ab}}_{\mathrm{IR}} \\ \mathbf{D}^{\mathrm{ba}}_{\mathrm{IL}} & \mathbf{D}^{\mathrm{bb}}_{\mathrm{IL}} & \mathbf{D}^{\mathrm{ba}}_{\mathrm{II}} & \mathbf{D}^{\mathrm{bb}}_{\mathrm{II}} & \mathbf{D}^{\mathrm{ba}}_{\mathrm{IR}} & \mathbf{D}^{\mathrm{bb}}_{\mathrm{IR}} \\ \mathbf{D}^{\mathrm{aa}}_{\mathrm{RL}} & \mathbf{D}^{\mathrm{ab}}_{\mathrm{RL}} & \mathbf{D}^{\mathrm{aa}}_{\mathrm{RI}} & \mathbf{D}^{\mathrm{ab}}_{\mathrm{RI}} & \mathbf{D}^{\mathrm{aa}}_{\mathrm{RR}} & \mathbf{D}^{\mathrm{ab}}_{\mathrm{RR}} \\ \mathbf{D}^{\mathrm{ba}}_{\mathrm{RL}} & \mathbf{D}^{\mathrm{bb}}_{\mathrm{RL}} & \mathbf{D}^{\mathrm{ba}}_{\mathrm{RI}} & \mathbf{D}^{\mathrm{bb}}_{\mathrm{RI}} & \mathbf{D}^{\mathrm{ba}}_{\mathrm{RR}} & \mathbf{D}^{\mathrm{bb}}_{\mathrm{RR}} \end{bmatrix} \begin{Bmatrix} \mathbf{u}^{\mathrm{a}}_{\mathrm{L}k} \\ \mathbf{u}^{\mathrm{b}}_{\mathrm{L}k} \\ \mathbf{u}^{\mathrm{a}}_{\mathrm{I}k} \\ \mathbf{u}^{\mathrm{b}}_{\mathrm{I}k} \\ \mathbf{u}^{\mathrm{a}}_{\mathrm{R}k} \\ \mathbf{u}^{\mathrm{b}}_{\mathrm{R}k} \end{Bmatrix}. \tag{21}$$

The superscript a denotes the DOFs of part a, while the superscript b denotes the DOFs of part b. The subscripts L, I, and R are used to distinguish between the DOFs on the left interface, the interior, and the right interface, respectively. In those cases where the left and right interface are not directly coupled, the coupling terms with subscripts LR and RL are zero. Assuming $\mathbf{f}^{\mathrm{a}}_{\mathrm{I}k} = \mathbf{0}$ and $\mathbf{f}^{\mathrm{b}}_{\mathrm{I}k} = \mathbf{0}$, the condensed dynamic stiffness matrix $\tilde{\mathbf{D}}_{\mathrm{ab}}$ is obtained by eliminating the interior DOFs (equation (3)):

$$\begin{Bmatrix} \mathbf{f}^{\mathrm{a}}_{\mathrm{L}k} \\ \mathbf{f}^{\mathrm{b}}_{\mathrm{L}k} \\ \mathbf{f}^{\mathrm{a}}_{\mathrm{R}k} \\ \mathbf{f}^{\mathrm{b}}_{\mathrm{R}k} \end{Bmatrix} = \begin{bmatrix} \tilde{\mathbf{D}}^{\mathrm{aa}}_{\mathrm{LL}} & \tilde{\mathbf{D}}^{\mathrm{ab}}_{\mathrm{LL}} & \tilde{\mathbf{D}}^{\mathrm{aa}}_{\mathrm{LR}} & \tilde{\mathbf{D}}^{\mathrm{ab}}_{\mathrm{LR}} \\ \tilde{\mathbf{D}}^{\mathrm{ba}}_{\mathrm{LL}} & \tilde{\mathbf{D}}^{\mathrm{bb}}_{\mathrm{LL}} & \tilde{\mathbf{D}}^{\mathrm{ba}}_{\mathrm{LR}} & \tilde{\mathbf{D}}^{\mathrm{bb}}_{\mathrm{LR}} \\ \tilde{\mathbf{D}}^{\mathrm{aa}}_{\mathrm{RL}} & \tilde{\mathbf{D}}^{\mathrm{ab}}_{\mathrm{RL}} & \tilde{\mathbf{D}}^{\mathrm{aa}}_{\mathrm{RR}} & \tilde{\mathbf{D}}^{\mathrm{ab}}_{\mathrm{RR}} \\ \tilde{\mathbf{D}}^{\mathrm{ba}}_{\mathrm{RL}} & \tilde{\mathbf{D}}^{\mathrm{bb}}_{\mathrm{RL}} & \tilde{\mathbf{D}}^{\mathrm{ba}}_{\mathrm{RR}} & \tilde{\mathbf{D}}^{\mathrm{bb}}_{\mathrm{RR}} \end{bmatrix} \begin{Bmatrix} \mathbf{u}^{\mathrm{a}}_{\mathrm{L}k} \\ \mathbf{u}^{\mathrm{b}}_{\mathrm{L}k} \\ \mathbf{u}^{\mathrm{a}}_{\mathrm{R}k} \\ \mathbf{u}^{\mathrm{b}}_{\mathrm{R}k} \end{Bmatrix}. \tag{22}$$

Parts c and d are uncoupled and assumed to be periodic. Equation (20) is used to construct the condensed dynamic stiffness matrix $\tilde{\mathbf{S}}_{\mathrm{cc}}$ of part c, consisting of N_{c} cells, from the free wave characteristics of a reference cell. A similar approach is followed to construct the condensed dynamic stiffness matrix $\tilde{\mathbf{S}}_{\mathrm{dd}}$ of part d consisting of N_{d} cells. The condensed dynamic stiffness matrix $\tilde{\mathbf{S}}_{\mathrm{cd}}$ of the union of parts c and d then becomes:

$$\begin{Bmatrix} \mathbf{f}^{\mathrm{c}}_{\mathrm{L}k} \\ \mathbf{f}^{\mathrm{d}}_{\mathrm{L}k} \\ \mathbf{f}^{\mathrm{c}}_{\mathrm{R}k} \\ \mathbf{f}^{\mathrm{d}}_{\mathrm{R}k} \end{Bmatrix} = \begin{bmatrix} \tilde{\mathbf{S}}^{\mathrm{cc}}_{\mathrm{LL}} & \mathbf{0} & \tilde{\mathbf{S}}^{\mathrm{cc}}_{\mathrm{LR}} & \mathbf{0} \\ \mathbf{0} & \tilde{\mathbf{S}}^{\mathrm{dd}}_{\mathrm{LL}} & \mathbf{0} & \tilde{\mathbf{S}}^{\mathrm{dd}}_{\mathrm{LR}} \\ \tilde{\mathbf{S}}^{\mathrm{cc}}_{\mathrm{RL}} & \mathbf{0} & \tilde{\mathbf{S}}^{\mathrm{cc}}_{\mathrm{RR}} & \mathbf{0} \\ \mathbf{0} & \tilde{\mathbf{S}}^{\mathrm{dd}}_{\mathrm{RL}} & \mathbf{0} & \tilde{\mathbf{S}}^{\mathrm{dd}}_{\mathrm{RR}} \end{bmatrix} \begin{Bmatrix} \mathbf{u}^{\mathrm{c}}_{\mathrm{L}k} \\ \mathbf{u}^{\mathrm{d}}_{\mathrm{L}k} \\ \mathbf{u}^{\mathrm{c}}_{\mathrm{R}k} \\ \mathbf{u}^{\mathrm{d}}_{\mathrm{R}k} \end{Bmatrix}. \tag{23}$$

Continuity of displacements and equilibrium of forces is imposed at the interface between parts a and c:

$$\mathbf{u}^{\mathrm{a}}_{\mathrm{R}k} = \mathbf{u}^{\mathrm{c}}_{\mathrm{L}k}, \tag{24}$$

$$\mathbf{f}^{\mathrm{a}}_{\mathrm{R}k} + \mathbf{f}^{\mathrm{c}}_{\mathrm{L}k} = \mathbf{0}. \tag{25}$$

Similarly, the following relations hold at the interface between parts b and d:

$$\mathbf{u}^{\mathrm{b}}_{\mathrm{R}k} = \mathbf{u}^{\mathrm{d}}_{\mathrm{L}k}, \tag{26}$$

$$\mathbf{f}^{\mathrm{b}}_{\mathrm{R}k} + \mathbf{f}^{\mathrm{d}}_{\mathrm{L}k} = \mathbf{0}. \tag{27}$$

Relations (24) to (27) are used to combine equations (22) and (23) into the following system of

equations:

$$\begin{Bmatrix} \mathbf{f}^{\mathrm{a}}_{\mathrm{L}k} \\ \mathbf{f}^{\mathrm{b}}_{\mathrm{L}k} \\ \mathbf{f}^{\mathrm{c}}_{\mathrm{R}k} \\ \mathbf{f}^{\mathrm{d}}_{\mathrm{R}k} \\ \mathbf{0} \\ \mathbf{0} \end{Bmatrix} = \begin{bmatrix} \tilde{\mathbf{D}}^{\mathrm{aa}}_{\mathrm{LL}} & \tilde{\mathbf{D}}^{\mathrm{ab}}_{\mathrm{LL}} & \mathbf{0} & \mathbf{0} & \tilde{\mathbf{D}}^{\mathrm{aa}}_{\mathrm{LR}} & \tilde{\mathbf{D}}^{\mathrm{ab}}_{\mathrm{LR}} \\ \tilde{\mathbf{D}}^{\mathrm{ba}}_{\mathrm{LL}} & \tilde{\mathbf{D}}^{\mathrm{bb}}_{\mathrm{LL}} & \mathbf{0} & \mathbf{0} & \tilde{\mathbf{D}}^{\mathrm{ba}}_{\mathrm{LR}} & \tilde{\mathbf{D}}^{\mathrm{bb}}_{\mathrm{LR}} \\ \mathbf{0} & \mathbf{0} & \tilde{\mathbf{S}}^{\mathrm{cc}}_{\mathrm{RR}} & \mathbf{0} & \tilde{\mathbf{S}}^{\mathrm{cc}}_{\mathrm{RL}} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \mathbf{0} & \tilde{\mathbf{S}}^{\mathrm{dd}}_{\mathrm{RR}} & \mathbf{0} & \tilde{\mathbf{S}}^{\mathrm{dd}}_{\mathrm{RL}} \\ \tilde{\mathbf{D}}^{\mathrm{aa}}_{\mathrm{RL}} & \tilde{\mathbf{D}}^{\mathrm{ab}}_{\mathrm{RL}} & \tilde{\mathbf{S}}^{\mathrm{cc}}_{\mathrm{LR}} & \mathbf{0} & \tilde{\mathbf{S}}^{\mathrm{cc}}_{\mathrm{LL}} + \tilde{\mathbf{D}}^{\mathrm{aa}}_{\mathrm{RR}} & \tilde{\mathbf{D}}^{\mathrm{ab}}_{\mathrm{RR}} \\ \tilde{\mathbf{D}}^{\mathrm{ba}}_{\mathrm{RL}} & \tilde{\mathbf{D}}^{\mathrm{bb}}_{\mathrm{RL}} & \mathbf{0} & \tilde{\mathbf{S}}^{\mathrm{dd}}_{\mathrm{LR}} & \tilde{\mathbf{D}}^{\mathrm{ba}}_{\mathrm{RR}} & \tilde{\mathbf{S}}^{\mathrm{dd}}_{\mathrm{LL}} + \tilde{\mathbf{D}}^{\mathrm{bb}}_{\mathrm{RR}} \end{bmatrix} \begin{Bmatrix} \mathbf{u}^{\mathrm{a}}_{\mathrm{L}k} \\ \mathbf{u}^{\mathrm{b}}_{\mathrm{L}k} \\ \mathbf{u}^{\mathrm{c}}_{\mathrm{R}k} \\ \mathbf{u}^{\mathrm{d}}_{\mathrm{R}k} \\ \mathbf{u}^{\mathrm{a}}_{\mathrm{R}k} \\ \mathbf{u}^{\mathrm{b}}_{\mathrm{R}k} \end{Bmatrix}. \tag{28}$$

The displacements $\mathbf{u}^{\mathrm{a}}_{\mathrm{R}k}$ and $\mathbf{u}^{\mathrm{b}}_{\mathrm{R}k}$ are subsequently eliminated by taking the Schur complement of the coefficient matrix in equation (28). This results in the condensed dynamic stiffness matrix of the reference cell, which relates forces to displacements at the cell interfaces. This condensed dynamic stiffness matrix is used to compute the free wave characteristics of the reference cell by solving the eigenvalue problem (11). The dynamic stiffness matrices $\mathbf{S}_{\mathrm{n}}$ and $\mathbf{S}_{\mathrm{p}}$ of the semi-infinite parts to the left and the right of the reference cell are computed using equations (16) and (17).

2.2.2 Forced vibration response

In order to study the forced vibration response due to a moving load, the transfer functions between the force and receiver locations are required in the frequency domain. Since the force moves along the bridge deck, two cases are distinguished: (1) a force $\mathbf{p}$ applied to the interior DOFs of part a (figure 3a), and (2) a force $\mathbf{p}$ applied to the interior DOFs of part c (figure 3b).

In the first case (figure 3a), the force $\mathbf{p}$ is applied to the interior DOFs of part a. Hence, the dynamic stiffness matrix $\mathbf{D}_{\mathrm{ab}}$ of the union of parts a and b is used in the following. At the interface between parts a and b, and the semi-infinite part on the left, continuity of displacements ($\mathbf{u}^{\mathrm{c}}_{\mathrm{R}k-1} = \mathbf{u}^{\mathrm{a}}_{\mathrm{L}k}$ and $\mathbf{u}^{\mathrm{d}}_{\mathrm{R}k-1} = \mathbf{u}^{\mathrm{b}}_{\mathrm{L}k}$) and equilibrium of forces ($\mathbf{f}^{\mathrm{c}}_{\mathrm{R}k-1} + \mathbf{f}^{\mathrm{a}}_{\mathrm{L}k} = \mathbf{0}$ and $\mathbf{f}^{\mathrm{d}}_{\mathrm{R}k-1} + \mathbf{f}^{\mathrm{b}}_{\mathrm{L}k} = \mathbf{0}$) is imposed. Furthermore, at the interface between parts c and d, and the semi-infinite part on the right, continuity of displacements ($\mathbf{u}^{\mathrm{c}}_{\mathrm{R}k} = \mathbf{u}^{\mathrm{a}}_{\mathrm{L}k+1}$ and $\mathbf{u}^{\mathrm{d}}_{\mathrm{R}k} = \mathbf{u}^{\mathrm{b}}_{\mathrm{L}k+1}$) and equilibrium of forces ($\mathbf{f}^{\mathrm{c}}_{\mathrm{R}k} + \mathbf{f}^{\mathrm{a}}_{\mathrm{L}k+1} = \mathbf{0}$ and $\mathbf{f}^{\mathrm{d}}_{\mathrm{R}k} + \mathbf{f}^{\mathrm{b}}_{\mathrm{L}k+1} = \mathbf{0}$) is imposed. The continuity of displacements and equilibrium of forces between the substructures in the reference cell are expressed in equations (24) to (27). The force-displacement relations are given by the dynamic stiffness matrices defined in equations (16), (17), (21) and (23). Subsequently, the force equilibrium equations are combined in the following system of equations:

$$\begin{Bmatrix} \mathbf{0} \\ \mathbf{0} \\ \mathbf{p} \\ \mathbf{0} \\ \mathbf{0} \\ \mathbf{0} \\ \mathbf{0} \\ \mathbf{0} \end{Bmatrix} = \begin{bmatrix} \mathbf{S}^{\mathrm{cc}}_{\mathrm{n}} + \mathbf{D}^{\mathrm{aa}}_{\mathrm{LL}} & \mathbf{S}^{\mathrm{cd}}_{\mathrm{n}} + \mathbf{D}^{\mathrm{ab}}_{\mathrm{LL}} & \mathbf{D}^{\mathrm{aa}}_{\mathrm{LI}} & \mathbf{D}^{\mathrm{ab}}_{\mathrm{LI}} & \mathbf{D}^{\mathrm{aa}}_{\mathrm{LR}} & \mathbf{D}^{\mathrm{ab}}_{\mathrm{LR}} & \mathbf{0} & \mathbf{0} \\ \mathbf{S}^{\mathrm{dc}}_{\mathrm{n}} + \mathbf{D}^{\mathrm{ba}}_{\mathrm{LL}} & \mathbf{S}^{\mathrm{dd}}_{\mathrm{n}} + \mathbf{D}^{\mathrm{bb}}_{\mathrm{LL}} & \mathbf{D}^{\mathrm{ba}}_{\mathrm{LI}} & \mathbf{D}^{\mathrm{bb}}_{\mathrm{LI}} & \mathbf{D}^{\mathrm{ba}}_{\mathrm{LR}} & \mathbf{D}^{\mathrm{bb}}_{\mathrm{LR}} & \mathbf{0} & \mathbf{0} \\ \mathbf{D}^{\mathrm{aa}}_{\mathrm{IL}} & \mathbf{D}^{\mathrm{ab}}_{\mathrm{IL}} & \mathbf{D}^{\mathrm{aa}}_{\mathrm{II}} & \mathbf{D}^{\mathrm{ab}}_{\mathrm{II}} & \mathbf{D}^{\mathrm{aa}}_{\mathrm{IR}} & \mathbf{D}^{\mathrm{ab}}_{\mathrm{IR}} & \mathbf{0} & \mathbf{0} \\ \mathbf{D}^{\mathrm{ba}}_{\mathrm{IL}} & \mathbf{D}^{\mathrm{bb}}_{\mathrm{IL}} & \mathbf{D}^{\mathrm{ba}}_{\mathrm{II}} & \mathbf{D}^{\mathrm{bb}}_{\mathrm{II}} & \mathbf{D}^{\mathrm{ba}}_{\mathrm{IR}} & \mathbf{D}^{\mathrm{bb}}_{\mathrm{IR}} & \mathbf{0} & \mathbf{0} \\ \mathbf{D}^{\mathrm{aa}}_{\mathrm{RL}} & \mathbf{D}^{\mathrm{ab}}_{\mathrm{RL}} & \mathbf{D}^{\mathrm{aa}}_{\mathrm{RI}} & \mathbf{D}^{\mathrm{ab}}_{\mathrm{RI}} & \mathbf{D}^{\mathrm{aa}}_{\mathrm{RR}} + \tilde{\mathbf{S}}^{\mathrm{cc}}_{\mathrm{LL}} & \mathbf{D}^{\mathrm{ab}}_{\mathrm{RR}} & \tilde{\mathbf{S}}^{\mathrm{cc}}_{\mathrm{LR}} & \mathbf{0} \\ \mathbf{D}^{\mathrm{ba}}_{\mathrm{RL}} & \mathbf{D}^{\mathrm{bb}}_{\mathrm{RL}} & \mathbf{D}^{\mathrm{ba}}_{\mathrm{RI}} & \mathbf{D}^{\mathrm{bb}}_{\mathrm{RI}} & \mathbf{D}^{\mathrm{ba}}_{\mathrm{RR}} & \mathbf{D}^{\mathrm{bb}}_{\mathrm{RR}} + \tilde{\mathbf{S}}^{\mathrm{dd}}_{\mathrm{LL}} & \mathbf{0} & \tilde{\mathbf{S}}^{\mathrm{dd}}_{\mathrm{LR}} \\ \mathbf{0} & \mathbf{0} & \mathbf{0} & \mathbf{0} & \tilde{\mathbf{S}}^{\mathrm{cc}}_{\mathrm{RL}} & \mathbf{0} & \tilde{\mathbf{S}}^{\mathrm{cc}}_{\mathrm{RR}} + \mathbf{S}^{\mathrm{aa}}_{\mathrm{p}} & \mathbf{S}^{\mathrm{ab}}_{\mathrm{p}} \\ \mathbf{0} & \mathbf{0} & \mathbf{0} & \mathbf{0} & \mathbf{0} & \tilde{\mathbf{S}}^{\mathrm{dd}}_{\mathrm{RL}} & \mathbf{S}^{\mathrm{ba}}_{\mathrm{p}} & \tilde{\mathbf{S}}^{\mathrm{dd}}_{\mathrm{RR}} + \mathbf{S}^{\mathrm{bb}}_{\mathrm{p}} \end{bmatrix} \begin{Bmatrix} \mathbf{u}^{\mathrm{a}}_{\mathrm{L}k} \\ \mathbf{u}^{\mathrm{b}}_{\mathrm{L}k} \\ \mathbf{u}^{\mathrm{a}}_{\mathrm{I}k} \\ \mathbf{u}^{\mathrm{b}}_{\mathrm{I}k} \\ \mathbf{u}^{\mathrm{a}}_{\mathrm{R}k} \\ \mathbf{u}^{\mathrm{b}}_{\mathrm{R}k} \\ \mathbf{u}^{\mathrm{c}}_{\mathrm{R}k} \\ \mathbf{u}^{\mathrm{d}}_{\mathrm{R}k} \end{Bmatrix}. \tag{29}$$

The system of equations (29) can be further condensed, for instance by eliminating the displacements $\mathbf{u}^{\mathrm{c}}_{\mathrm{R}k}$ and $\mathbf{u}^{\mathrm{d}}_{\mathrm{R}k}$.

In the second case, the force $\mathbf{p}$ is applied to the interior DOFs of part c (figure 3b). Part c is divided in the loaded cell c_2 and two unloaded parts c_1 and c_3 consisting of N_{c_1} and N_{c_3} cells, respectively. The dynamic stiffness matrix of the loaded cell is denoted by $\mathbf{D}_{\mathrm{c}_2}$. The

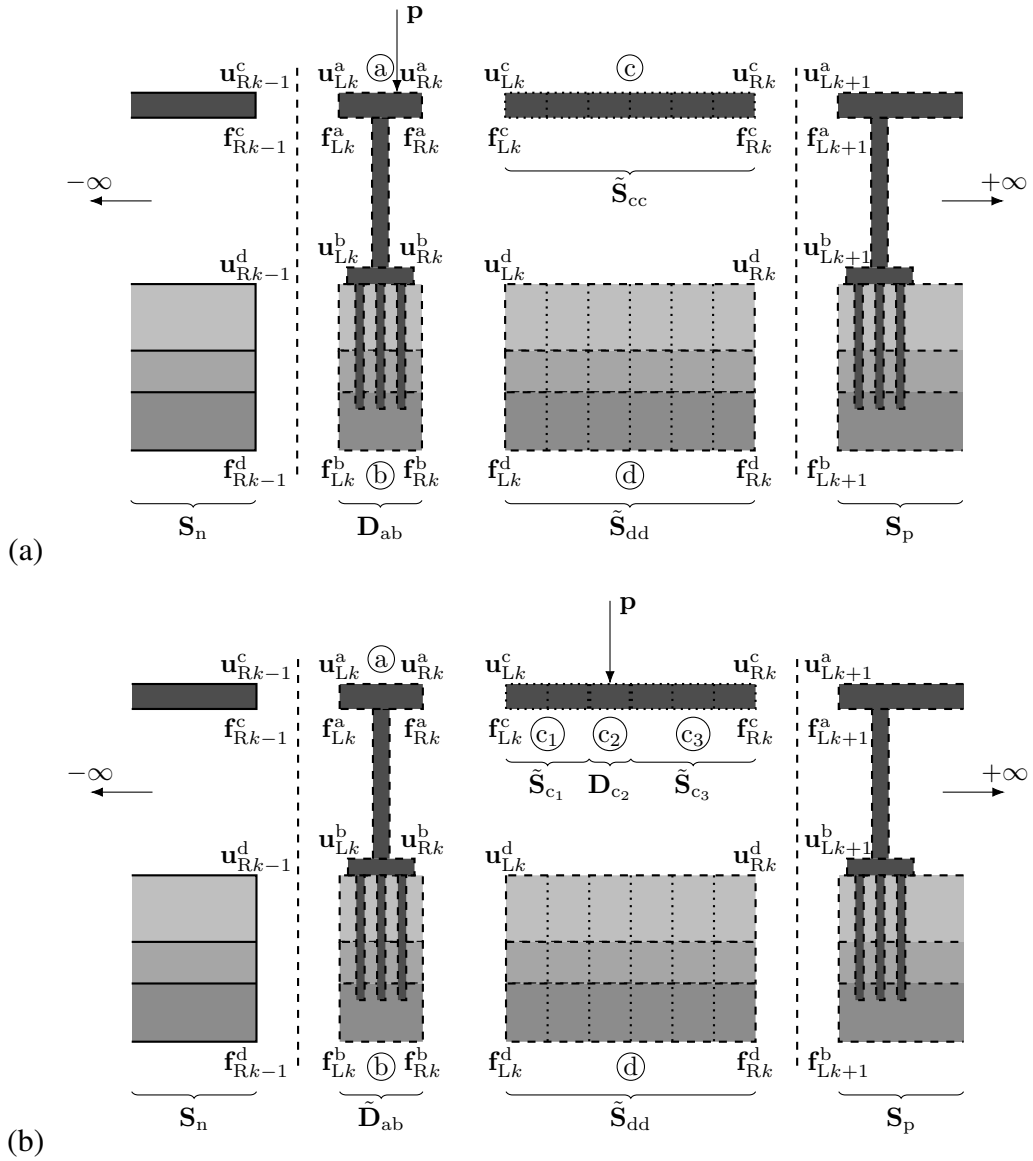

Figure 3: Force $\mathbf{p}$ applied to the interior DOFs of (a) part a, and (b) part c of the reference cell.

condensed dynamic stiffness matrices $\tilde{\mathbf{S}}_{\mathrm{c1}}$ and $\tilde{\mathbf{S}}_{\mathrm{c3}}$ of parts c_1 and c_3 are obtained from equation (20). The dynamic stiffness matrices of the substructures are now assembled into one global dynamic stiffness matrix by expressing continuity of displacements and equilibrium of forces on the interfaces between the substructures (as in the first case). Additionally, continuity of displacements is imposed between parts c_1 and c_2, and c_2 and c_3, respectively:

$$\mathbf{u}^{\mathrm{c}_1}_{\mathrm{R}k} = \mathbf{u}^{\mathrm{c}_2}_{\mathrm{L}k}, \tag{30}$$

$$\mathbf{u}^{\mathrm{c}_2}_{\mathrm{R}k} = \mathbf{u}^{\mathrm{c}_3}_{\mathrm{L}k}, \tag{31}$$

as well as equilibrium of forces:

$$\mathbf{f}^{\mathrm{c}_1}_{\mathrm{R}k} + \mathbf{f}^{\mathrm{c}_2}_{\mathrm{L}k} = \mathbf{0}, \tag{32}$$

$$\mathbf{f}^{\mathrm{c}_2}_{\mathrm{R}k} + \mathbf{f}^{\mathrm{c}_3}_{\mathrm{L}k} = \mathbf{0}. \tag{33}$$

The force-displacement relations are given by the dynamic stiffness matrices defined in equations (16), (17), (22) and (23), and the dynamic stiffness matrix $\mathbf{D}_{\mathrm{c}_2}$ of the loaded cell. Sub-

sequently, the force equilibrium equations are combined in the following system of equations:

$$\begin{Bmatrix} \mathbf{0} \\ \mathbf{0} \\ \mathbf{0} \\ \mathbf{0} \\ \mathbf{0} \\ \mathbf{p} \\ \mathbf{0} \\ \mathbf{0} \\ \mathbf{0} \end{Bmatrix} = \begin{bmatrix} \mathbf{S}_{\mathrm{n}}^{\mathrm{cc}} + \tilde{\mathbf{D}}_{\mathrm{LL}}^{\mathrm{aa}} & \mathbf{S}_{\mathrm{n}}^{\mathrm{cd}} + \tilde{\mathbf{D}}_{\mathrm{LL}}^{\mathrm{ab}} & \tilde{\mathbf{D}}_{\mathrm{LR}}^{\mathrm{aa}} & \tilde{\mathbf{D}}_{\mathrm{LR}}^{\mathrm{ab}} & \mathbf{0} & \mathbf{0} & \mathbf{0} & \mathbf{0} & \mathbf{0} \\ \mathbf{S}_{\mathrm{n}}^{\mathrm{dc}} + \tilde{\mathbf{D}}_{\mathrm{LL}}^{\mathrm{ba}} & \mathbf{S}_{\mathrm{n}}^{\mathrm{dd}} + \tilde{\mathbf{D}}_{\mathrm{LL}}^{\mathrm{bb}} & \tilde{\mathbf{D}}_{\mathrm{LR}}^{\mathrm{ba}} & \tilde{\mathbf{D}}_{\mathrm{LR}}^{\mathrm{bb}} & \mathbf{0} & \mathbf{0} & \mathbf{0} & \mathbf{0} & \mathbf{0} \\ \tilde{\mathbf{D}}_{\mathrm{RL}}^{\mathrm{aa}} & \tilde{\mathbf{D}}_{\mathrm{RL}}^{\mathrm{ab}} & \tilde{\mathbf{D}}_{\mathrm{RR}}^{\mathrm{aa}} + \tilde{\mathbf{S}}_{\mathrm{LL}}^{\mathrm{c_1}} & \tilde{\mathbf{D}}_{\mathrm{RR}}^{\mathrm{ab}} & \tilde{\mathbf{S}}_{\mathrm{LR}}^{\mathrm{c_1}} & \mathbf{0} & \mathbf{0} & \mathbf{0} & \mathbf{0} \\ \tilde{\mathbf{D}}_{\mathrm{RL}}^{\mathrm{ba}} & \tilde{\mathbf{D}}_{\mathrm{RL}}^{\mathrm{bb}} & \tilde{\mathbf{D}}_{\mathrm{RR}}^{\mathrm{ba}} & \tilde{\mathbf{D}}_{\mathrm{RR}}^{\mathrm{bb}} + \tilde{\mathbf{S}}_{\mathrm{LL}}^{\mathrm{dd}} & \mathbf{0} & \mathbf{0} & \mathbf{0} & \mathbf{0} & \tilde{\mathbf{S}}_{\mathrm{LR}}^{\mathrm{dd}} \\ \mathbf{0} & \mathbf{0} & \tilde{\mathbf{S}}_{\mathrm{RL}}^{\mathrm{c_1}} & \mathbf{0} & \tilde{\mathbf{S}}_{\mathrm{RR}}^{\mathrm{c_1}} + \mathbf{D}_{\mathrm{LL}}^{\mathrm{c_2}} & \mathbf{D}_{\mathrm{LI}}^{\mathrm{c_2}} & \mathbf{D}_{\mathrm{LR}}^{\mathrm{c_2}} & \mathbf{0} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \mathbf{0} & \mathbf{0} & \mathbf{D}_{\mathrm{IL}}^{\mathrm{c_2}} & \mathbf{D}_{\mathrm{II}}^{\mathrm{c_2}} & \mathbf{D}_{\mathrm{IR}}^{\mathrm{c_2}} & \mathbf{0} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \mathbf{0} & \mathbf{0} & \mathbf{D}_{\mathrm{RL}}^{\mathrm{c_2}} & \mathbf{D}_{\mathrm{RI}}^{\mathrm{c_2}} & \mathbf{D}_{\mathrm{RR}}^{\mathrm{c_2}} + \tilde{\mathbf{S}}_{\mathrm{LL}}^{\mathrm{c_3}} & \tilde{\mathbf{S}}_{\mathrm{LR}}^{\mathrm{c_3}} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \mathbf{0} & \mathbf{0} & \mathbf{0} & \mathbf{0} & \tilde{\mathbf{S}}_{\mathrm{RL}}^{\mathrm{c_3}} & \tilde{\mathbf{S}}_{\mathrm{RR}}^{\mathrm{c_3}} + \mathbf{S}_{\mathrm{p}}^{\mathrm{aa}} & \mathbf{S}_{\mathrm{p}}^{\mathrm{ab}} \\ \mathbf{0} & \mathbf{0} & \mathbf{0} & \tilde{\mathbf{S}}_{\mathrm{RL}}^{\mathrm{dd}} & \mathbf{0} & \mathbf{0} & \mathbf{0} & \mathbf{S}_{\mathrm{p}}^{\mathrm{ba}} & \mathbf{S}_{\mathrm{p}}^{\mathrm{ab}} + \tilde{\mathbf{S}}_{\mathrm{RR}}^{\mathrm{dd}} \end{bmatrix} \begin{Bmatrix} \mathbf{u}_{\mathrm{L}k}^{\mathrm{a}} \\ \mathbf{u}_{\mathrm{L}k}^{\mathrm{b}} \\ \mathbf{u}_{\mathrm{L}k}^{\mathrm{c}} \\ \mathbf{u}_{\mathrm{L}k}^{\mathrm{d}} \\ \mathbf{u}_{\mathrm{L}k}^{\mathrm{c_2}} \\ \mathbf{u}_{\mathrm{I}k}^{\mathrm{c_2}} \\ \mathbf{u}_{\mathrm{R}k}^{\mathrm{c_2}} \\ \mathbf{u}_{\mathrm{R}k}^{\mathrm{c}} \\ \mathbf{u}_{\mathrm{R}k}^{\mathrm{d}} \end{Bmatrix}. \tag{34}$$

This system of equations can further be condensed, for instance by eliminating the displacements $\mathbf{u}_{\mathrm{L}k}^{\mathrm{a}}$ and $\mathbf{u}_{\mathrm{L}k}^{\mathrm{b}}$.

3 CASE STUDY

In this section, the proposed methodology is demonstrated by computing the receptance of a floating slab track. The track properties are taken from Lombaert et al. [9].

Figure 4 shows the model of an infinitely long floating slab track. The track is symmetric in its cross-sectional plane. Hence, only one rail and half of the slab are modeled. The track consists of a UIC60 rail which is periodically supported by rail pads, which are modeled as spring-damper connections with stiffness $k_{\mathrm{r}} = 213.2 \times 10^6$ N/m and viscous damping constant $c_{\mathrm{r}} = 14.8 \times 10^3$ Ns/m. The slab with height $H = 0.55$ m and width $2B = 2.5$ m is made of concrete with a Young's modulus of 30 GPa, a Poisson's ratio of 0.25, a density of 2500 kg/m^3, and a hysteretic material damping ratio of 2%. The slab rests on a slab mat which is modeled as a continuous spring-damper connection with stiffness $K_{\mathrm{s}} = 15 \times 10^6$ N/m^3 and viscous damping constant $C_{\mathrm{s}} = 30 \times 10^3$ Ns/m^3. Multiplying K_{s} and C_{s} with B results in the stiffness $\bar{k}_{\mathrm{s}}$ and damping constant $\bar{c}_{\mathrm{s}}$ per unit length of the slab. The rail and the slab are modeled as Euler-Bernoulli beams consisting of n elements per periodic length $L = 0.6$ m. The external force $\mathbf{p}$ is a vertical unit harmonic point force applied to the rail at $y = 0$ m.

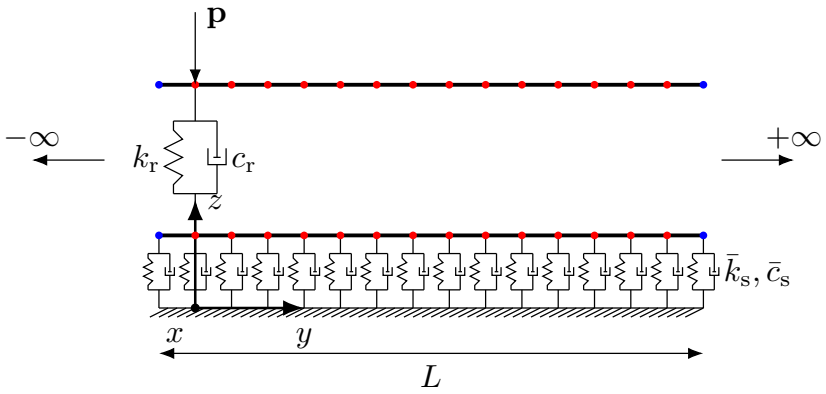

Figure 4: Model of one reference cell of the periodic slab track. The interface nodes are indicated in blue, while the interior nodes are indicated in red. The number of beam elements in the rail and slab is equal to n per length L. The external force $\mathbf{p}$ is applied to the rail at $y = 0$ m in the vertical direction.

Figure 5 shows the modulus and the phase of the vertical rail displacement at $y = 0$ m as a function of the excitation frequency. Figure 6 shows the modulus and the phase of the vertical

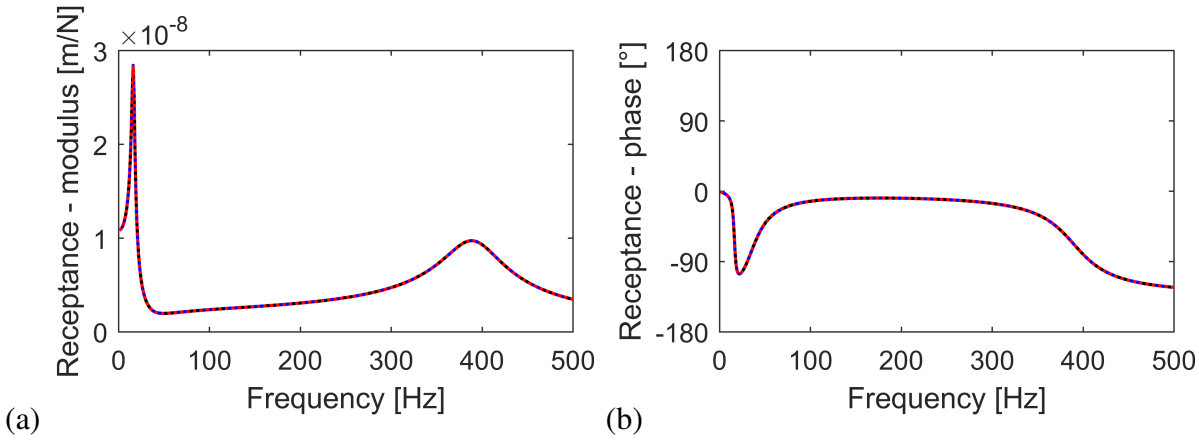

Figure 5: (a) Modulus and (b) phase of the vertical rail displacement at $y = 0$ m as a function of the excitation frequency computed with the Floquet transform method (black solid line), the classical WFEM (blue dashed line), and the adapted WFEM (red dotted line). The number of rail and slab elements in the FE model is $n = 10$.

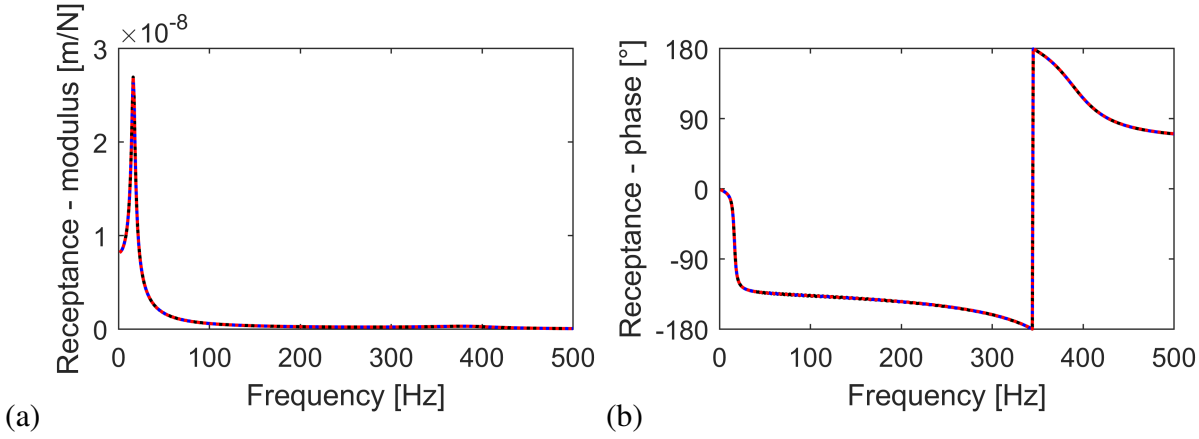

Figure 6: (a) Modulus and (b) phase of the vertical slab displacement at $y = 0$ m as a function of the excitation frequency computed with the Floquet transform method (black solid line), the classical WFEM (blue dashed line), and the adapted WFEM (red dotted line). The number of rail and slab elements in the FE model is $n = 10$.

slab displacement at $y = 0$ m as a function of the excitation frequency. Reference solutions are computed with (1) the classical WFEM and (2) the Floquet transform method. The frequency is sampled between 1 and 500 Hz with a frequency bin of 1 Hz, while the wavenumber κ_y in the Floquet transform method is sampled between $-\pi/L$ and π/L with a wavenumber bin of $\pi/(200L)$. The correspondence between the three methods is excellent over the entire frequency range. The resonance peaks correspond to the natural frequencies of a simplified 2DOF system of the periodic reference cell. The resonance of the rail and slab on the slab mat occurs at 16.3 Hz, while the resonance of the rail on the rail pads occurs at 393.1 Hz. In the low frequency range, the rail and slab move in phase and their amplitude is similar. In the high frequency range, the displacement of the slab reduces significantly and the system behaves as a rail on rail pads.

Table 1 gives an overview of the total computation time for each method with increasing number of elements n. It is observed that for the Floquet transform method and the classical WFEM the total computation time increases by increasing n. However, for the adapted WFEM the total computation time is unaffected, since the number of DOFs in parts a and b does not

increase by increasing n. For $n = 1000$, the computation time increases significantly for the classical WFEM. A breakdown of the computation time results in the following: 47% is required for the condensation of the dynamic stiffness matrix (equation (2)), while 44% is needed to solve the system of equations. For $n = 10$ on the other hand, the largest part of the total computation time is in the construction of the FE model and the computation of the free wave characteristics using equation (11). The computations for $n = 1000$ are not performed with the Floquet transform method.

	$n = 10$	$n = 100$	$n = 1000$
Classical WFEM	0.002	0.024	7.186
Adapted WFEM	0.003	0.003	0.003
Floquet transform method	0.091	14.842	-

Table 1: Comparison of the total computation time (in s) per frequency as a function of the number of elements n per length L. The results are not computed with the Floquet transform method for $n = 1000$.

Finally, it should be pointed out that the construction of a full FE model of the periodic reference cell is avoided in the adapted WFEM. This reduces memory requirements, which is a very important advantage when solving large-scale SSI problems.

4 CONCLUSIONS

An adapted wave finite element method is presented for structures consisting of two one-dimensional wavequides which are periodically coupled. The method exploits the periodicity of the waveguides between the coupling points to efficiently assemble the dynamic stiffness matrix of the entire periodic reference cell. In this way, the construction of a full FE model of the reference cell is avoided. The methodology is demonstrated by computing the response of a floating slab track. It is shown that the computational effort is significantly reduced. This is very promising for the solution of large-scale periodic soil-structure interaction problems such as railway bridges on piled foundations.

Abstract

During earthquake shaking, the dam-reservoir-foundation system has to be considered a coupled system. In this paper Soil-Structure Interaction (SSI) effect is investigated on a 2D plane model of a concrete gravity dam under earthquake excitation. Firstly, different approaches to simulate the unboundedness of soil domain are explored: the Perfectly Matched Layer (PML) technique, the Low Reflecting Boundary (LRB) condition and the Infinite Elements (IEs). Different options are compared in the time domain in the case of linear elastic material. The importance of taking into account the SSI in the seismic assessment of concrete dams is also highlighted by the energy balance during time. Successively, the effects of SSI are analysed on a full interacting nonlinear plane model. The results which are obtained in terms of material damage and dissipated energy through a parametric SSI simulation in the time domain show the importance of the choice of the damage constitutive law of the material.

Keywords: Gravity dams, Soil Structure Interaction, Perfectly Matched Layer, Low Reflecting Boundary, Infinite Elements, Time history analysis.

1 INTRODUCTION

The soil effects on the seismic behavior of buildings are seldom explicitly taken into account in finite element models. More often, in order to overcome the difficulties involved in modeling soil-structure interaction, code-provided response spectra depending on suitable soil categories are used. The particular characteristics of the retaining structures do not allow us to use the simplified methods which are commonly applied to ordinary buildings, so dam earthquake safety assessment requires the direct modeling of soil structure interaction.

Soil Structure Interaction is described to have two main components: kinematic and inertial interaction [1]. In the literature two contributions are relevant in approaching the problem of soil-structure interaction, those by Wilson [2] and Wolf [1]. Wilson describes the "massless foundation" method, basing on the consideration that the recorded ground motions are acquired at the terrain surface where the response has already experienced the effects of the soil. This model is governed by soil flexibility. The massless foundation model proposed by Clough in 1980 [3] has been extensively used in seismic analysis of dam-foundation problems. In this context, recorded displacements are imposed at the boundaries of the domain and the input motion reaches instantaneously the base of the dam disregarding the inertial interaction. In the massless model, the wave velocity in foundation becomes infinite, so the input motion reaches instantaneously the base of the dam and the structure takes all kinetic energy. These assumptions seem in general unrealistic [4].

Inertial interaction is generated by elastic waves that develop under dynamic loads, promoting the energy transport through the soil volume. Such a phenomenon that carries energy away from the structure is often referred as "radiation damping". So, while in static SSI analysis the simple truncation of the far field with setting of appropriate boundary conditions gives very often good results, in dynamic cases it makes results to be erroneous because of reflection waves.

The present paper addresses Soil-Structure Interaction (SSI) for existing concrete gravity dams, investigating its effects numerically on a 2D plane system under earthquake excitation. In order to simulate the unboundedness of soil domain, different modelling approaches are explored: the Perfectly Matched Layer (PML) technique [5], the Low Reflecting Boundary (LRB) condition [6] and the Infinite Elements (IEs) [7]. Moreover, the analysis in the time domain is performed in order to compare the response of the model in terms of base shear, using different modelling options. The energy balance during time shows the importance of modeling the SSI in the seismic assessment of concrete dams. The results in terms of base shear values for several modeling approaches are compared in order to highlight the differences among different modelling strategies.

Finally the effects of SSI are analysed on a full interacting nonlinear plane model with nonlinear material constitutive behaviour. The results in terms of material damage are obtained from a parametric SSI simulation in the time domain, in order to take into account the presence of soil beneath the dam.

The main contribution of this work is to compare different modeling strategies and to highlight the importance of SSI modelling for the evaluation of the seismic behaviour of concrete gravity dams.

2 MODELLING UNBOUNDED SOIL

Dam models seldom take into account full interaction effects, because of the lack of adequate numerical implementations or computational resources required by three dimensional detailed models. Recently, SSI for concrete retaining structures is addressed by many authors searching for a reliable simulation of wave propagation in a semi-infinite medium, modeling

the far field part of the foundation. The unboundedness of the terrain was first considered by Lamb [8] in its classical problem of a point load on a half space, for which he provided an analytical solution. Wolf [4], on the other hand, developed a formulation for appropriate spring-dashpot coefficients and boundary conditions. Some worth noting methods are Lysmer boundary conditions [6], hyperelements [9], infinite elements [10], [11], rational boundary conditions [12], boundary element method [13], scaled boundary element method [14] and high order non-reflecting boundary conditions [15].

In order to simulate the unboundedness of both solid and fluid domains, three different modeling options are explored in this work, the Perfectly Matched Layer (PML) technique, the Low Reflecting Boundary (LRB) condition and the Infinite Elements (IEs). PML have been widely used for simulating wave propagation in unbounded media to effectively avoid spurious wave reflections from the computational domain boundaries. This technique is able to absorb incident waves under any angle and frequency, preventing them from returning back to the medium after incidence to the model boundaries [16]. The procedure, which was first introduced by Berenger in 1994 [5], may be applied to different physical problems. It comes to a complex coordinate stretching of the domain to introduce a decay of the oscillation avoiding any reflection in the source domain, thus simulating a perfectly absorbing material. The rational scaling of PML is expressed by the following function of the dimensionless coordinate ξ [16]

$$f(\xi) = s \cdot \xi \left(\frac{1}{3p(1-\xi)+4} - \frac{i}{3p(1-\xi)} \right) \tag{1}$$

where p is the curvature parameter and s the scaling parameter.

Implementation of PML into most commercial FE software packages is performed only in the frequency domain, because the majority of the formulations in the time domain highly affect the computational time and resources.

IEs, which are used to incorporate unbounded domains into the finite element method, have a formulation similar to those of FEM, except for the infinite extent of the element region and shape function in one direction. IEs is based on a function which maps the global to the local coordinate system

$$f(\xi) = \frac{\xi}{\gamma - \xi} \Delta p \tag{2}$$

where Δp is the pole distance,

$$\gamma = \frac{\Delta s + \Delta p}{\Delta s} \tag{3}$$

and Δs is the scaled thickness [7].

Finally, the LRB condition is obtained by imposing a mechanical impedance on the foundation boundary of the model, following the equation

$$[T] \cdot n = -[D] \frac{du}{dt} \tag{4}$$

where u is the displacement vector, $[T]$ the stress tensor, n the unit vector of the boundary tangent plane, $[D]$ is the impedance matrix [17]

$$[D]=\frac{c_p+c_s}{2}[\mathbf{I}], \quad c_s=\sqrt{\frac{G}{\rho}}, \; c_p=\sqrt{\frac{K+4/3\,G}{\rho}} \tag{5}$$

where K is the bulk modulus of the soil, G the shear modulus, ρ the material's density and [I] the identity matrix.

3 A COMPARISON AMONG SSI MODELING STRATEGIES

Different modeling strategies are analyzed and compared in terms of resultant base shear force of a 2D plane strain system under earthquake excitation. The analyses are carried out in the time domain using COMSOL Multiphysics [18].
The dam and soil domains are modeled by applying the standard Solid Mechanics equations. Three different techniques which have been discussed above are used to simulate the unboundedness of the soil: the Perfectly Matched Layer (PML) technique, the Low Reflecting Boundary (LRB) condition and the Infinite Elements (IEs). The study in the time domain is performed on an Italian concrete gravity dam 65 meters tall, with a base of about 45 m, using four plane strain models, as shown in figure 1.
The reference model 1 simulates the dam on a rigid terrain. The solid mesh is composed by 453 default second-order serendipity elements and the displacements of the base nodes are restrained along both directions.
In this case, the basin was simulated by the added mass model [19].

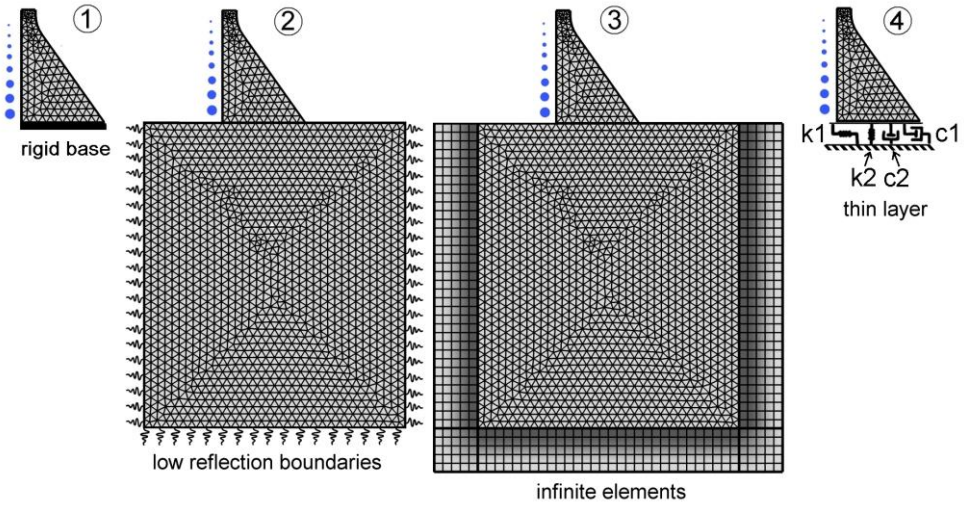

Figure 1. Different SSI modeling strategies for a plane strain model of an Italian dam.

The other three models account for massed foundation as an unbounded half-space.

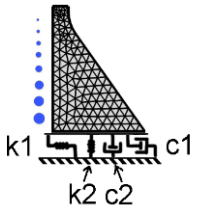
The second model simulates the dam with the soil equipped by low reflection boundaries. The solid mesh is composed by 3146 default second-order serendipity elements for both the soil and the dam. The low reflecting boundary condition is defined on the boundary of the soil domain. Its impedance parameter values derive from the elastic properties of the soil domain. The third model is similar to the second one, but in addition there are 550 infinite elements surrounding the physical soil region. The solid mesh is thus composed by 3696 default second-order serendipity elements. Infinite element pole distance is 400 m and the scaled thickness is $10^3 \cdot 400$ m.

The fourth model of fig. 1 simulates the unboundedness of the soil through the PMLs applied at the bottom and on the sides. Unfortunately, PML technique is not always available in

each program code or, if present, may not be compatible with time domain analyses. For this reason, a suitable 2D simplified model with horizontal and vertical springs and dashpots at the base was created in [20] to take into account the SSI by using tools and standard boundary conditions. Two viscous damping coefficients and two spring stiffness coefficients were calibrated in [20], starting from a model which is similar to that of case 2 of figure 1, but is equipped by PML boundary elements around the soil domain, instead of low reflecting boundaries. Calibration has been performed to provide the same resultant shear force at the base of the dam in the frequency domain for both models: a simplified model and the interacting 2D model with PML boundary condition. The result is that there is a set of coefficients which are capable to simulate SSI in terms of resultant shear force at the base of the dam. Their values are independent from the frequency in the range between 0 Hz and 25 Hz with good approximation and they are reported in table 1.

Table 1: Resulting parameters of the simplified model approximating the PML boundary technique.

parameter	[N/sqm]	[N·s/sqm]
k_1	8,6e+9 ± 1,1e+9	
k_2	9,7e+8 ± 9,3e+7	
c_1		3,6e+7 ± 2,3e+6
c_2		1.5e+7 ± 6,8e+6



The four models share the same plane-strain setting and material properties, whose values are reported in Table 2.

Table 2. Material properties which are assumed for the comparison among SSI modelling strategies.

Material property value	*Concrete*	*Foundation rock*
Density **ρ** *(kg/m^3)*	2450	2300
Young modulus **E** *(MPa)*	20500	22000
Poisson modulus **ν**	0.2	0.2
Damping coefficient ξ	0.05	0.05

In order to perform the analysis in the time domain for the fourth model of fig. 1, the Thin Elastic Layer boundary condition of COMSOL is applied at the base of the dam. It has both elastic and damping properties and can model a thin elastic layer with specified stiffness and damping properties.

The dynamic excitation which was used in the model belongs to one of the Italian strongest events occurred in the last 30 years, the earthquake of Central Italy of October 30th 2016 (06:40:17 UTC, 6.5 MW). It is the E-W component with about 7.8 m/sqs PGA, which was recorded by Savelli (PG) station [21] (Fig. 2). The duration of transient load is 30 s and the sampling is 5/1000 s.

The analysis has been carried out by assigning the seismic shaking in form of volume loads to the dam domain, in addition to the self-weight and the hydrostatic load. The results in form of base shear are reported in Fig. 3, where the graphs are overlapped. The similarity between the results obtained with the different modelling strategies for the semi-finite soil is remarkable, while a certain difference between these and the rigid case is noteworthy, although the heights of some main peaks remain quite unchanged.

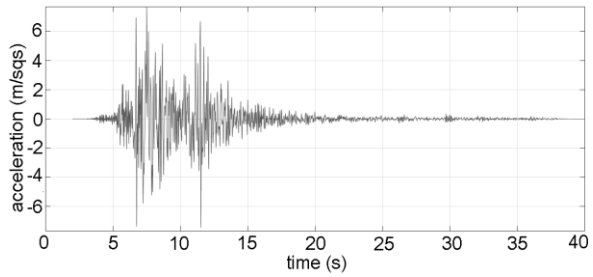


Figure 2. The acceleration time history recorded on October 30th 2016 by Savelli station (record 1).

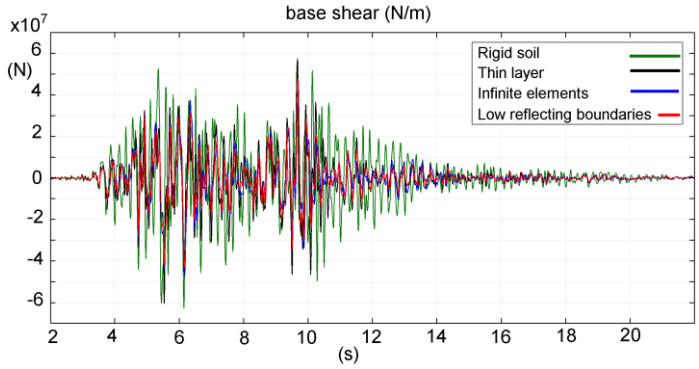

Figure 3. Base shear resultant force obtained from the transient analysis for the four different modeling options.

The FFT of the signal of Fig. 3 is reported in figure 4. The FFT graphs for the different modeling approaches substantially coincide except for the amplitude of some peaks, while, as expected, the graph of the rigid case shows higher peak frequencies and relative peak values.

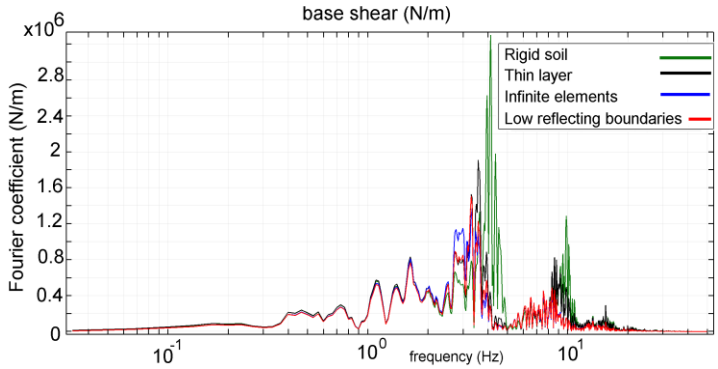

Figure 4. FFT of the base shear history for the different SSI modeling approaches.

Finally, in Fig. 5 the Root Mean Square value of the resultant base shear for different modeling options is displayed. Also this time, it may be observed that RMS values for the cases of thin layer, low reflection boundary and infinite elements are very similar to each other, while they substantially differ from the rigid base case. In addition, the models with IEs and LRB almost coincide.

The graph of the energy balance during the time history analysis on the model with LRB is displayed in Fig. 6. One can note that the most part of dissipated energy is radiated and the energy dissipated within both dam and soil material is about 45% of the radiated one. In its turn, the energy dissipated within the dam material only is about 70% of the energy dissipated within the solid domain. The contribution of radiation damping is therefore a no-negligible part of the total dissipated energy.

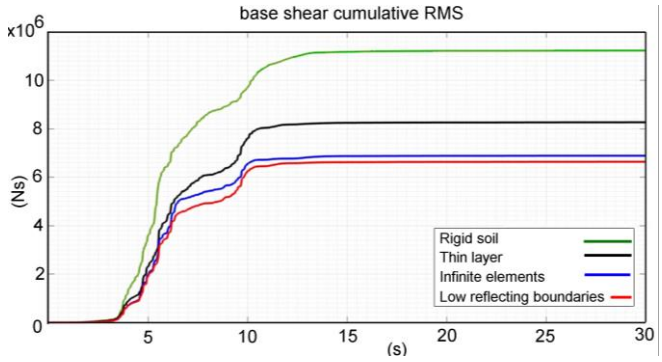

Figure 5. Base shear Root Mean Square value for different modeling options.

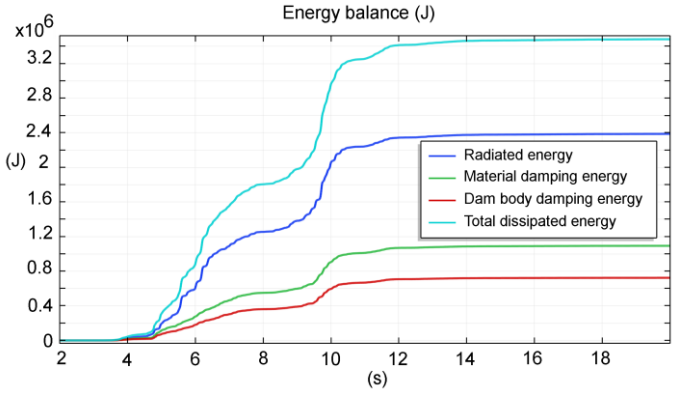

Figure 6. Energy balance (J) during the time history analysis for the LRB model.

4 SSI IN NONLINEAR 2D MODELS

In order to evaluate the effects of taking into account SSI in a more detailed nonlinear model, a 2D full interacting model was created in Abaqus r.6.14 [22]. It simulates a dam 55 m tall, with a base length of 40 m, in plane stress state. The soil domain dimensions are 260 m x 110 m and the reservoir level is 53 m high. The thickness of the plane model is 1 m.

The standard Solid Mechanics equations are applied to the dam and soil domains. The solid mesh is composed by 774 linear quadrilateral elements CPS4R for the soil domain and by 1149 linear triangular elements CPS3 for the dam domain. 79 infinite elements CINPS4 surrounding the soil domain allow one to simulate the soil unboundedness.

The fluid subsystem is simulated by the Helmoltz equation derived from the full Navier-Stokes equation, assuming small vibrations and neglecting viscosity. The mesh of the fluid domain is composed by 2912 linear triangular elements AC2D3.

As for the boundary condition for the fluid domain, a zero pressure condition is imposed at the free surface of the water and a rigid wall condition at the bottom of the reservoir. The fluid-structural interaction condition at the interface between the two domains is the following

$$\begin{cases} -\boldsymbol{n}\left(\frac{1}{\rho}\nabla\sigma\right) = -\boldsymbol{n}\cdot\boldsymbol{u}_{tt} \\ F_A = \sigma\cdot\boldsymbol{n} \end{cases} \tag{6}$$

where σ is the fluid pressure, $\boldsymbol{n}$ is the normal direction to the interface, F_A is the acoustic force on the structure and $\boldsymbol{u_{tt}}$ is the solid acceleration. The first equation transfers the structural acceleration to the fluid, while the second applies the fluid pressure load on the structure. Such a

system of equations expresses a *fully coupled* problem, where the solid and the acoustic parts have to be solved simultaneously.

In order to simulate the unboundedness of the fluid domain, an acoustic impedence in form of Improved Planar nonreflecting boundary condition was introduced at the upstream side of the fluid domain. The total number of elements within the model is 4914, whereas the total number of nodes is 3170.

The constitutive model selected for the dam is the Concrete Plastic Damage Model (CPDM) following the formulation proposed by Lee and Fenves [23], which uses the concepts of fracture-energy-based damage and stiffness degradation in continuum damage mechanics. In order to avoid mesh-dependency problem when simulating damage, a constitutive law formulation in terms of displacements was selected. The values of material properties are reported in table 2 and the parameters of the CPDM implementation in Abaqus [22] are reported in table 3 [24].

The seismic shaking of figure 1 was applied in form of displacement to 12 nodes of the base contour of the solid domain, once it was reduced with a scale factor of 0.6.

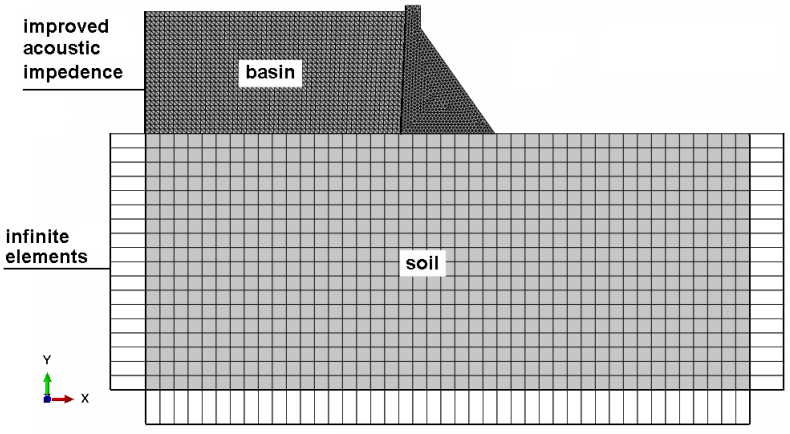

Figure 7. The model for nonlinear time history analysis.

Table 3. Parameters of the CPDM [22].

parameters for the concrete	
Dilation angle *(°)*	32
Flow potential eccentricity ε	0.1
σ_{b0}/σ_{c0} ratio of initial equibiaxial compressive yield stress to initial uniaxial compressive yield stress	1.16
Shape factor Kc	0.66
Compressive strength *(MPa)*	17
Tensile strength *(MPa)*	1
Fracture energy *(Nm)*	150

In order to apply the recorded seismic shaking to the base of the soil model, the deconvolution of the signal was performed through the algorithm of Sooch and Bagchi [24].

As a first evaluation on the SSI effects, one can wonder whether the interaction forces are able to change the basement motion as compared to the free-field ground motion (i.e. motion recorded on the free surface of the soil without structure). To this aim, in Fig. 8 the acceleration of a point on the soil surface near to the dam base (red dashed line) has been compared with the acceleration of the same point in a model that does not include the dam (black continuous line). In Fig. 9 the FFT of both signals is reported. One can note that the peak acceleration is higher in the free-field model. The FFT shows that the greatest amplifications of the

free-field model in respect to the model with dam take place in the interval between 5 Hz and 10 Hz, although the peak frequencies remain almost unchanged. It can be concluded that the interaction forces are able to considerably change the soil motion in this case.

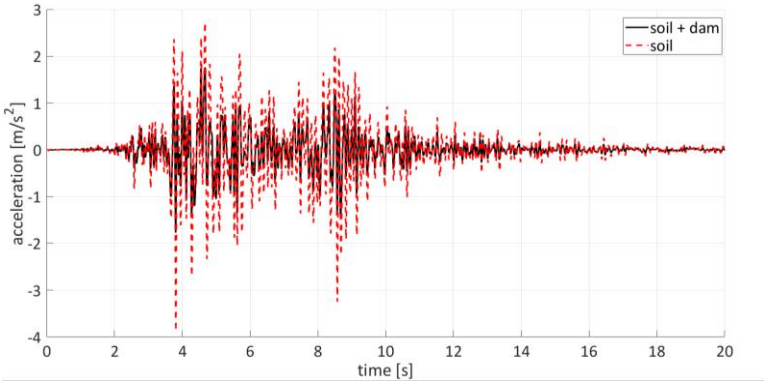

Figure 8. Acceleration history on a point of the soil surface for the model including the dam (red dashed line) and for the free-field model (black continuous line).

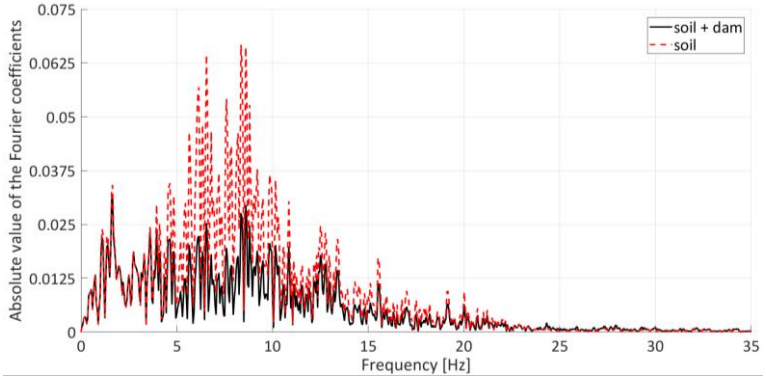

Figure 9. FFT of the signals of Fig. 8.

Another issue concerns the damaging mode of the dam after shaking when CPDM is used to simulate the material behaviour. In this regard, the influence of both soil density and damping ratio variation was investigated and the effects of different acceleration records applied to the model were explored.

As soil density seems to be a key parameter for SSI effects [20], it was varied in order to evaluate the damaged state of the dam after shaking. In Figure 10 the damage level after the seismic sequence is presented. The legend reports the values of the complement to unity of the ratio between damaged deformability modulus and undamaged one. Cracks begin on the upstream side and at the interface between dam and soil and develop downstream across the dam body. Two different soil density values are considered: the first is greater than the actual density of an order of magnitude and the second is near to zero. Figure 10 reports the damaged areas in the two extreme cases in comparison with the case with actual density. Despite the considerable variation in the soil density value, the influence in terms of material damage is not significant. One can conclude that there are no effects on the type and extent of damage as a result of the different or incorrect appreciation of the soil density value.

The influence of viscous damping can be evaluated for the full interacting nonlinear system in term of dissipated energy. Two different values for damping ratio were considered: $\xi = 1\%$ and $\xi = 5\%$. The energy balance was calculated in both cases. In figure 11 the dam body damping dissipated energy versus time is represented by a red line, the plasticity dissipated energy is indicated by a yellow line and the damage dissipated energy by a blue line.

One can note that in both cases the dissipated energy due to plasticity is of the same order of magnitude as the dam body damping energy, while material damage dissipates a very low energy amount in respect to the other two quantities.

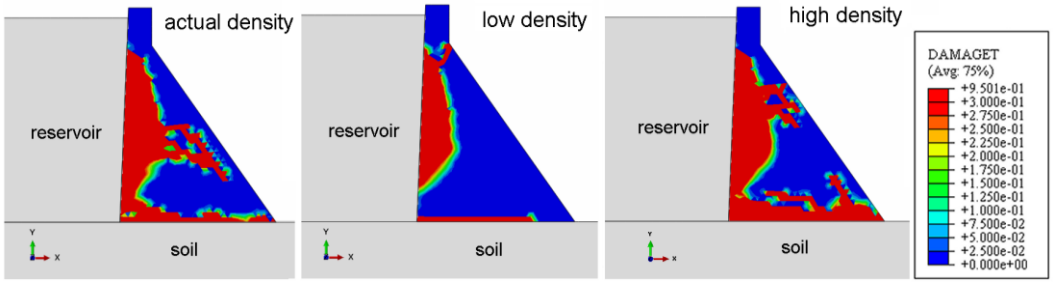

Figure 10. Damage on the dam, varying density.

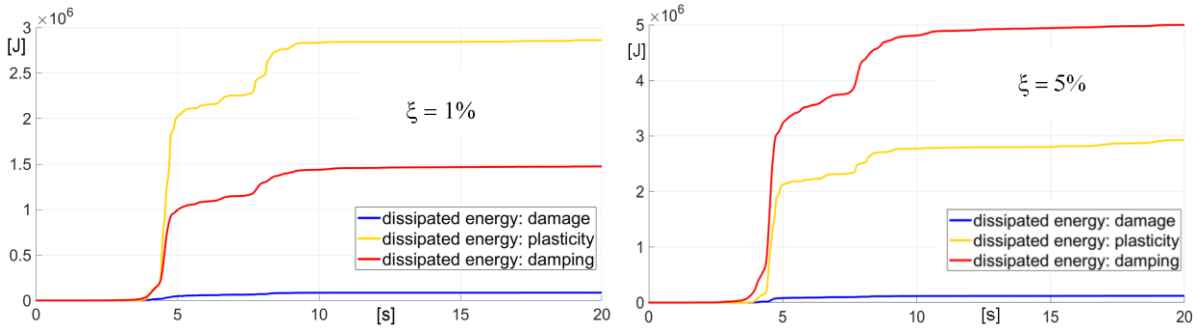

Figure 11: Dissipated energy for damage, plasticity and dam body damping for different values of ξ.

The effect of the type of seismic shaking was evaluated, in its turn, by comparing the damaged state after the shaking of October 30th 2016 (record 1) with that after the shaking of August 24th 2016 (record 2) in Central Italy (Fig. 12).

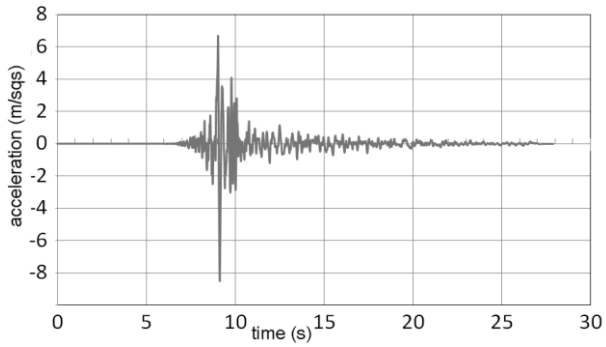

Figure 12. The acceleration time history recorded on August 24th 2016 by Amatrice station (record 2).

This latter, belonging to the seismic sequence of August 24th 2016 (03:36:32 UTC, 6 MW), is the E-W component recorded by Amatrice (RI) station [21] with about 8.5 m/sqs PGA. As in the previous case, it was reduced by 0.6 before being applied.

Resulting damage of the dam is displayed in figure 13 for both dynamic excitations applied at the base of the soil domain. For each record, the initial and final damage state are reported. The damaged state is different in the two cases both in the initial and in the final phase. In the case of record 1 and tensile strength of 1 MPa, cracks initiate from the upstream side of the dam, whereas in the second case, they initiate from the downstream side. Damage evolves in a very different way, as can be seen from the figures of final damage.

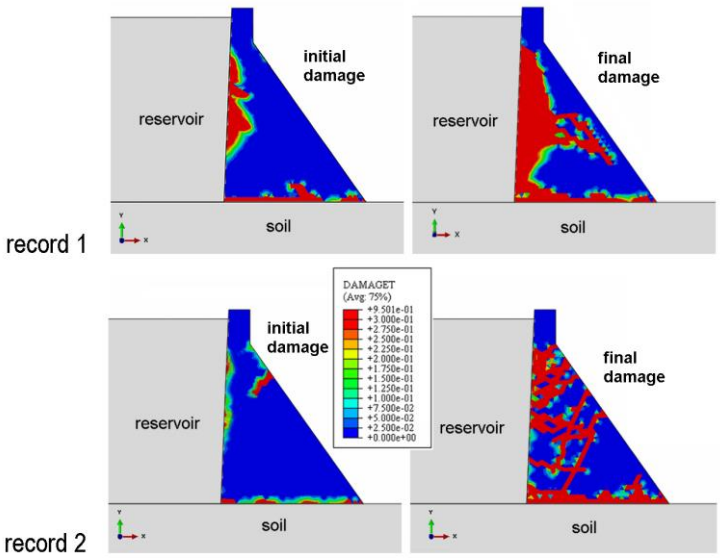

Figure 13: Damage of the dam during the shaking of October 30th 2016 (record 1) and August 24th 2016 (record 2).

5 CONCLUSIONS

We can conclude that different modelling strategies for simulating the soil unboundedness provide very similar results in terms of base shear force and dissipated energy. Moreover, the most part of dissipated energy is the radiated one, thus, the simulation of the unbounded soil appears very important.

When the material is nonlinear, the amount of dissipated energy due to plastic deformation has the same order of magnitude of the dissipated energy due to material damping. On the contrary, the energy that is dissipated by the material damage is particularly low. Hence, the assumption of plastic behaviour of the material could provide large consequences in terms of dissipated energy. Finally, the damaged state of the dam is not affected by the variation of soil density, nor by that of the material damping, but it is largely influenced by the frequency content of the shaking. In conclusions, in order to obtain reliable results, SSI modeling and the material damage law selection must be carefully considered.

Abstract

During the last couple of decades, it was recognized that the soil on which a structure is constructed might interact dynamically with the structure during earthquakes, especially when the soil is relatively soft and the structure is stiff. This kind of dynamic soil-structure interaction can sometimes modify significantly the stresses and deflections of the full structural system from the values that can be developed if the structure were designed on a rigid foundation. Two important characteristics that distinguish the dynamic soil-structure interaction system from other general dynamic structural systems are the unbounded nature and the nonlinearity of the soil medium. Generally, when establishing numerical dynamic soil-structure interaction models, the following problems should be taken into account.

Keywords: Seismic, Safety, Reliability, SSI, Nuclear Power Plants, ANSYS.

1 INTRODUCTION

After the accident of nuclear power plant (NPP) in Fukushima the IAEA in Vienna adopted a large-scale project "Stress Tests of NPP", which defines new requirements for the verification of the safety and reliability of NPP. Based on the recommendations of the ASCE standard and IAEA in Vienna [1- 3], the effective seismic resistance of objects is assessed in PGA sites up to 0.3g according to the "Seismic Margin Assessment" methodology (SMA) [1].

The required methodology was based on a reference earthquake (RLE) or a "Seismic Margin Earthquake" (SME) earthquake, which is an earthquake with seismological parameters of a given site and response spectrum at the free terrain level corresponding to 84.1% probability of non-elevation (median overs), including Peak Ground Acceleration (PGA) for a given acceptable annual occurrence probability (typically 10^{-4}/year). The dynamic soil-structure interaction can sometimes modify significantly the stresses and deflections of the structural system.

The building of the nuclear fuel storage VJP in the J. Bohunice is located near the NPP areal [4]. This building consists of a reinforced concrete and steel hall. The nuclear fuel storage capacities are located in seven modules by 7 meters (Fig.1). The dimensions of the object in the plan view are 58.8m.x.36m. The elevation of the building is designed asymmetrically from 14m to 30m. The building is based on a massive reinforced concrete slab with a thickness of 1.5m. The base joint is located at a depth of -6.5 m.

The design response spectra were prepared based on results of the PSHA (Probabilistic Seismic Hazard Analysis) study for the NPP J. Bohunice site developed by GFÚ SAV [4]. The value of the PGA for horizontal and vertical excitation for the annual occurrence probability (typically 10^{-4}/year) is following

- horizontal acceleration peak $PGA_{H.iRLE} = 0.250g$, $PGA_{H.RLE} = 0.367g$
- vertical acceleration peak $PGA_{V.iRLE} = 0.130g$, $PGA_{V.RLE} = 0.229g$

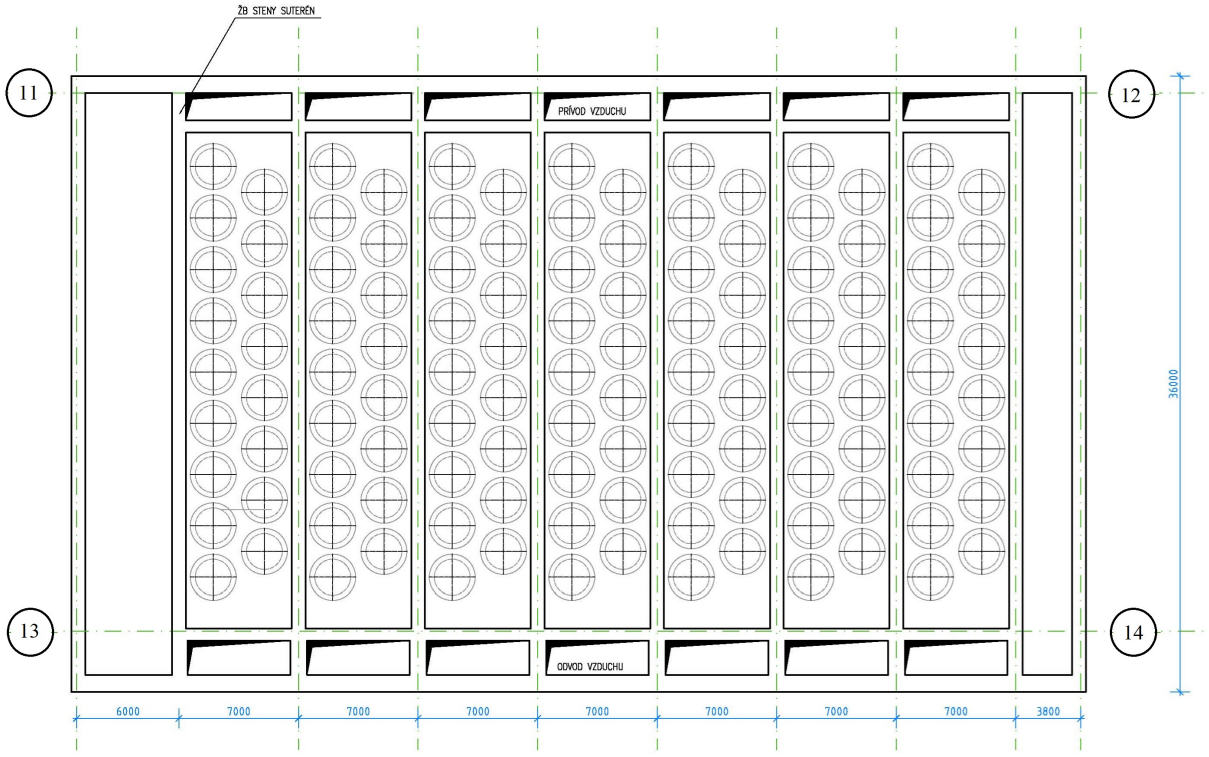

Figure 1: Ground floor basement of the nuclear fuel storage VJP SO841M_B-VT

The values of seismic motion (see Fig.2) for the nuclear fuel storage VJP are taken from the report of the Geophysical institute [4]. The horizontal and vertical response spectrum RLE are shown in the graphs. These spectra were used as inputs for generating a synthetic three-component accelerograms.

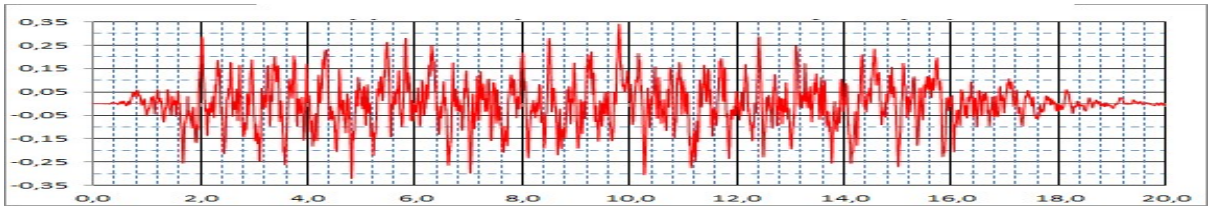

Figure 2: The spectrum compatible synthetic accelerogram.

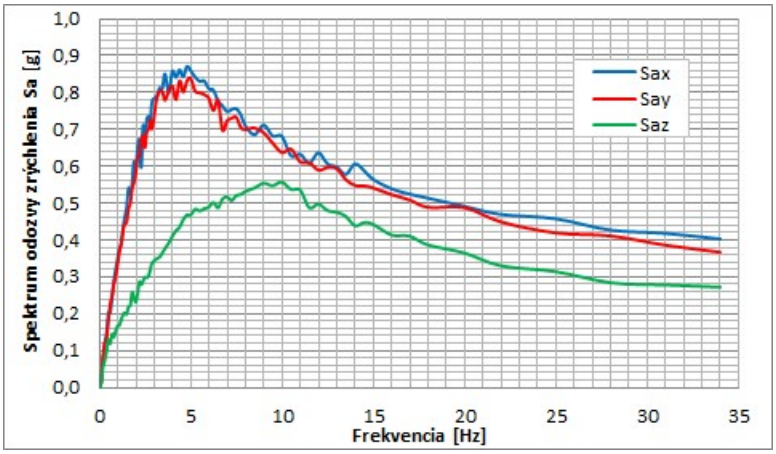

Figure 3: The response spectrum from the synthetic accelerograms in direction *X*, *Y* and *Z* for 5% damping

2 GEOPHYSICAL SUBSOIL PROPERTIES OF THE LOCALITY

For seismic analyzes, it was recommended to use the seismic assignment for the nuclear fuel storage VJP at J. Bohunice site according to data in the feasibility study.

Table 1: Geological profile under the building of the nuclear fuel storage VJP SO841M_B-VT

This seismic assignment corresponds to the results of the original seismological surveys (see Tab.1) based on the recommendations of the standards IAEA 50-SG-S1 and NS-G-3.3.

Dynamic soil characteristics were obtained with sufficient accuracy from the refractive and reflexive survey of a given site [3, 5, 6]. Depending on the propagation rates of the longitudinal and transverse waves in the soil, we can determine its physical characteristics.

The basic rigid parameter characterizing the earth body for dynamic calculations is the dynamic G_{dyn} (or Young's elastic modulus modulus)

$$G_{dyn} = v_s^2 \rho, \quad E_{dyn} = v_s^2 \rho 2\left(1+\nu_{dyn}\right), \quad \nu_{dyn} = \left(v_p^2 - 2v_s^2\right) / \left[2\left(v_p^2 - v_s^2\right)\right] \tag{1}$$

where ρ is the soil density, v_s - the velocity of the shear waves propagation in the respective earth (layer), v_p is the velocity of the longitudinal waves.

3 STIFFNESS AND DAMPING SOIL PARAMETERS IN THE SUBSOIL

Dynamic soil characteristics were obtained with sufficient accuracy from the refractive and reflexive survey of a given site [4]. Depending on the propagation rates of the longitudinal and transverse waves in the soil, we can determine its physical characteristics [3].

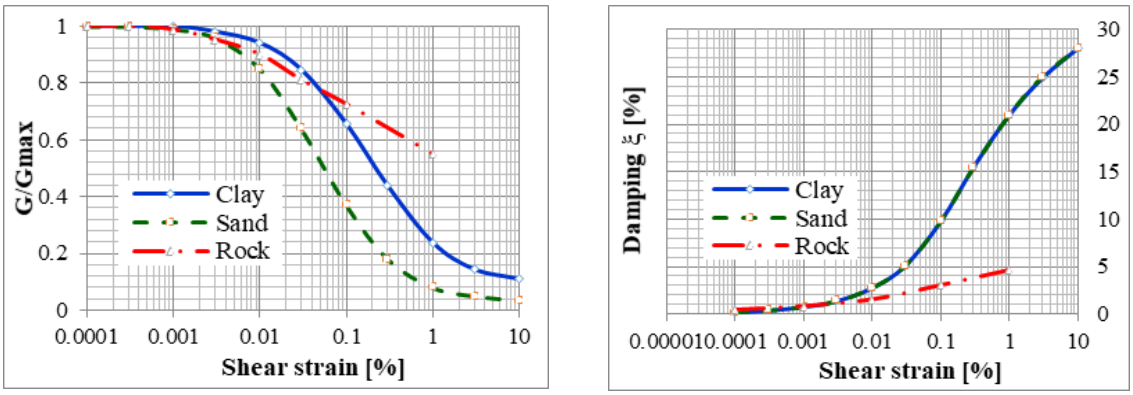

Figure 4: Shear modulus dependence on the shear strain and proportional damping.

In the case of earthquakes, there is a large movement of the soil, and because of plastic deformation, the value of the dynamic soil module also drops. According to the recommendations of international standards, this reduction will maximally reach 65% of the dynamic module measured for small seismic events. The process of the shear modulus and the damping can be seen in Fig. 4 depending on the shear strain [3].

4 SEISMIC HAZARD CONSIDERING SITE EFFECTS

The methodology for analyzing the influence of the layered subsoil of type 3 (for $v_s < 300$ m/s) according to the requirements of the IAEA NS-G-3.6 was used to define the seismic load for the nuclear fuel storage. The seismic load RLE was defined assuming that seismic waves are transformed from the source to the site in a rock bed (for $v_s > 1100$m/s).

Local design acceleration spectra were calculated considering the SSI effects used the SHAKESI program in accordance with the recommendations of the standards IAEA [2] and U.S. NRC.

Therefore, the methodology for calculating local design spectra is based on the following assumptions:

- PGA values for RLE seismicity were determined for the free field assuming the rigidity of the bed of the corresponding to the rock subsoil (for $v_s > 1100$m/s)

- The response spectrum acceleration for SL-2 [3] were defined based on a probabilistic analysis of the site effects,
- Synthetic 3D accelerograms compatible with response spectra were generated in accordance with the requirements [3].

Based on these input data, the calculation of local design spectra, taking into account the real geological composition at the location of the VJP object, is carried out in the following steps:

- Calculation of the synthetic accelerograms on the base at level -100m from the free level in accordance with IAEA [2] standards,
- Calculation of the local synthetic accelerograms and the design response spectra at level of foundation (-6.5m) and at level of the pile foundations (-18.5m) from the excitation synthetic accelerations using the program SHAKESI for original and modified geological conditions,
- Calculation of the smoothed design spectra at foundation level (-6.5m) and pile level (-18.5m) than the median values and the statistical envelope for 84.5% probability of failure is based on previous analyzes for characteristic excitation frequencies.

For these analyses, the modified SHAKESI [3] program was used to determine a best estimate of the transformation from free field to base level for the 1D model of the subsoil.

The amplification factors of the program SHAKESI are presented in the fig.5.

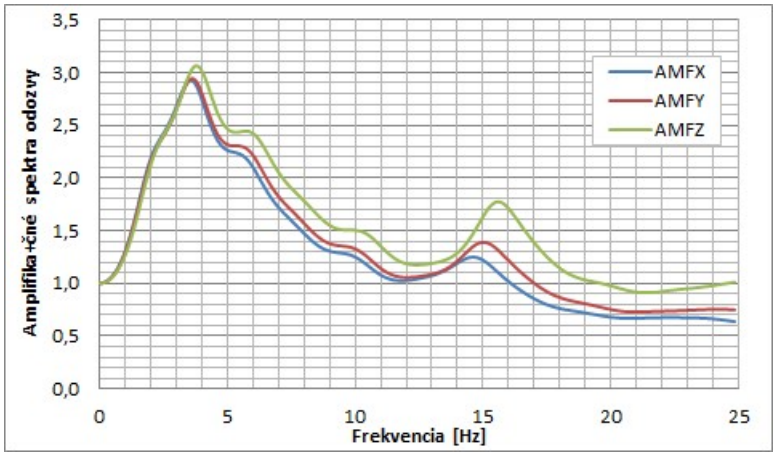

Figure 5: The amplification factors between the base and free field - SHAKESI

Acceleration response spectrum [m/s^2]

5 CONCLUSIONS

This paper describes the soil-structure interaction effects in the case of the nuclear fuel storage VJP during earthquake excitation. The methodology of the calculation of the soil-structure interaction effects was presented. The local design acceleration spectra were calculated considering the SSI effects used the SHAKESI program in accordance with the recommendations of the standards IAEA. The considering the local effects in accordance with the subsoil properties is very significant.

Abstract

Concrete-filled double skin steel tubular (CFDST) columns could be utilized in structures such as bridges, high-rise buildings, viaducts and electricity transmission towers due to its great structural performance. Alternatively, lean duplex stainless steel has recently gained significant interest for its high structural performance, similar corrosion resistance and lower cost compared to the austenitic steel grade. Hence, this paper presents nonlinear numerical simulations of rectangular outer lean duplex stainless steel (EN 1.4162) CFDST short columns under compression, based on the finite element (FE) method, The FE model and its validation were initially presented. Then, the effect of the key parameters that influence the behavior of these types of columns was introduced. Based on that model, the behavior and design of rectangular outer lean duplex stainless steel (EN 1.4162) CFDST short columns under compression were discussed. All classes of the outer rectangular hollow section according to the depth-to-thickness (D/t) ratios were considered. The results showed that the axial ultimate strength of rectangular CFDST short columns increased linearly by increasing the concrete compressive strength, while it does not influence when changing the hollow ratios. Finally, the axial capacities were compared with the available design methods, and recommendations were conducted for the design strength of this type of column. The presented design model, for calculation of the ultimate axial strength of rectangular CFDST short columns with external lean duplex stainless steel outer tubes, gave suitable conservative results if compared with the other literature model.

Keywords: Concrete-filled double skin columns, Finite element analysis, Ultimate axial strength, Short columns, Lean duplex stainless steel, Compressive strength.

1 INTRODUCTION

Steel-concrete composite columns represent a very attractive structural form that is now benefiting from extensive success. The composite construction ideally combines the advantages of both steel and concrete elements, where's the high strength and the light weight of steel combine the inherent mass, stiffness, damping, and economy of concrete [1, 2]. To reduce the weight of the structure while still maintaining a large energy absorption capacity against different loading cases, concrete-filled double skin steel tubular (CFDST) columns were suggested. With composite construction advantages, CFDST columns were recognized to have a series of beneficial properties, such as a good fire and seismic performance [3-6]. CFDST columns consist of concentric inner and outer steel tubes with infill concrete between them. The steel tubes are hollow structural sections, it may be supplied with carbon steel material, these sections can be circular (CHS) [3-9], square (SHS) [10] and rectangle (RHS) [11, 12].

On the other hand, Stainless steel materials have many advantages like the aesthetic appearance, high corrosion resistance, smooth and uniform surface, high fire resistance, high ductility and impact resistance, reuse and recycling capability. Due to these advantages many researchers [13-18] encouraged to investigate the behaviour of this material on the concrete-filled tubular columns with different cross-section, and motivated the authors to perform this study on the short concrete-filled double skin steel tubular (CFDST) stub columns with external stainless steel material as an introduction study of the long CFDST.

The austenitic stainless steels have been used for many years in structural applications as minor elements; see [19-21]. Due to the lower cost of lean duplexes compared with austenitic stainless steel, its applications are spread recently. However, most design codes [22-24] consider duplexes as the same design as austenitic stainless steels because the majority of the presented numerical and experimental results were for austenitic or duplex alloys as discussed by Gardner [19]. Many studies show that, the structural behaviour of stainless steel and carbon steel are differ, the main difference is that stainless steel has no definite yield strength, it has a round stress-strain curve, and shows an early departure from linear elastic behaviour with strong strain hardening [19-21]. The carbon steel has high proportional limit stress (at least 70% of the yield point) compared to stainless steel (from 36%- 60% of the yield stress) [25].

The rectangular sections are preferred when large major-axis bending moments occur in beam or beam–column. Based on the above background, the behaviour of rectangular CFDST short columns with external lean duplex tubes of Grade EN 1.4162 has never been studied. Hence, the present paper focuses on the behaviour and strength of short rectangular CFDST columns with external lean duplex tubes. The nonlinear analysis, behaviour and design of rectangular lean duplex stainless steel-concrete-carbon steel double skin tubular short (CFDST) columns were presented. The finite element (FE) model for CFDST short columns, were developed by using the general purpose finite element package ABAQUS [26]. Different classification of cross-sections of outer tubes; fully effective (F), slender (S) and very slender (VS) cross-sections were considered. The high and ultra-high strength concrete (HSC and UHSC) were also investigated for current rectangular CFDST short columns. The results were discussed and compared with the available design strength found in the literature.

2 NUMERICAL MODELLING

Nonlinear numerical simulations, based on the FE method and utilizing the software package ABAQUS/Standard [26], were made in this section to widen the available results on short rectangular CFDST columns which are not found in the literature. The FE model and its vali-

dation were initially presented. Finally, the effect of key parameters that influence the behaviour of these types of columns was discussed.

2.1 General description of FE model

A detail of the current FE model was previously presented in several papers published by the first author, such as [15-17]. The FE model can be summarized as following:

- Both inner and outer steel tubes were modelled using element S3 ABAQUS [26], S3 is a three-node triangular general-purpose shell element with finite membrane strains element.
- The sandwiched concrete and the two end plates were modelled by C3D4 ABAQUS [26], where C3D4 is a three dimensional four-node linear tetrahedron solid element.
- The initial imperfections were neglected in the FE modelling as previously discussed by Tao et al. [27]. Because of the reduction in strength of the thin-walled hollow tubes is not significant (about 1% in average) owing to the delaying effect of the concrete core on the tube buckling.
- The mesh size was chosen as approximately 25 mm for modelling the tubes and the sandwiched concrete.
- Interface between tubes and the sandwiched concrete was modelled by surface-based interaction with a contact pressure-overclosure model in the normal direction and a Coulomb friction model in the longitudinal direction; more details of interaction between surfaces were discussed by Hassanein et al. [15, 16].
- Only a quarter of the short rectangular CFDST columns were modelled, where's the geometry and the loads were symmetric, as shown in Figure 1 (a), in which the upper end plates at the loaded end were removed to illustrate the cross-section.

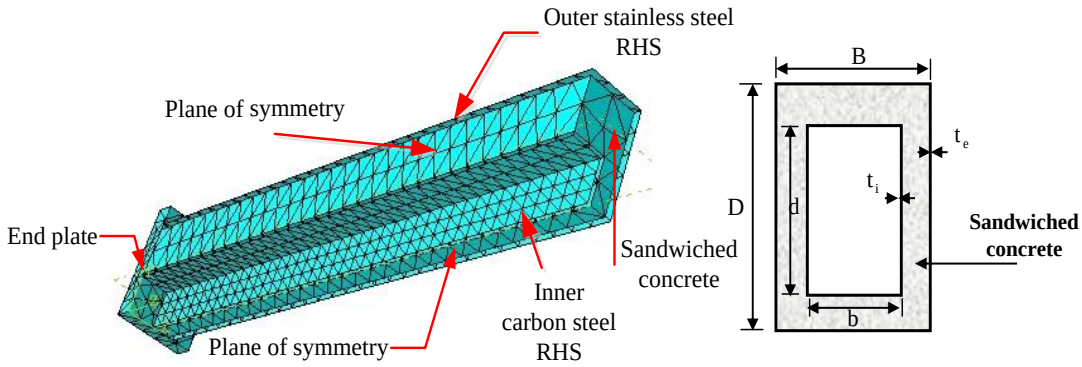

Figure 1(a). FE mesh of short rectangular CFDST column

Figure 1(b): Cross-section CFDST column

Figure 1: FE mesh and Cross-section of short rectangular CFDST column

2.2 Stainless steels material model

Lean duplex stainless steel Grade EN 1.4162 was used in this study with proof stress ($\sigma_{0.2}$) and ultimate strength (σ_u) of 530 MPa and 700 MPa, respectively according to EN 10088-4 [24]. The material behaviour can be modelled using a multi-linear stress-strain curve in ABAQUS [26], as shown in Figure 2; see Ref. [15, 18].

2.3 Carbon steels material model

The carbon steel tube with steel grade S235 material was used. According to EN 1993-1-1 [28], S235 has a minimum yield (f_{sy}) of 235 MPa, an ultimate strength (f_{su}) of 360 MPa and the Young's modulus of E_0 = 210 GPa. A von Mises material with isotropic hardening was used for modelling the steel material. The bilinear elastic-plastic stress-strain curve with linear strain hardening was used to model the steel material.

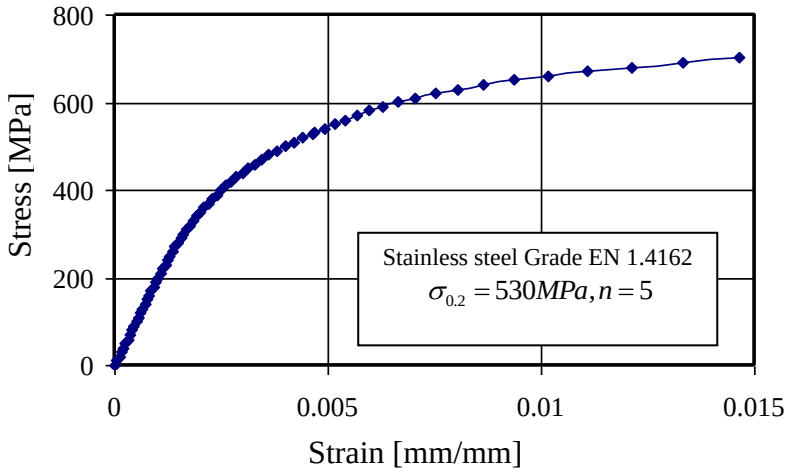

Figure 2. Stress-strain curve of the lean duplex stainless steel material Grade EN 1.4162

2.4 Sandwich concrete material model

The confinement of concrete by steel tube occurred at the four corners of the rectangular CFST column. This confinement does not have a considerable effect on the compressive strength of the concrete core so that it can be ignored in the analysis and design of rectangular CFST columns, as studied by Patel et al. [29]. In spite of that, the ductility of the concrete core in rectangular CFST columns was improved and was included in the presented concrete model, as discussed by Liang [30] and Patel et al. [29].

2.5 Validation of the FE model

2.5.1 CFDST short columns with both carbon steel tubes

To assess the accuracy of the generated FE models, the validity of the current FE model is made in this section. First, the model was verified by the behaviour of carbon rectangular CFDST short axial columns tested by Tao et al. [12]. A short specimen of a rectangular cross-section of CFDST short axial column was given in Figure 1 (b). Two replicate tests for this specimen were tested. The details of the specimens' simulation are given in Table 1, where D, B and t_e are the depth, width and thickness of the outer square tube, and d, b and t_i are the depth, width and thickness of the inner square tube respectively. Second, additional simulation to validate the FE model was developed, the model was used to predict the behaviour of square tubes CFDST short axial columns with inner circular tubes tested by Han et al. [31]. The comparison between the current FE ultimate strengths ($P_{ul,FE}$) and the experimental results ($P_{ul,Exp}$) is listed in Table 1. The mean value of $\frac{P_{ul,FE}}{P_{ul,Exp}}$ is 0.96 with a coefficient of variations of 0.043.

Figure 3 (a) shows a comparison between the experimental and FE load-axial strain curve for the rectangular CFDST column tested by Tao et al. [12]. Also, Figure 3 (b) shows a com-

parison between the experimental specimens tested by Han et al. [31] and FE load-axial strain curves of sample results of square CFDST columns with circular inner tubes presented by the first author with the same model [10]. It can be observed that the FE model gives good predictions for the ultimate load and axial load-strain curves for the short CFDST columns with both square and rectangular cross-sections.

2.5.2 Short columns with external stainless steel tubes

In this subsection, the verification of the FE model to simulate the behaviour of stainless-steel tubes was assessed. The developed FE model was used to predict the behaviour of square and rectangular hollow section (SHS and RHS) short columns with the lean duplex stainless steel tubes, tested by Theofanous et al. [32]. Table 2 presents the dimensions and material properties of these columns. The ultimate axial loads and end shortening at the ultimate load of SHS and RHS columns obtained from the finite element analyses were compared with the test data in Table 3. The FE model yields good predictions of both ultimate loads (P_{ul}) and end shortening at the ultimate load (δ_u) of SHS and RHS columns. The mean values of $\frac{P_{ul,FE}}{P_{ul,Exp}}$ and $\frac{\delta_{u,FE}}{\delta_{u,Exp}}$ are 0.98 and 0.95 with a coefficient of variations of 0.019 and 0.042, respectively. Figure 3 (c) shows the comparison of predicted FE and experimental results with respect to the load-axial strain relationships for SHS and RHS columns with a lean duplex stainless steel tubes. It can be concluded that the FE model gives good predictions for the behaviour of axial load-strain relationships compared with the tested specimens.

On the other hand, other verifications were made by the first author on circular CFDST short columns tested by Han et al. [14] with external stainless steel tubes and inner carbon tubes [17].

3 PARAMETRIC STUDY

The verified FE model was used to generate parametric results for short rectangular CFDST columns. The length of the column (L) was taken as three times the external depth (D) of the outer rectangular hollow section (RHS) to avoid global buckling effects. Table 4 shows the dimensions of the current cross-sections considered in this study. The material properties were considered as discussed in sections 2.3 to 2.5. The outer RHSs were classified into three groups (G1, G2 and G3) based on the maximum depth-to-thickness ratios for the compression parts of the cross-sections $(D-2t_e)/t_e$ according to EC3 Part 1.4 [24]. The first group (G1) was fully-effective (F: $(D-2t_e)/t_e \leq 30.7$), and the second group (G2) was considered as slender sections (S: $(D-2t_e)/t_e > 30.7$); $\varepsilon = \sqrt{235/f_{ye}}$. Finally, the value of $(D-2t_e)/t_e$ exceeded the maximum value of 52ε for group 3 (G3) as specified in EC4 [33], hence these cross-sections were considered to be very slender (VS). It worth pointing out that, in the current paper, the inner tubes were selected to have full-effective cross-sections.

The cylinder strength (f'_c) of the concrete and the hollow section ratio ($\chi = \sqrt{\frac{b*d}{(B-2t_e)*(D-2t_e)}}$) were considered as the key parameters in the analyses. The values of f'_c ranging from 25 MPa to 120 MPa, covering the normal strength (NSC), high strength (HSC) and ultra-high strength concrete (UHSC) according to the EC4 [33] in each group. The values of the hollow section ratio (χ) are 0.34, 0.54 and 0.66 in each group. The ultimate axial loads of the current model were given in Table 4.

The failure mode of short rectangular CFDST column presented in Figure 4. The failure local buckling mode was observed clearly in the outer tube than the inner one. An outward local buckling failure mechanism of the outer tube was observed, this behaviour is similar to that observed by Tao et al. [11, 12] in CFDST specimens. A separation of the tube from the concrete core was noticed.

Group	Column	Outer tube				Inner tube				f'_c [MPa]	χ	$\frac{t_i}{t_e}$	$P_{u,FE}$ [kN]

4 EFFECTS OF THE KEY PARAMETERS (f'_c & χ)

In this section, the effect of the cylinder strength (f'_c) of the concrete was discussed, as well as the hollow section ratio (χ) on the behaviour of the rectangular CFDST short columns. The effects of the key parameters on the axial load-strain relationships and the ultimate axial strength ($P_{u,FE}$) were provided.

4.1 Effects of concrete compressive strengths

To study the influence of the concrete compressive strengths (f'_c) on the behaviour of axial rectangular CFDST short columns, the compressive concrete strengths varied between 25 and 120 MPa, so that the current investigation includes normal strength concrete (NSCs) (25 and 40 MPa), high strength concrete (HSCs) (60 and 80 MPa) and ultra-high strength concrete UHSCs of 100 and 120 MPa EC2 [29]. Table 4 shows that increasing in the f'_c values of the sandwiched concrete increases the compressive strength of the rectangular CFDST short columns with full-effective, slender and very slender sections of outer stainless steel tubes for the same hollow ratio.

The relationship between the load and axial strain for sample results was provided in Figure 5. It can be concluded that, the increase in the concrete compressive strength (f'_c) caused increment in the ultimate axial strength of rectangular CFDST short columns in an almost linear manner as shown in Figure 6. Also, it was found that by increasing the concrete compressive strength the initial stiffness is nearly the same. Moreover, the CFDST short columns have favorable ductile behaviour.

4.2 Effects of hollow ratio

The effect of the hollow ratio (χ) on the ultimate axial strength ($P_{u,FE}$) of rectangular CFDST short columns under axial compression was studied for fully effective, slender and very slender sections, as shown in Figure 7. For the same concrete compressive strength (f'_c), it can be observed that, changing of the values of the hollow ratio has minimum effects on the ultimate compressive strength ($P_{u,FE}$). This can be explained, as the hollow ratio increases the area of sandwich concrete decreases, and the strength remains nearly the same due to the increase in the area of the inner tube, which raises the strength and covers the decrease caused by the concrete.

5 DESIGN STRENGTH

A comparison of the FE strengths ($P_{u,FE}$) generated in the parametric study, the ultimate axial strength predicted according EC4 (P_{EC4}) [33] and AISC specification (P_{AISC}) [34] proposed for short stainless steel CFDST columns are discussed here.

Based on the design model proposed by Hassanein et al. [17] and developed by the same authors [15, 16], For determining the ultimate axial strength of short stainless steel CFDST columns, a new modified model was suggested for the rectangular (CFDST) specimens based on the current parametric study, whereas the proposed ultimate axial strength ($P_{ul,Prop}$) can be calculated as the summation of the component strength, as follow:

$$P_{ul,Prop} = \gamma_{ss}\sigma_{0.2}A_{se} + f_c'A_{sc} + \gamma_s f_{yi}A_{si} \quad (1)$$

where A_{sc}, A_{se} and A_{si} are the cross-sectional area of the sandwiched concrete, gross sectional area of the external and internal steel tube respectively, f_{yi} is the yield stress of the inner steel tube. γ_{ss} and γ_s are factors to consider the effects of strain hardening as given by Liang [30] and Hassanein et al [15-17], which can be calculated as follow:

$$\gamma_{ss} = 1.62\left(\frac{D}{t_e}\right)^{-0.1} \quad (\gamma_{ss} \le 1.2) \quad (2)$$

$$\gamma_s = 1.458\left(\frac{d}{t_i}\right)^{-0.1} \quad (0.9 \le \gamma_s \le 1.1) \quad (3)$$

Note that, for slender and very slender section, the gross sectional area of the external tube (A_{se}) is calculated as the effective cross-sectional area ($A_{se,eff}$). The effective cross-sectional areas ($A_{se,eff}$) of the external steel tubes were calculated by using EN 1993-1-5 [35] while the reduction factor ρ should be taken according to Eurocode 3 Part 1.4 [24].

$$\rho = \frac{0.772}{\overline{\lambda}_p} - \frac{0.125}{\overline{\lambda}_p^2} \text{ but } \le 1 \quad (4)$$

where; $\overline{\lambda_p}$ is the element slenderness defined as: $\overline{\lambda_p} = \frac{\bar{b}/t}{28.4\varepsilon\sqrt{k_\sigma}}$.

t is the relevant thickness, $k_\sigma$is the buckling factor corresponding to the stress ratio ψ and boundary conditions from Table 4.1 or Table 4.2 in EN 1993-1-5 [35].

A comparison of the FE strengths generated in the parametric study and predicted strengths were listed in Table 5. From Table 5, it can be observed that the average values of $\frac{P_{EC4}}{P_{ul,FE}}$ $\frac{P_{AISC}}{P_{ul,FE}}$, and $\frac{P_{ul,Prop}}{P_{u,FE}}$ are 0.82, 0.87 and 0.90 with standard deviations of 0.046, 0.095 and 0.031, respectively. Hence, the strength predictions using $P_{ul,Prop}$ are therefore recommended for short rectangular CFDST columns with an external lean duplex stainless steel outer tubes.

6 SUMMARY AND CONCLUSIONS

The main objective of this paper was to examine the behaviour of short rectangular concrete-filled double-skin tubular (CFDST) columns with external lean duplex stainless steel tubes. External rectangular hollow sections (RHSs) with different local slenderness (i.e. fully-effective, slender and very slender cross-sections) were considered. From this paper, the following conclusions can be drawn:

- Increasing in the cylinder strength values of the sandwiched concrete increases linearly the compressive strength of the rectangular CFDST short columns with full-effective, slender and very slender sections of outer stainless steel tubes for the same hollow ratio.
- Changing the values of the hollow ratio has minimum effects on the compressive strength of the rectangular CFDST.
- It was observed that the design strength of EC4 is high conservative compared with both the AISC and the proposed design method based on design method found in literature.
- The design strength of AISC and the proposed method gave suitable conservative results but the AISC has the highest standard deviation.
- Hence, the proposed design model was recommended to use for the prediction of the ultimate axial strength of rectangular CFDST short columns with external lean duplex stainless steel outer tubes which is suitable for all classifications of cross-sections under axial loading.

Abstract

The analysis of steel constructions for their seismic design is commonly based on structural models including just the main frame members and relevant connections, while cladding panels are considered only in evaluating the seismic mass. Exceptions to this common approach can be found in a few studies available in the literature. A recent contribution was presented on the cladding damage under seismic input, as well as on the role of cladding panels in the overall seismic response of single-storey steel buildings. The results pointed out that claddings might have an important role on seismic response and should not be neglected in a refined finite element model. Starting from the available previous studies, the current work contributes in terms of both methodology and results. Regarding the methodology, a multi-criteria approach adopted for evaluating damage to cladding panels is reviewed and its applicability is discussed based on the results of a probabilistic study performed via multiple-stripe analyses. Regarding the results, a case study designed according to the Eurocodes and the recent 2018 Italian National Building Code is analysed with the aim of investigating the influence of cladding panels with non-symmetric plan distributions, which introduce torsional effects even if the structural elements have a symmetric configuration.

Keywords: Cladding, Non-structural damage, Serviceability limit state, Steel structures.

1 INTRODUCTION

The analysis of steel constructions for their seismic design is commonly based on structural models where only beams, columns, and braces contribute to the seismic response, while cladding panels are considered in the overall seismic mass but are not included as components explicitly influencing the structural behaviour [1][2]. Few exceptions to this common approach can be found in the literature with studies involving the following aspects: (i) development of nonlinear cyclic models for cladding panels to be included in advanced models incorporating structural and non-structural elements; (ii) design of cladding panels as structural elements providing bracing functions; (iii) analysis of the influence of the cladding panels on the structural response under seismic conditions as compared to the results obtained when only beams, columns, and braces are considered in the model definition; (iv) analysis of the seismic damage that cladding panels undergo through explicit modelling of their response as component of the structural model. A review of the state of the art on such topics can be found in Scozzese et al. [3]. Attention is here focused on the latter two aspects, i.e. cladding panels are included in the structural model with two objectives: 1) evaluate their influence on the simulated seismic response, and 2) estimate their damage under seismic excitations.

Previous studies on single-storey steel buildings [3][4] pointed out that claddings have an important role on the seismic response and should not be neglected in a refined finite element model. Starting from the obtained outcomes [3], the current study contributes in terms of both methodology and results. Regarding the methodology, the multi-criteria approach proposed in [5] for reinforced concrete frames and used in [3] for the evaluation of the damage to the cladding panels is reviewed and its applicability is discussed. Regarding the obtained results in the description of the development and extent of non-structural damage, comparisons are made between two sets of a case study designed according to the Eurocodes [6][7] and the recent 2018 Italian National Building Code [8]. Specific attention is given to the investigation of the influence of cladding panels with non-symmetric distributions in plan, not previously evaluated in [3].

2 METHODOLOGY FOR ASSESSING NON-STRUCTURAL DAMAGE

2.1 Methodology review

According to the European [6][7] and Italian [8] seismic codes, the assessment of non-structural damage of buildings is conventionally pursued by monitoring global response quantities, such as the interstory drift. The main limit of this conventional approach is represented by the lack of an explicit relationship with the actual level of deformation of the non-structural elements, whose behaviour is not explicitly considered during seismic analyses, and the relevant lack of the description of the interactions between structural and non-structural elements. In this study, following former investigations [3][4], the damage evaluation of the non-structural elements is pursued through their inclusion in the structural model, thus, allowing an explicit estimation of their local seismic demand. A direct comparison with the outcomes achieved by means of a global drift-based approach applied to the conventional analysis of bare-frame models allows comparing the results of the proposed methodology to the results of the conventional code-based damage verifications.

Multi-criteria approach for the assessment of the Damage Limit State

In order to assess the onset of the Damage Limit State (DLS), a multi-criteria approach was adopted. Specifically, a three-level local damage criterion [3] was proposed to characterize

the attainment of the DLS of buildings: (1) low-damage level: a percentage of panels exceeds the elastic response limit (a 50% value is considered in this study); (2) medium-damage level: the totality of panels is beyond the elastic field; (3) strong-damage level: at least one panel exceeds its maximum shear resistance. A global condition is added besides the three-level local damage criterion, i.e. attainment of the 95% of the maximum base shear force resistance of the whole structural system, in order to consider cases where significant structural damage might occur before the development of damage in non-structural elements, as discussed in [3][4].

DLS fragility functions

A probabilistic unconditional approach [9], i.e., based on the Intensity Measure (IM), is used for the fragility functions estimation at the DLS. In particular, the widely used Multiple Stripe Analysis (MSA) method [10][11] is adopted to build the conditional demand model $P(D|IM) = P[D > d \mid IM = im]$, providing information about the probability that a given response quantity D exceeds a certain threshold value *d* characterising the attainment of given limit state (focus of this study is on DLS), conditional to different levels of seismic intensity, as described by specific values of IM. The seismic hazard curve is discretized in 10 intensity levels corresponding to the following return periods (expressed in years): 10, 50, 100, 250, 500, 1000, 2500, 5000, 10000, 100000. The spectral pseudo-acceleration $S_a(T_1)$ at the system period T_1 is assumed as IM. The seismic record-to-record variability is accounted by using a set of 20 pairs (two horizontal seismic components) of ground motion time-histories for each IM level. Further details about the adopted seismic records and related scale factors can be found in [12][13].

A simplified method based on pushover analyses is proposed for identifying the limit values (*d*) corresponding to the DLS attainment, in which the roof drift ratio is assumed as response quantity for the aim of the present work. The whole methodology used for estimating the fragility functions can be summarised through the following four steps: (1) Pushover analyses are performed separately along the two orthogonal directions (X, Y); (2) The control node displacements (nodes located at the roof level) corresponding to the attainment of all of three local damage conditions defined above (i.e., low, medium and strong damage) are evaluated and the corresponding drift ratios identified; (3) Nonlinear time-history analyses are performed within the probabilistic context of MSA; (4) A set of fragility functions is provided by comparing the roof drift ratios monitored during time-history analysis (for all of the ground motions and for different IM values) with the limit values identified via pushover analysis.

Non-structural element modelling approach

A class of lightweight sandwich panels widely used as enclosure elements in both industrial and civil constructions is considered in this study. In particular, the type A panels tested by De Matteis and Landolfo [14] were adopted. The panels consist of external embossed steel sheets (thickness of 0.6 mm) with slight stiffening ribs and insulating polyurethane core, for a total thickness of 40 mm. The connection of panels to the main structural frame is made through cladding rails (for vertical cladding panels) or purlins (for roof panels) by means of bolts (generally of 8 mm in diameter and 110-120 mm spacing) [14].

Each panel was modelled by means of a couple of diagonal truss elements with nonlinear axial behaviour following the Pinching4 model, able to catch the main features of the shear-

displacement experimental response of cladding panels typically used in steel constructions [14][15]. Further details about the Pinching4 implementation can be found in [3][4][16].

For the purposes of the present investigation, the Pinching4 model was calibrated based on the experimental results available from cyclic shear loading tests performed on individual units of panel type A, having size of 1000 mm × 2500 mm × 40 mm. The backbone curve for the panel at hand is schematically represented in Figure 1a, superimposed to the envelope of the experimental cyclic response. It consists of a trilinear model characterized by: a yielding point at 12 kN (d = 20 mm), a hardening behaviour until the maximum shear of 17 kN (d = 80 mm), and a gradual softening branch where the force drops to zero at d = 320 mm. The simulated quasi-static nonlinear response is shown in Figure 1b.

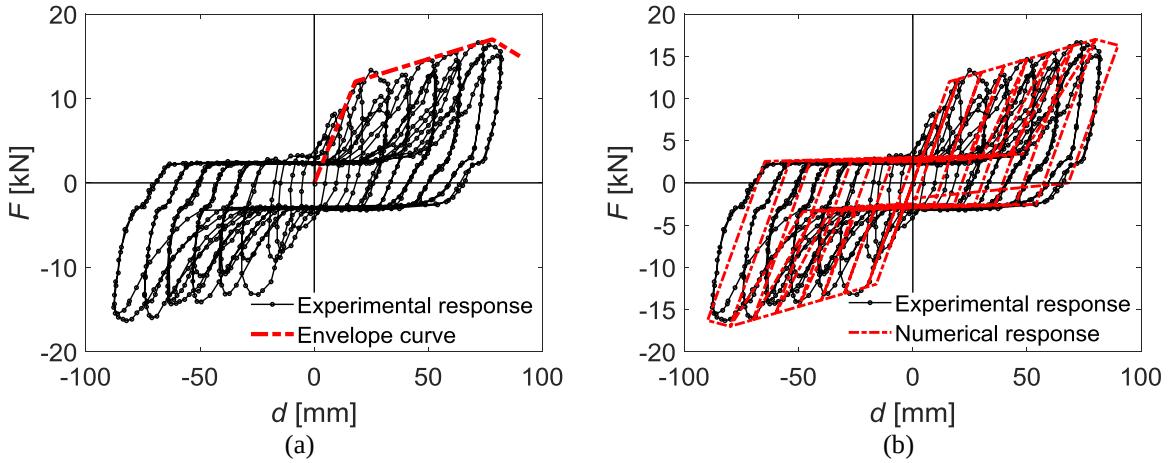

Figure 1: (a) Cyclic envelope curve of a panel unit and (b) experimental vs. numerical cyclic response.

It is worth noting that the panel type A presented above is not used as individual unit within the buildings, but panel assemblies are adopted, made of a number of single panels varying according to the specific geometric configuration of the structural system. To cope with that, the equivalent truss model calibrated for the single panel is extended to simulate the nonlinear contribution of whole panel assemblies, and this is done by making the following hypothesis: (i) the presence of several adjacent panels is accounted by increasing the strength and the stiffness of each pair of truss elements by a factor equal to the number of panels, i.e. the actual number of panels, which can also be a fractional number (this assumption is consistent with the condition of panels working in parallel); (ii) the presence of multiple rows of panels along the height is accounted by following the analogy of a system working in series, according to which the displacements of Ns rows of panels are Ns times larger than those of a single row, while the stiffness of the whole system is reduced by a factor equal to 1/Ns; (iii) the presence of concentrated openings is accounted by introducing a reduction factor equal to 0.5 for both stiffness and strength of the truss elements; (iv) the cladding panels are assumed not connected side by side. For sake of clarity, according to the assumption discussed above, a panel assembly located within a structural field with length 6 m and height 4.5 m will have strength and stiffness respectively 6 and 3.3 times higher than a single panel.

2.2 Applicability and open problems

The methodology as presented in the previous section was used in [3] to evaluate the intensity and extent of non-structural damage in steel buildings with cladding panels with symmetric distributions in plan in a high seismic hazard area in Italy (L'Aquila). On the other hand, in

the present work focus is made to the evaluation of the intensity and extent of non-structural damage in steel buildings with cladding panels with symmetric as well as non-symmetric distributions in plan in a medium seismic hazard area in Italy (Naples). Specifically, two different panel distributions are considered: perfectly symmetric along both X and Y directions; with asymmetric distribution along the X direction, as thoroughly discussed in the following section 3 of this article.

Moreover, the effect of the choice of the control node used to evaluate the drift ratio is analysed. This is an aspect of high relevance for the type of buildings herein investigated, characterized by the absence of a rigid diaphragm at the roof level. This implies that differential movements are not restraint among the frames, and, thus, the choice of the nodes with respect to which the drifts are computed might affect the outcomes. The relevance of this matter is further amplified by the consideration of panels with asymmetric distribution that introduce torsional effects even if the structural elements have a symmetric configuration.

3 CASE STUDY

3.1 Geometry and structural design

The considered case study is composed of five single span duo-pitch portal frames repeated in the longitudinal direction at a constant distance. The frames are connected in the longitudinal direction by hot-rolled beams at the apex, at the eaves and at the crane-supporting bracket level. A three-dimensional view of the structural system is presented in Figure 2. The transverse X-direction has its abscissa labelled with the letters A and B, the longitudinal Y-direction has its ordinates labelled with numbers. Horizontal forces are withstood by two different structure typologies: in the X-direction the resistance to lateral forces is due to moment resisting action of the portal frames, i.e. moment resisting frames (MRFs); in the Y-direction the resistance is provided by vertical concentric bracings, i.e. concentrically braced frames (CBFs), placed in the outer spans. The same geometry was considered in in the case studies analysed in [3][4][16] and a detailed description of its structural configuration, considered loading conditions, and general design approaches, can be found in [16].

The considered case study is located in Naples, soil type C, topography condition T1 [7][8]. The transverse bay width is L_x = 20.00 m, the longitudinal bay width is L_y = 6.00 m, the height at the eaves is H = 6.00 m, and the height of the crane-supporting bracket (measured at top surface of the bracket) is H_c = 4.50 m. The roof pitch is equal to 6°. Purlins are used to support the roof cladding and are positioned every 2.5 m. Roof bracings are arranged in the outer bays to transfer horizontal forces to the vertical bracings. Steel grade is S275.

The presence of a travelling overhead crane was considered as illustrated in details in [16]. Variable environmental loads (snow, wind, thermal actions) and seismic loads were determined accordingly to the Italian code prescription for the considered site [8]. Following the current European and Italian seismic code [7][8], the design model assumed that horizontal forces can be resisted by tension-only diagonal braces, i.e. the contribution of the compression diagonals to the lateral force resistance was neglected at the design stage. Equivalent geometric frame imperfections were included in the design according to the simplified approach suggested by the Italian code [8] and described in [16]. The roof purlins were modelled as simple spanned between two consecutive frames. All the columns were modelled as hinged at their base.

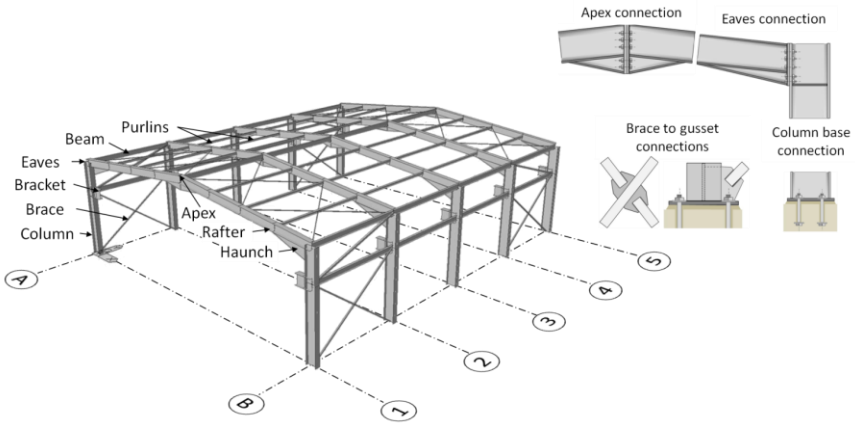

Figure 2: View of the steel structure of the considered case study.

Two different seismic designs were made by assuming a dissipative structural behaviour: 1) ductility class medium (DCM) of Eurocode 8 [7], providing a behaviour factor q = 4 for both the moment resisting frames and the frames with concentric braces; 2) ductility class high of the 2018 Italian Code [8] (indicated in the code as CD"A"), providing a behaviour factor q > 4 for the moment resisting frames and q = 4 for the frames with concentric braces. While it was assumed q = 4 for both designs and the same results were attained for the moment resisting frames (Table 1), a ductility requirement of the 2018 Italian Code [8] enforce a width-to-thickness ratio smaller than or equal to 18 for the box cross section of braces, leading to different brace designs. Efforts were made to select cross sections for the braces to reduce as much as possible the difference in resisting areas; inevitably the other inertial properties present large variations, as indicated in Table 2.

Element	Eurocode design	Italian code design
Column	HE 600 M	HE 600 M
Rafter	HE 450 A	HE 450 A
Vertical X braces	60x2	50x3
Vertical single brace	90x2.6	70x4
Longitudinal beam	IPE 270	IPE 270
Purlins	HE 160 A	HE 160 A
Roof bracings	L 20x3	L 20x3

Table 1: Designed cross section for the considered case study.

Property	60x2	50x3	90x2.6	70x4
Width b (mm)	60.00	50.00	90.00	70.00
Thickness t (mm)	2.00	3.00	2.60	4.00
Area A (mm^2)	450.30	554.00	885.70	1040.00
Inertia moment I (mm^4)	248300	202000	1112000	746000
Gyration radius i (mm)	23.48	19.10	35.43	26.78
b/t	30.00	16.67	34.62	17.50
Ductility class	1	1	2	1

Table 2: Comparisons of the properties of the designed brace sections.

Serviceability limit state verifications for the horizontal displacements of the portal frame for the characteristic combination of loads was limited to $\Delta_i/H=1/300$. For the damage limitation limit state (SLD), the horizontal drift was limited to 1/200. The difference of horizontal deflection between two consecutive portal frames, Δ_{ij}/L_y, was also checked to not exceed 1/200 [16].

3.2 Nonlinear finite element model and analysis

The nonlinear response of the case study was investigated using the finite element open source software OpenSees [17] including both geometric and material nonlinearities. All the structural elements were modelled using nonlinear fibre sections with nonlinear behaviour assigned to each section fibre using the Steel02 constitutive law (Giuffré-Menegotto-Pinto steel material object with isotropic strain hardening) available within the OpenSees libraries. Attention was given to the following aspects of the vertical brace modelling: description of the buckling phenomenon in compression; proper modelling of the gusset plate connections that in real structures are neither pinned nor fixed joints. The method followed for modelling the bracings is that proposed by Hsiao [18][19] and consisting in simulating the nonlinear out-of-plane rotational behaviour of the gusset plate connections by means of a rotational nonlinear spring located at the physical end of the brace. Details of the nonlinear finite element model of the structural elements can be found in [3][4]. Material parameters are considered as deterministic, being the evaluation of the influence of model uncertainties beyond the scope of this study. Studies involving response sensitivity analysis to material parameters, either using direct differentiation or finite difference strategies, e.g. [20][21], could be considered in possible future developments. Further information on model uncertainties can be found in [4] where the methodology illustrated in [22] was adopted.

Modelling of panels in OpenSees was made through couples of nonlinear truss elements adopted to reproduce the contribution of groups of assembled panels belonging to different structural fields. As already discussed, for each truss element, the Pinching4 uniaxial material available in the OpenSees library was adopted to simulate the nonlinear cyclic behaviour of the panel assembly, and the experimental results provided in [14][15] were used to calibrate the parameters required. The presence of concentrated openings was accounted by a reduction factor equal to 0.5 to both the stiffness and the strength of the truss elements. Details of the nonlinear finite element model of the non-structural elements can be found in [3][4].

MSA at 10 IM levels (with IM chosen to be the spectral pseudo-acceleration at the fundamental period of the system) were carried out, by using a set of 20 X-Y-pairs of ground motions for each IM level in order to simulate the seismic record-to-record variability, as already discussed. More details at this regard can be found in [3][4][13][16].

3.3 Numerical results

As previously introduced, the present work considers the influence of cladding panels with non-symmetric distributions in plan. Two different panel distributions are considered: 1) distribution with perfect symmetry along both X and Y directions (Figure 3a); 2) asymmetric distribution along the X direction, i.e., with cladding panels located within one extreme portal frame only (Figure 3b). Figures also show the opening locations, whose effects are numerically accounted by following the modelling strategy discussed in section 2.1.

Pushover analysis results

A preliminary study on the influence of the cladding panels was carried out by performing nonlinear static (pushover) analysis on the building designed in CD“A” according to the Italian seismic code [8]. It is worth noting that differential movements are possible among the portals (in X direction) and the braced frames (in Y direction), because of the lack of a rigid diaphragm at the roof level. Different control nodes were monitored in order to catch this phenomenon and consequently assess the impact on the results provided by both pushover analysis (as discussed in the current subsection) and MSA (discussed later). Despite the rela-

tive movements are mainly expected along the portal direction (X), because of both the presence of a middle portal not restrained by roof braces and the asymmetric panel distribution, a set of three control nodes was also utilized to monitor the longitudinal (Y) direction. The assumed control nodes are identified in Figure 3. The analyses were performed in control of displacement, by pushing the building in each direction by means of sets of uniform horizontal forces applied at the nodes of the roof level.

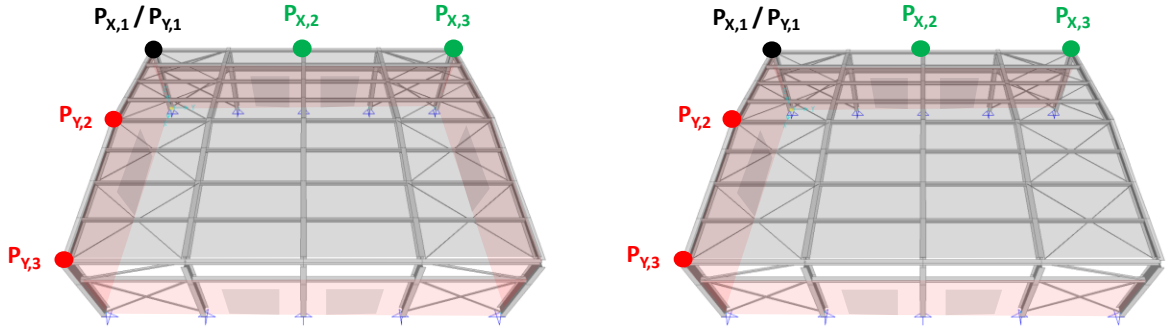

Figure 3: Scheme of panel distribution: (a) symmetric case; (b) asymmetric distribution along the X direction.

The capacity curves for the case with symmetric panels are reported in Figure 4, while those related to the asymmetric panel distribution are shown in Figure 5. Curves related to different control nodes are superimposed in the charts by using different colours. It is worth noting that the choice of the control node has no influence for the response along the longitudinal direction, because of the symmetry of both structural and non-structural components. On the contrary, a higher sensitivity is observed in the X direction, due to the following reasons: (1) the presence of a middle portal not restrained by roof braces, which experiences higher displacements with respect to the lateral ones even for a symmetric panel assemblies' configuration (see Figure 4a); (2) the asymmetric panel distribution, which amplifies the effect said above on the central portal frame and, moreover, leads the extreme portal frame without panels to experience higher deformability, as witnessed by the pushover curves comparison in Figure 5a. It is also worth noting the asymmetric distribution of panels along X modifies the lateral response of the system, as can be observed by the different trends of the capacity curves in X of Figure 4a (symmetric) and Figure 5a (asymmetric): hardening post-elastic behaviour with symmetric panels and softening branch with asymmetric ones.

For what concerns the local damage criterion, the four performance states introduced in section 2.1 are highlighted on the capacity curves of Figure 4 and Figure 5 by coloured markers: (GD) a green dot for the low-damage level; (RST) a red star for the medium-damage level; (BD) a blue diamond for the strong-damage level; (RSQ) a red square for the base-shear limit. According to these results, the following comments can be done: (1) low-damage and medium-damage levels are attained simultaneously, and this is due to the particular geometry of the building, with one storey only and panel assemblies of the same type and with the same heights along each direction; (2) the attainment of the limit on the base-shear (i.e., 95% $V_{b,max}$) is always posterior to the panel strong-damage state, except for the case with symmetric panels in X direction (Figure 5a), where a non-negligible structural damage occurs before the development of strong-damage level on panels; this testifies the worsening of the lateral structural response due to the presence of non-structural elements with asymmetric distribution in plan; (3) as expected, no differences are observed in the longitudinal direction (Y) in terms of both capacity curves and panel performance points.

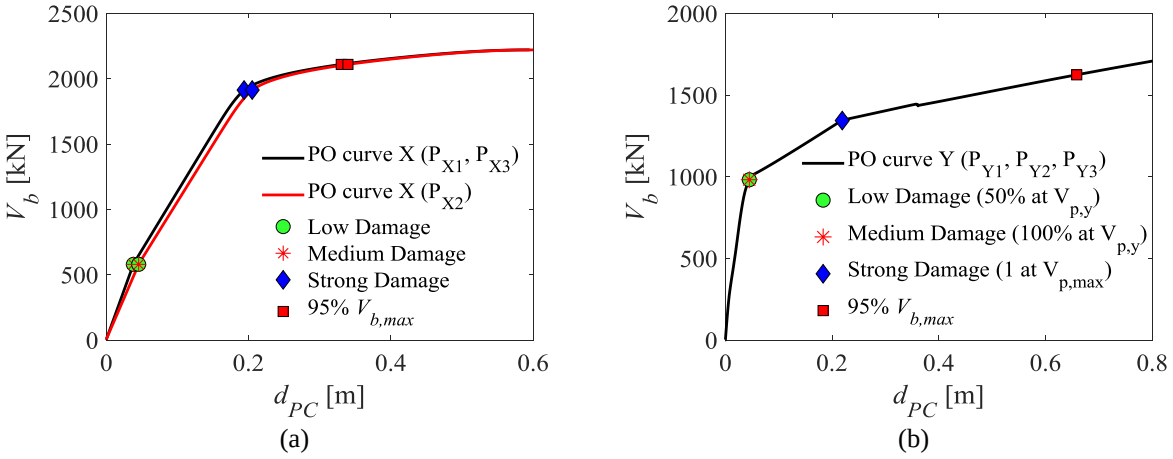

Figure 4: Pushover curves for symmetric panel distribution along X (MRF) (a) and Y (CBF) (b) direction.

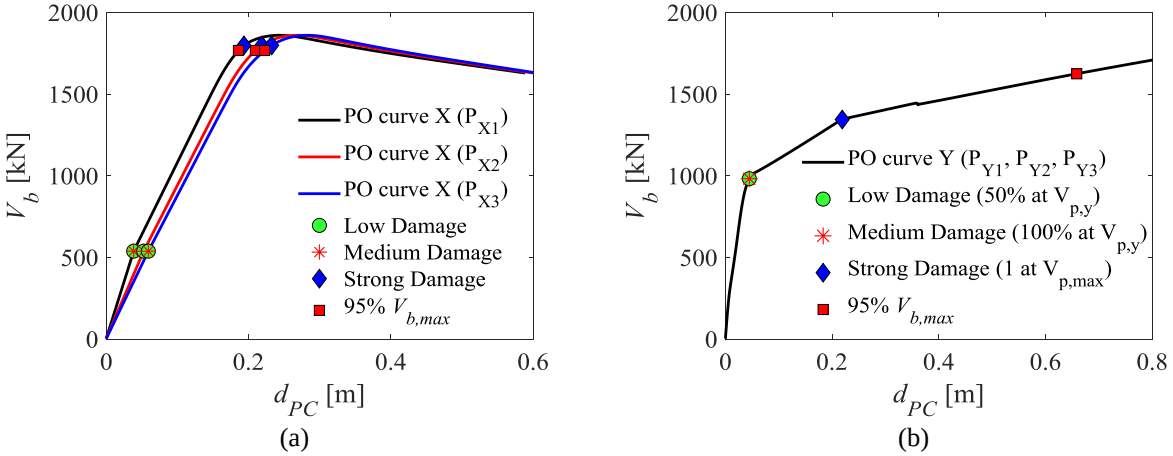

Figure 5: Pushover curves for asymmetric panel distribution: direction X (MRF) (a) and Y (CBF) (b).

Table 4. DLS limit drift values for asymmetric panel distribution.

To conclude this section, the drift limit values, estimated by using the different control nodes of Figure 3, are summarised in Table 3 for the case with symmetric panels and in Table 4 for the case with asymmetric ones. These limits were used as threshold values to estimate and compare the conditional probability (fragility) functions at the DLS, as described in the next subsection.

Fragility functions estimated via MSA

The probability of exceeding the performance level corresponding to DLS at different intensity levels, is herein estimated for the building designed in CD"A" according to the Italian seismic code [8]. This task is achieved through the application of the local damage criteria introduced in section 2.1, i.e. the attainment of the DLS is defined by monitoring the onset of the damage levels of the cladding panels. MSA is used to estimate the fragility functions P(D|IM) = P[D > *d* | IM = im] at the DLS. Specifically, the drift ratios measured at the roof nodes (see Figure 3) of the models with infill panels are used as response parameter (D), while the limit threshold values *d* consist of the drift ratios computed via pushover analysis and summarised in Table 3 and in Table 4.

Fragility curves for the building with symmetric panels are shown in Figure 6 (X direction in Figure 6a and Y direction in Figure 6b). Given the panel symmetry, the probabilistic response does not change significantly by varying the control node, and, thus, only the results related to node $P_{X1/\ Y1}$ are shown in the chart. The fragility curves corresponding to the exceedance of the conventional code-based limit drift value of 0.5% are also provided in the same charts. It is worth noting that, in this case, the response parameter consists of the drift ratios monitored on the bare-frame model (with panel assemblies modelled as mass only), that is the most frequently adopted seismic analysis method for steel constructions.

Fragility curves for the building with asymmetric panels are shown in Figure 7 (X direction in Figure 7a,b,c and Y direction in Figure 7d). Given the panel asymmetry, the probabilistic response changes by varying the control node as can be observed comparing the results for the considered control nodes: P_{X1} (Figure 7a), P_{X2} (Figure 7b), P_{X3} (Figure 7c).

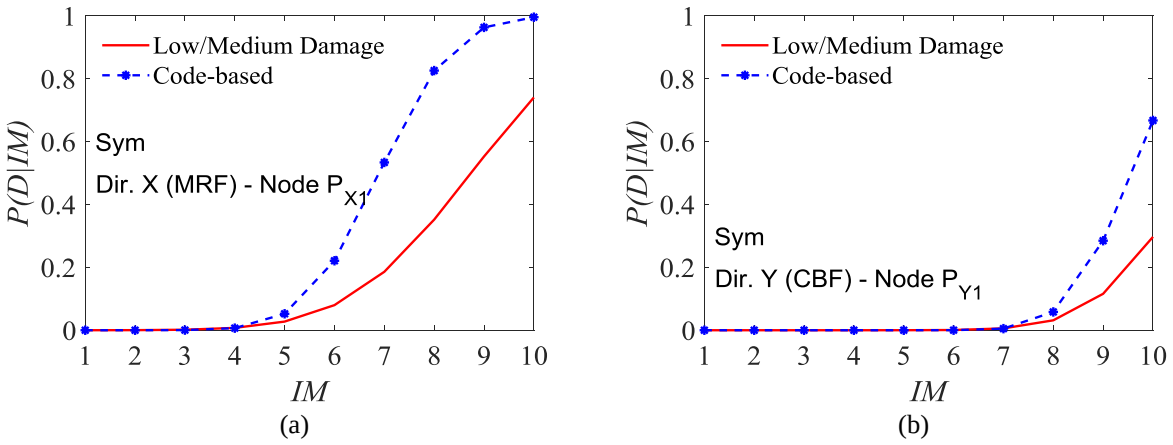

Figure 6: DLS fragility curves for symmetric panel distribution. Results along the X direction (MRF) refer to drift values computed on control node P_{X1} (a). Results along the Y direction (CBF) refer to node P_{Y1} (b).

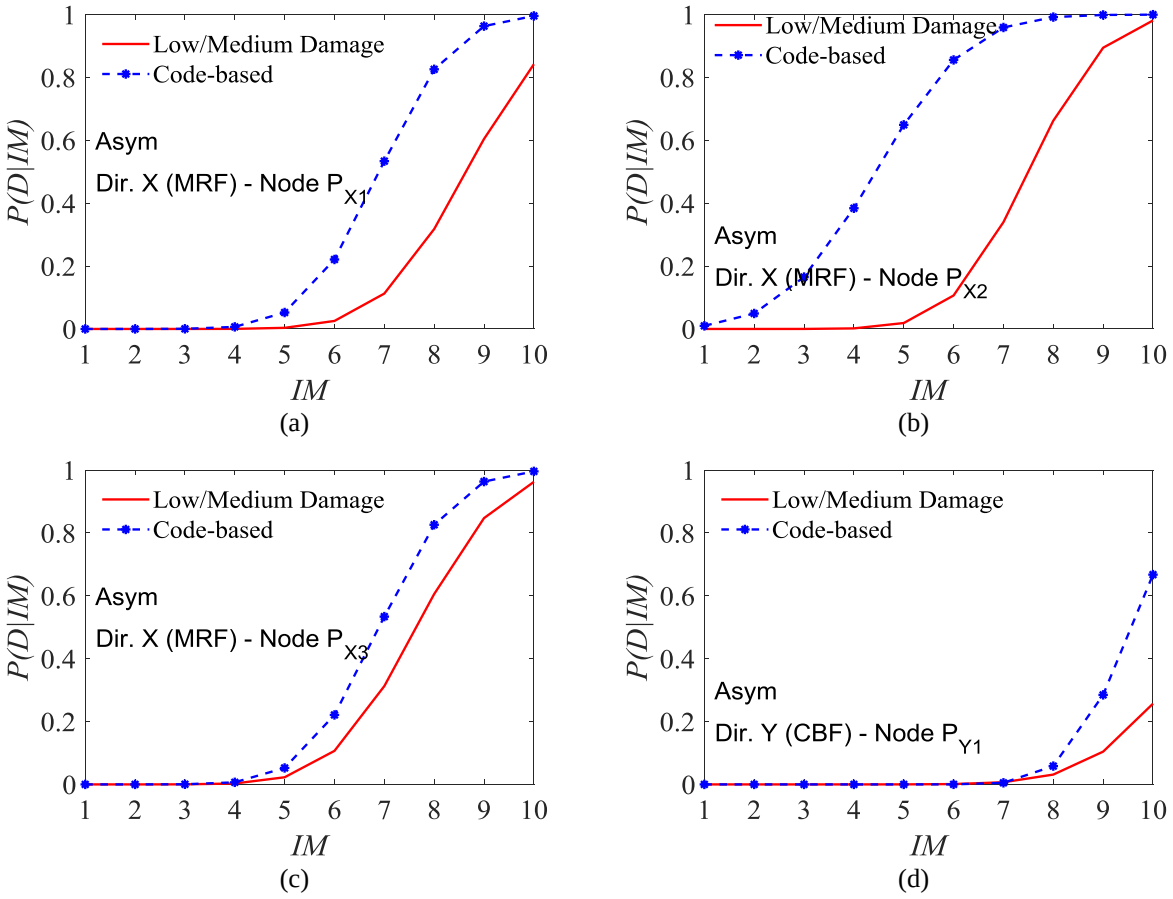

Figure 7: DLS fragility curves for asymmetric panel distribution. Results along the X direction (MRF) refer to drift values computed on different control nodes: P_{X1} (a), P_{X2} (b), P_{X3} (c). Results along the Y direction (CBF) refer to node P_{Y1} (d).

Influence of the design of braces

The probability of exceeding the performance level corresponding to DLS considering the differences in the design of the vertical braces as discussed in section 3.1 is herein presented. The methodology is the same illustrated in the previous section. The drift values are computed with respect to node P_1. Fragility curves for the building designed in DCM are shown in red (Figure 8), by using continuous lines for the curves exceeding the low-damage level (also equal to the medium-damage level) and dashed lines for the code-based curve with 0.5% conventional drift ratio). Fragility curves for the building designed in CD"A" are shown in black. Results for the two brace designs are generally comparable with the fragility of the building designed in medium ductility class (DCM) and slightly higher only at the very large IM = 10. Similar trends are observed in terms of code-based fragility curves.

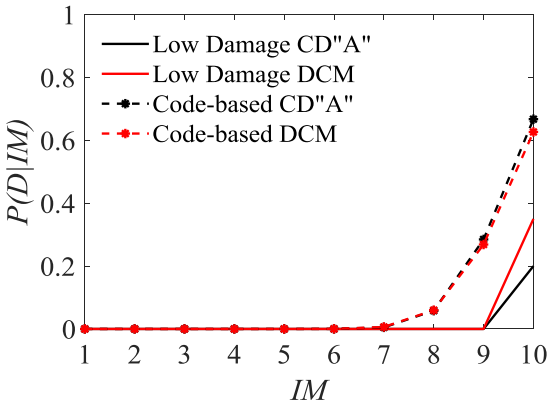

Figure 8: DLS fragility curves along the Y direction (CBF) for the buildings design in medium and high ductility. Results refer to drift values computed with respect to the node P_{X1}.

4 CONCLUSIONS

This paper focused on the influence of cladding panels on seismic response of non-residential single-storey steel buildings. Starting from a previous work carried out by the authors, where cladding panels were explicitly included in the structural seismic analysis, the current study aimed at investigating the influence of cladding panels with non-symmetric distributions in plan. In addition, as a supplementary work, two different seismic design philosophies were investigated: structural design in medium ductility class according to the Eurocodes and structural design in high ductility class according to the recent 2018 Italian National Building Code. Moreover, the effect of the choice of the control node used to evaluate the drift ratio was analysed. In order to assess the onset of the Damage Limit State (DLS), a multi-criteria approach was adopted. Multiple-stripe analysis was used to estimate the DLS fragility curves.

According to the outcomes provided in this work, the following main conclusions can be drawn:

- Because of the specific building geometry, characterized by the absence of a rigid diaphragm at the roof level, the choice of the nodes for which the drift ratio is evaluated might affect the fragility estimation, either underestimating or overestimating the conditional exceedance probabilities at the DLS. An asymmetric distribution of panels could exacerbate the changes of the fragility curves with respect to the control node.
- The ductility class selected for brace members was observed to have negligible effects on the DLS fragility functions.

For what concerns some possible future developments, these might be oriented to: (1) extend the current study to different typologies and different asymmetric configurations of cladding panels; (2) improve the local damage criterion and tailor it to better fit on single story buildings; (3) analyse the influence of structural and non-structural parameters on the obtained results through response sensitivity analysis; (4) evaluate the effect of model uncertainties both for structural and non-structural components. Regarding the second point, it is remarked that, due to the specific geometric features, all cladding panels experience almost simultaneously the same damage state, thus, reducing the usefulness of a criterion based on the attainment of a given damage condition by subsets of panel assemblies (such as, 50% of panels at a given damage condition).

Abstract

Steel plate shear walls (SPSWs) are a lateral force-resisting system in which thin infill plates (web plates) are connected to the boundary frame (i.e., beams and columns) along four edges. Despite shear buckling of thin plates upon lateral loading, web plates still provide lateral strength and stiffness in the post-buckling range owing to a mechanism called tension field action. The boundary frame (particularly columns) needs to satisfy stringent strength and stiffness requirements to anchor the inclined forces in web plates resulting from tension field action. An alternative system to conventional SPSWs, steel plate shear walls with beam-connected web plates (B-SPSWs), is proposed in the literature where web plates are connected to beams only. Therefore, high flexural and axial load demands in columns induced by tension field forces are eliminated. However, due to the difference in boundary conditions of web plates, the load path of steel plate shear walls with beam-connected web plates significantly differs from that of conventional SPSWs. In this study, a simplified strip model of beam-connected web plate is proposed to simulate the cyclic behavior of beam-connected web plates. As it is typical and conservative to ignore the compressive strength of strips, strip models underestimate the strain energy dissipated under cyclic loading. An equation for the compressive strength of strips is proposed to accurately capture the energy dissipation capacity of beam-connected web plates. A three-way comparison between the proposed strip model, a strip model from the literature, and a validated continuum model is provided. The results reveal that the proposed strip model is capable of successfully estimating the boundary frame demands, lateral load capacity, and energy dissipation of beam-connected web plates.

Keywords: Steel Plate Shear Walls, Beam-connected Web Plates, Strip Model, Partial Tension Field, Compressive Strength.

1 INTRODUCTION

Steel plate shear walls (SPSWs) are a reliable lateral force-resisting system with high ductility, high lateral stiffness, and stable hysteretic behavior [1–7]. SPSWs comprise thin infill plates (web plates) connected to beams and columns on all four edges. Under lateral loads, web plates experience shear buckling; however, they are still capable of resisting lateral loads and providing lateral stiffness in the post-buckling range due to diagonal tension stresses developing in web plates called tension field action (TFA) [8]. As the current design practices rely on TFA for the design of SPSWs, diagonal tension stresses in the web plates must be anchored to very stiff beams and columns to utilize TFA efficiently. This diagonal tension might cause significant force demands in beams and columns and require stringent stiffness requirements. It is worthwhile noting that the vertical component of TFA in the web plates of the adjacent stories acting on the intermediate-story beams are in the opposite direction. Consequently, except for the base and roof beams, the flexural demands in the beams of SPSWs might be minimal. However, as diagonal tension stresses in the web plates are exerted on the columns of SPSWs on one side only, the significant internal force demands develop in the columns, which is a design challenge. To mitigate high flexural and axial demands in the columns due to TFA and to facilitate field installation of web plates, an alternative SPSW configuration called SPSWs with beam-connected web plates (B-SPSW) is proposed, in which the web plates are connected to the beams of SPSWs only and the vertical edges of the web plates are free. Within the scope of this paper, the focus is on the modeling of beam-connected web plates. Details of B-SPSWs system design and seismic performance can be found in Ozcelik and Clayton [9–12].

The web plate behavior is typically simulated using two modeling techniques, namely, the continuum model and the strip model. In the former technique, the web plate is modeled using shell-based finite elements with specified initial out-of-straightness to explicitly simulate the shear buckling behavior and to capture the development of TFA under lateral loads. In the later approach, the strip model, the web plate is modeled using a series of inclined tension-only truss elements connected to beams and columns to represent the diagonal tension field of the web plate. The strip model has been utilized successfully by many researchers [2,8,13–17] to simulate the cyclic response of fully-connected web plates (i.e., web plates connected to beams and columns). However, there has been little work done on the development of a strip model for the simulation of cyclic behavior of beam-connected web plates in B-SPSWs.

In the strip model, it is essential to determine the extent and inclination angle of TFA and the hysteretic behavior of individual strips to simulate the cyclic behavior of web plates and to obtain member demands accurately. For fully-connected web plates, design codes [18,19] provide an equation for the inclination angle of tension field. In addition, recent research [20,21] proposed an inclination angle of 45 degrees for fully-connected web plates provided that beams and columns have sufficient stiffness to anchor the web plate to develop full TFA, i.e., diagonal tension stresses develop in the whole plate. As the beam-connected web plates are not restrained by columns along their vertical edges, the extent and inclination angle of the tension field differ from these of fully-connected web plates due to the formation of partial TFA (Figure 1) instead of full TFA. In addition, recent research [20,21] revealed that the tension-only strip behavior is not in alignment with experimental findings and the fully-connected web plates have non-negligible compressive resistance upon loading and unloading. As the compressive strength of the strips depends on the web plate connectivity and thickness, it should be investigated for beam-connected web plates.

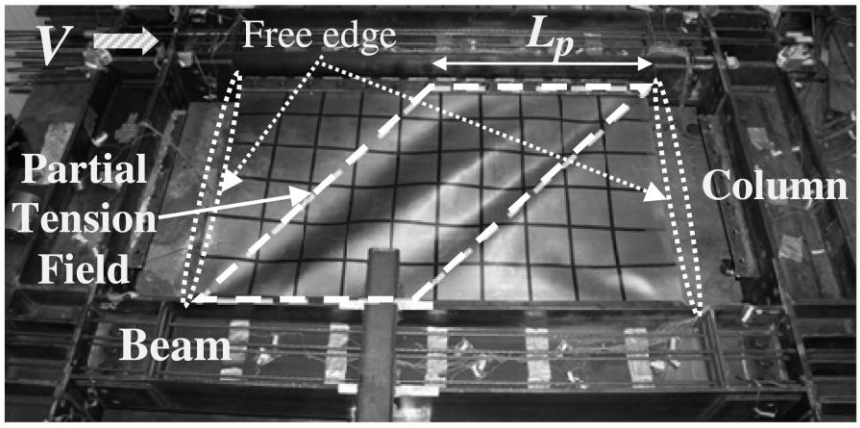

Figure 1: A test photo of partial tension field (adapted from Clayton et al. [16])

In this study, to simulate the beam-connected web plate behavior, a strip model is proposed, providing equations for the inclination angle of tension field and the compressive strength of strips. The details of the strip model are explained and a three-way comparison between the proposed strip, a strip model in the literature, and a continuum model is presented.

2 STRIP MODEL FOR BEAM-CONNECTED WEB PLATES

Thorburn et al. [8] was proposed a strip model for fully-connected web plates with infinitely flexible columns. In this model, Thorburn et al. [8] assumed that partial TFA would form in the web plate between the beams over the partial TFA length (L_p) as the columns could not anchor the diagonal tension stresses in the web plate. Assuming the PTF orients itself to resist the maximum shear force, Thorburn et al. [8] proposed an equation for the inclination angle of partial TFA (Equation 1), where γ is a non-dimensional inclination angle parameter given as 0.5.

$$\theta = \gamma \tan^{-1}(L/H) \tag{1}$$

Thorburn et al. [8] defined L_p based on web plate geometry and an assumed θ (Equation 2), where L and H are the web plate length and height, respectively:

$$L_p = L - H\tan\theta = L\left(1 - \frac{\tan\theta}{L/H}\right) \tag{2}$$

The strip model proposed by Thorburn et al. [8] can be extended to beam-connected web plates as partial TFA is observed in beam-connected web plates under lateral loads. Characterizing thin beam-connected web plate behavior adopting a mechanics-based analytical model and a validated detailed finite element of a beam-connected web plate, Equation 3 is proposed for γ. Details of Equation 3 can be found in Ozcelik and Clayton [22,23].

$$\gamma = 0.55 - 0.03\,(L/H) \geq 0.51 \tag{3}$$

As discussed herein, compressive strength of SPSW web plates is typically neglected since it is assumed that web plates have limited shear buckling strength. A parametric study was conducted by Ozcelik and Clayton [22] to quantify the compressive strength of strips representing beam-connected web plates. A parameter, β, is defined as the ratio of compressive strength of the strip to the yield strength, F_y, of the web plate material, given by Equation 4, where t_w is the web plate thickness:

$$\beta = -0.04 + 0.02\,(L/H) + \frac{2.75}{\sqrt{H/t_w}} \geq 0 \tag{4}$$

Adding an elasto-plastic material with a compressive strength determined by Equation 4 (Figure 2(b)) to the tension-only pinched material for which tensile stresses do not develop until reaching the maximum plastic strain from previous cycles (Figure 2(a)) in parallel, a parallel material (Figure 2(c)) can be used to simulate the strip behavior under cyclic loading. The normalized stress and strain diagrams of the materials are given in Figure 2, where σ is the stress in strips, ε is the normal strain of strips, and ε_y is the yield strain of the web plate material.

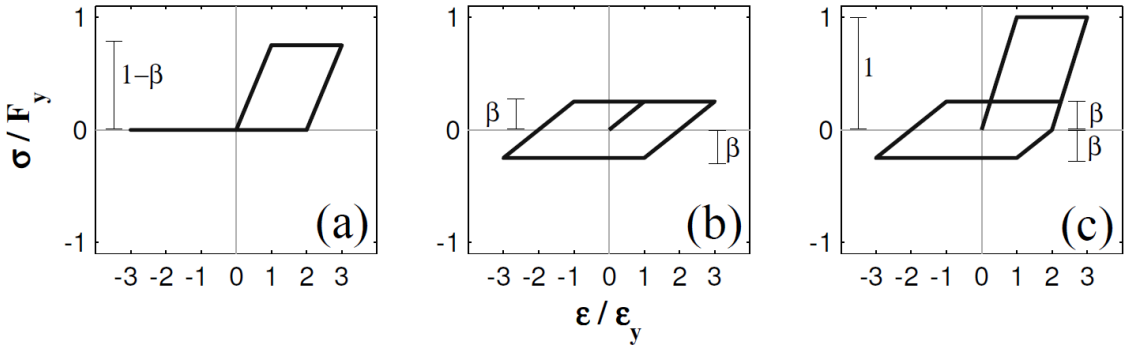

Figure 2: Material models for strips: (a) pinched tension-only material, (b) elasto-plastic tension-compression material, and (c) resulting strip response when (a) and (b) are used in parallel. (adapted from Ozcelik and Clayton [22])

The area of a strip, A_s, can be calculated using Equation 5, where n_s is the number of strips in each direction:

$$A_s = t_w\, L_p \cos\theta\, / n_s = t_w\, L \left(1 - \frac{\tan\theta}{L/H}\right) \cos\theta\, / n_s \tag{5}$$

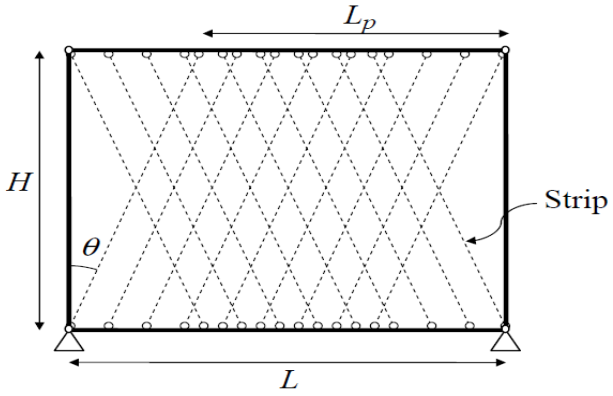

Figure 3: Strip model. (adapted from Ozcelik and Clayton [22])

The step-by-step modeling of the proposed strip model is described as follows:

- Determine γ and θ using Equations 3 and 1, respectively.
- Calculate L_p using Equation 2.
- Select the number of strips (at least 10 strips to improve accuracy) and calculate A_s from Equation 5.

- Estimate β from Equation 4.
- Define the strip material as a combination of materials in parallel given in Figure 2(a) and Figure 2(b).
- Create a series of evenly-spaced inclined strips using truss elements as shown in Figure 3.

3 COMPARISON OF B-SPSW MODELS

A three-way comparison between the proposed strip model, a strip model in the literature, and the continuum model is provided. B-SPSWs with various aspect ratios (L/H) between 0.8 and 2.5 keeping H constant (4 m) and height-to-thickness ratios between 160 and 3200 are analyzed under a cyclic drift history in ABAQUS [24] adopting the continuum model approach where the web plates are represented by shell elements (S4R) with an initial imperfection and beams and columns are modeled using very stiff line elements (B31). These models will be referred to as finite element models (FEM). The same B-SPSWs are modeled in OpenSEES adopting the strip model approach proposed herein. As the proposed strip model accounts for the compressive strength of the strips, it will be referred to as tension-compression strip model (TC). In addition to the proposed strip model, B-SPSWs are modeled in OpenSEES adopting the strip model proposed by Thorburn et al. [8], in which γ is 0.5 and β is 0 (i.e., tension-only strips). The strip model proposed by Thorburn et al. [8] will be referred to as tension-only strip model (TO). Similar to FEM, the beams and columns of the TC and TO models are modeled using very stiff line elements. Further details on the modeling of FEM, TC, and TO can be found in Ozcelik and Clayton [22].

The analysis results from the strip models (TC and TO) and FEMs are compared in terms of base shear capacity of beam-connected web plates, beam and column demands, and energy dissipation capacity of B-SPSWs. Figure 4 shows the comparison of the base shears, V, normalized with respect to the web plate lateral load capacities, V_y, of three models with an aspect ratio of 1.5 for various H/t_w ratios. V_y can be calculated from Equation 6:

$$V_y = 0.5\, F_y t_w L_p \sin 2\theta \tag{6}$$

As depicted in Figures 6(a) and 6(b), for thinner web plates (higher H/t_w), both TO and TC match the FEM results closely as the strips representing thinner web plates have limited compressive strength. The normalized base shear capacities and the normalized unloading base shears are closed to 1 and 0, respectively, for all models, as expected. For thicker plates (Figures 6(d) and 6(e)), TC still shows a very similar response to FEM while TO does not match FEM. As thicker plates are used, TC is able to predict peak capacities accurately; however, it does tend to underestimate the web plate strength during unloading and loading. The loading and unloading strengths might have a substantial impact on the energy dissipation capacity; however, they do not affect the peak beam and column demands as will be discussed.

By integrating the area under the base shear vs. displacement response for each model, energy dissipation (E) is determined. For a L/H of 1.5 and H/t_w of 213, Figure 5 shows E for each model normalized with respect to the total energy dissipated in FEM (E_{max}). As mentioned, the TC model underestimates the unloading and loading strengths; consequently, the TC model underpredicts E by approximately 25% for thicker plates with respect to the FEM results. On the other hand, the TO model underestimates E by approximately 75% for the same plate thickness with respect to the FEM results.

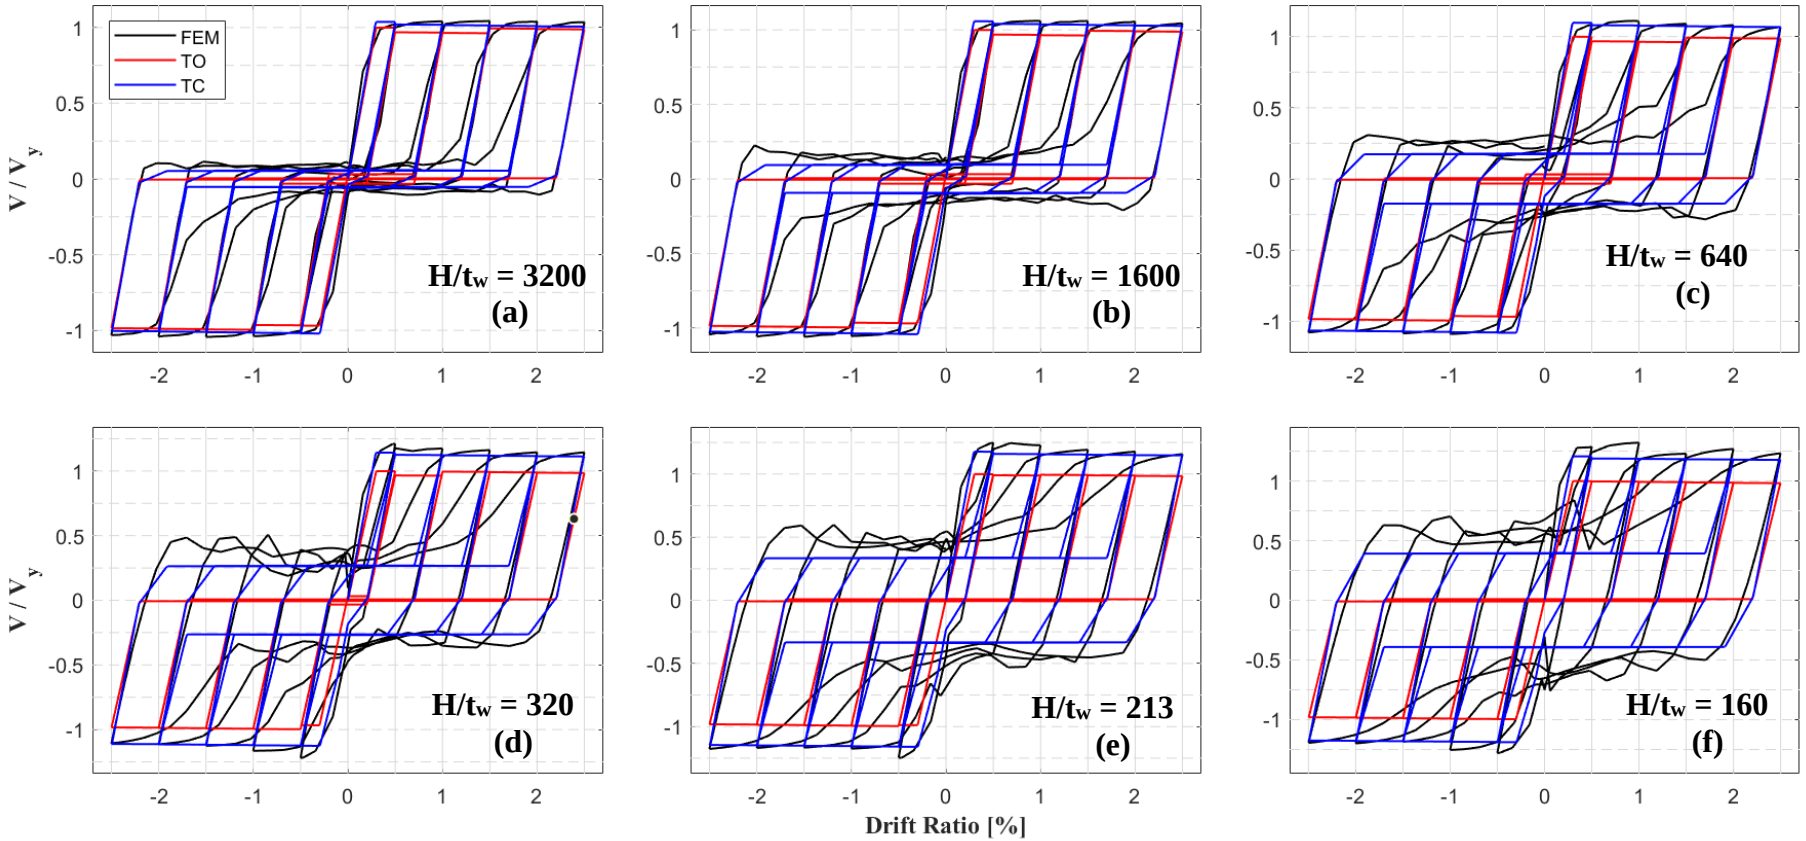

Figure 4: Comparison of normalized base shear vs. drift ratio for an aspect ratio of 1.5

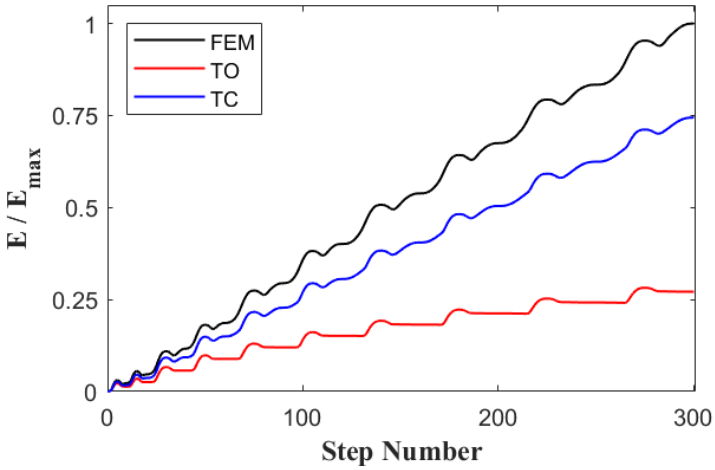

Figure 5: Normalized strain energy for a L/H of 1.5 and H/t_w of 213

For various L/H and H/t_w, the normalized strain energy (E/E_{max}) values are tabulated in Tables 1 and 2 for TC and TO models, respectively. For the thinnest and the thickest plates considered in this study ((H/t_w of 1600 and 160, respectively), TO can dissipate approximate 50% and 25% of E_{max} (on average), respectively. However, TC can dissipate as high as 84% of E_{max} on average. Despite underprediction of energy dissipation, TC shows a great improvement in simulating beam-connected web plate behavior compared to the existing TO in terms of energy dissipation capacity.

Table 2: Beam Moment, Column Axial Load, Base Shear, and Energy Ratios (TO Model to ABAQUS Ratios)

Tables 1 and 2 tabulate the ratios of maximum moment in beams (M_{max}), maximum axial compressive load in columns (P_{max}), and V of strip models to those of FEM. TO overestimates

M_{max} and P_{max} conservatively for all H/t_w values; however, TO becomes overly conservative as plate thickness increases. TO successfully predicts V for thinner plates while V of TO can be as low as 60% of V of FEM for thicker plates. These differences stem from the negligible compressive strength assumption for TO. TC predicts the M_{max} P_{max}, and V accurately regardless of the plate thickness as TC accounts for the compressive strength of strips. For the cases in which TC deviates from FEM, the member demands are typically conservatively overestimated and base shear tends to be conservatively underestimated for TC. In brief, TC can be used to model beam-connected web plates for a wide range of L/H and H/t_w values.

4 CONCLUSIONS

In this study, a simplified model called strip model is proposed to simulate the behavior of beam-connected web plates under cyclic loading. An equation is presented for the inclination of tension field action observed in beam-connected web plates and another equation is provided that estimates the compressive strength of strips. A three-way comparison between the proposed strip model, the strip model proposed by Thorburn et al. [8], and the shell-based finite element model is presented. The results of the comparative study appear to indicate that the proposed strip model matches the finite element results and shows a significant improvement in simulating beam-connected web plate behavior compared to the strip model proposed by Thorburn et al. [8].

Abstract

Cross concentrically braced frames are commonly used in seismic design of steel buildings at any seismicity, owing to their large lateral stiffness, simplicity of design and limited constructional cost. The seismic design criteria provided by current EC8 aim at assuring ductile global plastic mechanism occur, namely restraining the plastic deformation into the diagonals, while the remaining structural members and connections should elastically behave. However, several studies, show that the design process compliant to Eurocode 8 is affected by several criticisms, it entails several efforts and often leads to massive, uneconomical systems solution exhibiting poor seismic performance. EN1998-1 recommends estimating the lateral resistance of X-CBFs by performing structural analysis on a tension-only (T-O) diagonal scheme in which solely the tension braces resist the lateral loadings, while the contribution given by the compression diagonals is neglected. As highlighted by the comments given by European designers coming from the survey promoted by CEN TC 250/SC8 for the systematic review of EC8, this type of model can induce misleading interpretation of the structural behavior and relevant modelling of X-CBFs, leading to uneconomical and oversized systems characterized by heavy structural solutions and poor plastic engagement. The research presented in this paper is addressed to critically discuss and revise the detailing rules codified within the current EN 1998-1 for X-CBF, to simplify the design process and to improve the seismic behavior. Whit this aim, an extent set of nonlinear dynamic analyses has been performed on a set ow low, medium, and high-rise 2D frames extracted from residential steel buildings to assess the effectiveness of currently codified requirements and to validate the beneficial effects of the proposed revision.

Keywords: concentrically braced frames; seismic design; Eurocode 8; ductility demand; steel structures.

1 INTRODUCTION

Cross concentrically braced frames (X-CBFs) are widely used in multi-story steel buildings as seismic resisting systems at any seismicity, due to their simplicity of design and low constructional costs, although the limited available ductility and redundancy as respect to moment resisting frames (MRFs).

To ensure a global ductile behavior, seismic codes [1-3] provide capacity design criteria devoted restraining the plastic deformations into the diagonal members and preventing damage of beams, columns and connections.

Numerous researchers [4-22] critically discussed and revised the design rules codified within EN 1998-1 and even identified some issues needing upgrading and/or amendment.

EN1998-1 [1] recommends calculating the lateral resistance of cross bracings by performing structural analysis on a tension-only (T-O) diagonal scheme in which solely the tension braces withstand the lateral loadings, and the contribution given by the compression diagonals is neglected. As highlighted by the comments given by European designers coming from the survey promoted by CEN TC 250/SC8 for the systematic review of EC8, this type of model can induce misleading interpretation of the structural behavior and relevant modelling of X-CBFs. In detail, one of the most critical aspect deals with the evaluation of brace slenderness. Indeed, the use of T-O model instills in many designers that only the diagonal subjected to tensile forces is mechanically active and the mutual restraint between the braces could be disregarded, thus considering the entire length of the element as buckling length. Conversely, as highlighted by several Authors [12, 22-29], the presence of the complementary brace and the mutual connection degree at the diagonals mid length has considerably importance for the accurate prediction of both in-plane and out-of-plane buckling phenomena; theoretical and experimental results by [22-29] confirmed that the tension brace can effectively restrain both in-plane and out-of-plane displacements of the diagonal under compression at the brace-to-brace intersection. Therefore, to accurately evaluate the brace slenderness and the brace hysteretic response, half length of the brace can be conservatively assumed as buckling length.

According to current EC8 [1] the brace slenderness ratio should be in the range (1.3 – 2); the lower limit is introduced to avoid overloading of the columns due to the force demand transferred by the compression diagonals omitted in the models. However, the EC8 do not discriminate continuous and discontinuous diagonals, being likely unconservative: indeed, in absence of specific guidance, the designer can disregard the brace-to-brace mutual restraint, thus selecting diagonals that are stockier than expected.

Another critical aspect of EC8-compliant design is related to the requirement on the capacity-to-demand ratios $\Omega_i = N_{pl,br,Rd,i}/N_{Ed,br,i}$ (being $N_{pl,br,Rd,i}$ the brace yield strength and $N_{Ed,br,i}$ the design forces due to the seismic actions) which should vary in the range (Ω; 1.25Ω) to guarantee uniform distribution of plasticity along the building height and thus mitigating the tendency of CBFs to soft-story mechanisms. Several Authors [11-18] showed that this requirement is not adequate to guarantee an overall plastic engagement of the dissipative elements and it also leads to oversize the diagonals at lower and intermediate stories. Indeed, to contemporarily satisfy the requirements of slenderness limits and the overstrength variation often leads to impractical solutions with significant difficulties to select the proper member for braces, being both requirements closely interrelated and juxtaposed [4-9, 11-12, 14-15]. These considerations motivated the research presented in this paper, which is addressed to identify the main criticisms of the current EC8 [1] and to propose some amendments to design rules in order to obtain more cost-effective and structurally efficient X-CBFs.

With this aim, the paper is organized in three main parts: (i) Section 2 describes the design rules of the current Eurocode 8, providing a critical discussion; In Section 3, revised design

rules are proposed; the proposed design rules are validated by mean of a numerical parametric study described and discussed in Section 4

2 EC8 DESIGN PROCEDURE

For regular structures equipped with X-CBFs, EN 1998-1 recommends a behavior factor q equal to 4 to reduce the elastic spectrum for both medium and high ductility classes.

To calculate the internal forces, EC8 allows simplified design procedure, performing a linear-elastic analysis on a T-O model where the contribution of compression diagonals is neglected (Fig. 1a).

The slenderness ratio $\bar{\lambda}$ of diagonal members should be in the range [1.3, 2]. As mentioned in the previous Section, the lower bound limit ($\bar{\lambda} \geq 1.3$) is introduced to limit the forces transferred to the columns by compression braces, omitted in the T-O model, while upper bound limit ($\bar{\lambda} \leq 2$) is devoted to assure satisfactorily hysteretic behavior and undesired buckling under serviceability loads. The imposition of the lower bound limit ($\bar{\lambda} \geq 1.3$) is direct consequence of using T-O model and it entails significant difficulties in sizing of brace cross-section, and it often involves the need to increase the number of braced bays to select smaller diagonal members.

The upper bound limit for brace slenderness ($\bar{\lambda} \leq 2$) also influences the design process of bracing elements, especially due to its interrelation with the control of the variation of the brace overstrength ratios Ωi. To assure uniform distribution of plastic deformations along the building height, Eurocode 8 limits the variation of the brace overstrength ratios $\Omega_i = N_{pl,br,Rd,i}/N_{Ed,br,i}$ for braces at i-th story within the range [Ω - 1.25Ω], being Ω the minimum value.

The diagonal members at the roof story are indeed generally characterized by large overstrength ratio due to the need of selecting large cross section to satisfy the slender upper bound limit. As consequence, to meet the requirement on the Ω variation, the designer is forced to oversize the diagonals at all story. In such situation, typical values of Ω ratios for bracings in X configurations can largely overcome the unit, resulting in poor plastic engagement of dissipative zones and unsatisfactorily energy dissipation capacity [5,7,9].

The hierarchy of resistance is deemed to be satisfied by amplifying the seismic-induced effects evaluated by mean of the linear-elastic analysis by the overstrength factor Ω. In detail, the required strength of non-dissipative should meet the following:

$$N_{pl,Rd}(M_{Ed}) \geq N_{Ed,G} + 1.1 \cdot \gamma_{ov} \cdot \Omega \cdot N_{Ed,E} \tag{2}$$

where $N_{pl,Rd}(M_{Ed})$ is the design axial strength of the beam or column calculated in accordance with EN 1993:1-1 [31], taking into account the interaction with the design value of bending moment, M_{Ed}, in the seismic design situation; $N_{Ed,G}$ is the axial force in the beam or in the column due to the non-seismic actions included in the combination of actions for the seismic design situation; $N_{Ed,E}$ is the axial force in the beam or in the column due to the design seismic action; γ_{ov} is the factor accounting for random variability of the steel yield stress.

As previously mentioned, this design procedure often leads to uneconomical and oversized structures practically behave in elastic range [4-5, 8-9, 11-12, 34-39]. The reason for using T-O structural scheme is based on the assumption that compression diagonals have negligible contribution to resist lateral action due to buckling. However, this idealization is a reasonable approximation only for slender braces in post-buckling condition, while in the first stages of seismic response, as well as for stocky braces, both diagonals are active in tension and com-

pression and the axial force transferred to the columns and connections by the compression diagonals could be significant. In order to clarify this aspect, Figure 2 depicts the force transfer mechanisms obtained by considering T-O model (Fig. 1a) and by using a tension-compression (T-C) scheme in which both braces are explicitly accounted for (Fig. 1b). It is trivial to observe that T-O model underestimates the force acting in the columns, thus potentially resulting in unconservative design.

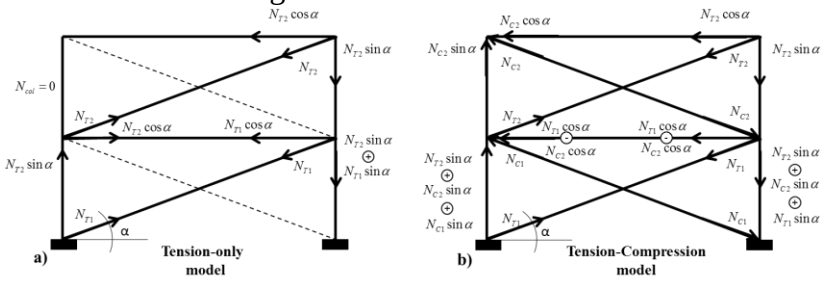

Figure 1: Tension-only (a) Tension-Compression (b) model.

Moreover, as previously mentioned, the use of T-O model can lead to misleading interpretation of structural behavior, inducing the designer to inaccurately calculate the buckling length of the diagonal disregarding the role of the complementary bracing and of the brace-to-brace mutual degree of connection.

3 SEISMIC DESIGN CRITERIA TO IMPROVE THE PERFORMANCE OF X-CBFS

The current section presents new design criteria to improve the ductility of X-CBFs and at the same time to simplify the design process. The suggested rules are consistent with those provided by Authors [11, 13] for chevron CBFs, to develop and validate a unified approach for seismic design of both cross and chevron bracings, thus avoiding the definition of two sub-categories based on the bracing configurations as it is in the current version of EC8.

The behavior factor currently recommended by EC8 for X-CBFs, i.e. q = 4, is retained.

The required strength of bracings is determined by performing global elastic analysis on the structural scheme with both braces active in tension and compression (T-C scheme). Thereby, the bracing members should be designed to meet the following condition:

$$N_{b,br,Rd,i} \geq N_{br,Ed,i} \tag{3}$$

Where $N_{\mathrm{b,br,Rd,i}}$ is the factored buckling capacity of the i-th bracing member evaluated according to EN 1993-1 [30]; $N_{\mathrm{br,Ed,i}}$ is the axial force acting in the bracing members evaluated according to the following equation:

(i) at the roof story:

$$N_{br,Ed,rf} = q \cdot N_{br,Ed,E,rf} + N_{br,Ed,G,rf} \tag{4}$$

where $N_{\mathrm{br,Ed,rf}}$ is the required strength in compression of bracings at the roof story; $N_{\mathrm{br,Ed,E,rf}}$ is the axial force contribution at the roof story due to the seismic action; $N_{\mathrm{br,Ed,G,rf}}$ is the axial force contribution at the roof story due to the non-seismic actions included in the combination of actions for the seismic design situation; q the behavior factor assumed at design stage.

(ii) at the i-th story:

$$N_{br,Ed,ri} = N_{br,Ed,E,i} + N_{br,Ed,G,i} \tag{5}$$

being $N_{\mathrm{br,Ed,i}}$ the required strength in compression of bracings at the i-th story; $N_{\mathrm{br,Ed,E,i}}$ the axial force at the i-th story due to the seismic action; $N_{\mathrm{br,Ed,G,i}}$ the axial force at the i-th story

due to the non-seismic actions included in the combination of actions for the seismic design situation.

The requirement expressed by Eq. 4 is devoted to favor uniform distribution of drift along the building height. Results of nonlinear dynamic analyses performed by [10, 12] showed that medium and high-rise multistory braced frames designed according to EN 1998 generally exhibit cantilever-like displacement profile with high damage concentration at the upper stories. Restraining the bracings at roof story in the elastic range allows to control the distribution of drift along the building height. Results from non-linear analyses performed within previous studies by the Authors [11-15] clearly validated the effectiveness of requirement expressed by Eqn. 4 in assuring shear-like behavior and more uniform distribution of drifts and plastic deformations along the building height. In low-rise buildings up to three story, such requirement can be neglected, being the behavior of low-rise buildings mostly shear-type.

Since, the brace under compression is explicitly accounted for in the global analysis, the lower bound limit currently provided for by EC8 is disregarded, while the maximum allowable slenderness is retained (i.e. $\overline{\lambda} \le 2$).

The brace slenderness is evaluated assuming that both in-plane and out-of-plane initial buckling is effectively restrained by the complementary brace, namely the buckling length is assumed equal to the half-length of the element.

The requirement on capacity-to-demand ratio variation is amended as follow:

$$[(\Omega_{b,i} - \Omega_b)/\Omega_b] \ge 0.25 \tag{6}$$

Where:

$$\Omega_b = \min(\Omega_{b,i}) = \mathrm{mi}\left(\frac{\chi \cdot N_{pl,br,Rd,i}}{N_{Ed,br,i}}\right);\ \ i \in [1,(n-1] \tag{7}$$

being n the number of stories.

The overstrength Ω_b at each story is defined considering the buckling strength of the brace $\chi N_{pl,br,Rd,i}$ rather than the tensile one, to better control the sequence of buckling and fostering uniform engagement of braces.

Differently from current EC8, the design forces acting in the non-dissipative members are evaluated by explicitly considering the force transfer mechanisms occurring in the post-buckling range; thereby the most severe condition among the following is considered:

1) pre-buckling stage: both braces are active, and their axial forces are equal to $\gamma_{ov}\chi_i N_{pl,br,Rd,i}$.

2) post-buckling stage: the design forces in the non-dissipative members are estimated by a free-body distribution of plastic forces corresponding to the braces fully yielded under tension and those under compression in the post-buckling range. In detail, the brace under tension is assumed transmitting its full plastic strength as follow:

$$N_T = 1.1 \cdot \gamma_{ov} \cdot N_{pl,br,Rd,i} \tag{8}$$

where, $N_{pl,br,Rd,i}$ is the design plastic strength of brace cross-section, γ_{ov} is the material randomness coefficient and 1.1 accounts for material strain-hardening.

The compression diagonal is assumed attaining its average post-buckling strength set equal to:

$$N_C = 0.3 \cdot \gamma_{ov} \cdot \chi \cdot N_{pl,br,Rd,i} \tag{9}$$

It should be noted that in current EN 1998, plastic mechanism analysis is recommended solely for calculating the unbalanced force occurring on the brace-intercepted beam in chevron concentrically braced frames. According to current EC8, the post-buckling strength of

brace under compression should be assumed equal to $\gamma_{pb}N_{pl,br,Rd,i}$, where the recommended value for γ_{pb} is 0.30. As observed in [9-12], $\gamma_{pb}N_{pl,br,Rd,i}$ leads to inconsistent distribution of forces when slender braces are used. Indeed, for very slender bracings close to the upper bound limit 2, the brace buckling strength tends to the 20% of the plastic resistance (the buckling reduction factor χ is about 0.2), thus resulting lower than the value suggested by the code to evaluate the brace post-buckling strength. Consistently to what recommended by AISC 341-16 [2] Eqn. 9 overcomes this criticism and it provides the post-buckling strength accounting for the brace slenderness by mean of the buckling coefficient χ.

In addition, consistently with CSA-S16 [3], the columns belonging to the braced bays are verified to withstand the combined action of the axial force evaluated for the condition (2) and bending moments with uniform distribution equal to the 20% of the plastic bending resistance of the column cross section.

Moreover, in order to enhance the redundancy of the system and to favor a uniform distribution of plasticity along the height the beam-to-column connections belonging to the braced bays are designed to be full strength and full-rigid (i.e. of moment resisting type).

4 NUMERICAL VALIDATION OF PROPOSED DESIGN CRITERIA

4.1 Parametric study

In order to validate the design criteria described in Section 3, a set of frames with three, six and twelve-story was alternatively designed according to the proposed design rules and the EC8-compliant criteria and analyzed by means of nonlinear dynamic analyses. In addition, in order to highlight the influence of brace-to-brace mutual restraint in the estimation of brace slenderness, the EC8 design criteria were applied twice, alternatively considering both design rules, namely:1) buckling length factor K = 1 (i.e. the effective length equal to the full length of the brace); 2) buckling length factor K = 0.5 (i.e. the effective length equal to the half-length of the brace).

The building archetypes is shown in Fig. 2. At each floor, the rigid diaphragm transmitting the horizontal actions is obtained by means of composite slabs with profiled steel sheetings supported by the hot-rolled steel beams (both primary and secondary), which are considered as restrained to avoid flexural-torsional buckling.

The structural design for gravity loads is carried out according to the non-seismic European codes [31-33] for all the examined frames, considering the Eurocode recommended parameters in place of those nationally determined. Permanent loads (G_k) and live loads (Q_k) are assumed equal to 5.20 kN/m^2 and 2.00 kN/m^2, at both intermediate and roof story. The inertial effects in the seismic design situation are evaluated in accordance with EN 1998-1 [1]. A reference peak ground acceleration equal to a_{gR} = 0.25g (being g the gravity acceleration), a type C soil, a type 1 spectral shape are assumed.

Cold formed circular hollow profiles are used for the diagonal members; IPE and HE profiles are used for beams; HE and HD for the columns. The cross sections of all steel members (i.e. beams, bracings and columns) are selected to satisfy the Class 1 requirements according to EN 1993:1-1 [31].

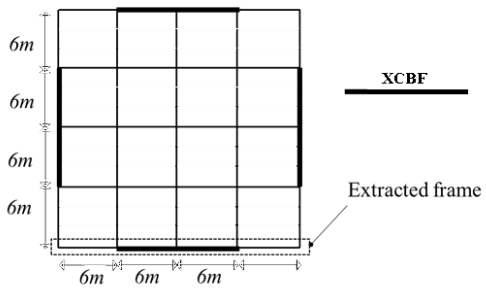

Figure 2: Reference building archetype

The geometrical properties of structural members for the three, six and twelve story buildings are reported in [12].

The non-linear behavior of the 2D examined frames is simulated by means of Seismostruct ; the modelling assumptions are described and validated against experimental results in [12]. A suite of 14 natural earthquake acceleration records has been considered to perform the non-linear dynamic analyses on the examined cases. More details on the selection of the signals and the relevant data can be found in [12].

4.2 Discussion of results

The plots in the current Section report the average values of performance parameters obtained for the 14 records. Figure 3 shows the average peak interstory drift ratios (IDR) for all examined cases. The frames designed according to the proposed design rules meet the requirement for non-structural damage at DL limit state, being the seismic demand smaller than 0.75% (i.e. EC8 limit for ductile non-structural elements). In addition, they exhibit more uniform distribution of displacements along the building height than EC8-compliant frames. These results confirm the effectiveness of proposed criteria to force a shear-type distribution od deformation and to avoid damage concentration at upper story. Figure 4 report the profiles of the maximum brace ductility demand $\mu = \left(\frac{d}{d_y} \right)$, where d is the axial elongation and dis the axial elongation and d_y is the value corresponding to the yielding. The frames designed according to proposed rules exhibit the lager plastic engagement of bracings, while limited ductility is recognized for EC8 frames with K = 0.5 and significant damage concentration is recognized solely at the upper story for EC8-compliant frames designed assuming K = 1.

5 CONCLUSIVE REMARKS

The paper discusses the main criticism of the design procedure for XCBFs currently codified in EN 1998-1 and seismic design criteria to improve the ductility of this type of systems are provided and numerically validated.

The interpretation of obtained results infers the following remarks:

T-C scheme (see Fig. 1b) with both braces active in tension and compression allows estimating the force-transfer mechanism induced by seismic action more effectively than T-O model (see Fig. 1a).

Using T-C model allows removing the lower bound limit on normalized brace slenderness making easier to select proper brace cross sections and allowing to obtain more ductile and effective systems.

The requirement of current EC8 on the capacity-to-demand variation of brace is not adequate to avoid soft-story mechanism and assuring uniform distribution of plasticity along the building height. In addition, it entails difficulties to design the brace cross sections and it leads to overdesigned and uneconomical structures, almost behaving elastically up to NC limit state. On the contrary, controlling the story-to-story variation of brace buckling overstrength is more effective to limit soft-story mechanisms and to assure uniform sequence of buckling along the building height.

The requirement devoted to keep the braces at the roof story in elastic range (Eqn. 4) is effective to obtain a shear-type overall structural response in six and twelve-story buildings with more uniform distribution of plastic deformations along the height.

Abstract

Steel moment resisting frames (MRFs) compliant with EN1998-1 are largely overdesigned owing to the need to satisfy the severe requirements for lateral deformability and P-Delta effects. On the contrary, the North American codes (e.g. ASCE7) introduce different rules to consider the structural sensitivity to the P-Delta effects. In lines with the latter approach, the current draft version of the amended EN1998-1-1 introduces a different methodology to account for the structural lateral displacements. This work aims to investigate, using static non-linear analysis, the effectiveness of the new EC8 provisions with respect to the former version of EC8 and the current ASCE7. The analyses have been carried out by accounting for the real dimension of beam-to-column joints and their behavior, which was simulated by means of a non-linear spring, properly calibrated against experimental tests. The results show that the structures designed according to the latest draft version of the EN1998-1-1 and those compliant with the North American code have a similar behavior.

Keywords: Seismic design, moment resisting frame steel structures, non-linear analyses, P-Delta effect, extended stiffened joint.

1 INTRODUCTION

Moment resisting frames (MRFs) are largely used for steel multi-story low and medium rise buildings in seismic areas, since they can provide high ductile behavior thanks to the formations of plastic hinges at the ends of the beams and at the base of the column of the base level. [1-13].

However, owing to their large lateral deformability, MRFs are highly sensitive to second-order (P-Delta) effects as well as severely penalized by the verification checks of the drifts at damage limitation state [14]. The current version of EN1998-1-1 [15] recommends to verify the sensitivity of the structures to P-Delta effects by means of the Horne method, where the critical multiplier is estimated considering the secant stiffness of the structure assuming that the theoretical strength is set equal to the design base shear and the corresponding displacement is set equal to the seismic demand given by the equal displacement rule.

On the contrary, in the United States of America (USA), the rules given by the ASCE7 codes [16] account for the design overstrength, and the stiffness is evaluated at a displacement demand computed more efficiently and more accurately than the equal displacement rule adopted in EN1998-1-1. In addition, ASCE7 gives less stringent requirements for the limitations of lateral drifts for MRFs. In lines with this approach, the current draft version of the amended EN1998-1-1 evaluate the Horne secant stiffness accounting for the structural overstrength mainly due to (i) the selection of slightly larger members, (ii) the hardening related to the formation of plastic mechanism, and (iii) the expected strength of the materials, which are larger than the design values. All these aspects clarify the reasons why EC8-compliant MRFs are often overdesigned as shown by Tenchini et al. [17] and Cassiano et al. [18].

Therefore, the second order sensitivity coefficient (defined as θ) is evaluated considering two overstrength parameters. The aim of this work is to investigate, by means pf static non-linear analyses, the effectiveness of the new EC8 provisions with respect to the former version of EC8 and the current ASCE7. Therefore, for each of the investigated design approaches (current EC8, modified EC8 and ASCE7) a set of four MRFs was designed varying the spam length (6 or 8m). Moreover, since the MRF's response is strongly influenced by the beam-to-column joint typologies and behavior, the connections were modelled by a lumped non-linear spring.

The paper is organized into three main parts, namely (1) the introduction of the investigated parameters with the descriptions of the three design approaches; (2) the description of the geometrical features of the examined structures and the modelling assumptions; (3) the discussion of the results.

2 GENERAL SPECIFICATIONS

The current EN1998-1-1 (hereinafter also referred as "EC8-C") recommends to calculate the stability coefficient ($\theta_{EC8\text{-}C}$) for P-Delta effects as follows:

$$\theta_{EC8-C} = \frac{P_{tot} \cdot d_r}{V_{tot} \cdot h} \tag{1}$$

Where P_{tot} is the total vertical loads due to the gravity loads in the seismic loading combination, d_r is the design interstorey drift, V_{tot} is the total seismic shear and h is the interstorey height. If $\theta_{EC8\text{-}C}$ is smaller than 0.1, the second order effects can be neglected at design stage, while if $\theta_{EC8\text{-}C}$ is smaller than 0.2 the calculated internal effects should be magnified by the factor α equal to $1/(1-\theta_{EC8\text{-}C})$. If $\theta_{EC8\text{-}C}$ exceed 0.3 the structure should be re-designed.

The design interstorey drift (d_r) is evaluated as follows:

$$d_{r,i} = d_{s,i} - d_{s,i-1} \tag{2}$$

Where d_s is a structural displacements induced by the design seismic action and is evaluated on the basis of the equal displacement rule by the following equation:

$$d_s = q \cdot d_e \tag{3}$$

Where q is the adopted behavior factor and d_e is structural displacement evaluated by means a response spectrum linear analysis.

According to this method, the displacements are evaluated considering the secant stiffness of the structure by assuming that the ultimate resistance is equal to the design base shear, disregarding either any source of overstrength or the hardening effects associated with redundancy and plastic redistribution. From these considerations a proposal to amended EC8 rule (hereinafter referred as "EC8-M") may be to compute the stability coefficient by increasing the secant stiffness as follows:

$$\theta_{EC8-M} = \frac{P_{tot} \cdot d_r}{V_{tot} \cdot h \cdot \gamma_{ov} \cdot \Omega_d} \tag{4}$$

Where γ_{ov} accounts for the randomness of the yield stress of the steel and Ω_d is equal to $\min(R_{d,i}/E_{d,i})$ being $R_{d,i}$ the plastic resistance of the i-th dissipative component and $E_{d,i}$ is the corresponding design effect.

This criterion is very similar to the proposal by Vigh et al. [19], but it is more stringent because the overall hardening due to the redundancy of the structural system is not considered. The stability coefficient (θ_{ASCE}) recommended by ASCE7 is evaluated according to the following equation:

$$\theta_{ASCE} = \frac{P_x \cdot \Delta \cdot I_e}{V_x \cdot h_{sx} \cdot C_d} \tag{5}$$

Where P_x are the total vertical loads at level x (which perfectly corresponds to the P_{tot} in the European approach), I_e is the importance factor (which is assumed equal to 1 in this study), V_x is the seismic shear force acting between levels x and $x - 1$, h_{sx} is the storey height, C_d the deflection factor (that was assumed equal to 5.5) and Δ the design story drift occurring simultaneously with V_x. With this regard, the design interstorey drift Δ are computed as the largest difference of the displacement δ_x and δ_{x-1}, where δ_x is estimated as follows:

$$\delta_x = \frac{C_d \cdot \delta_{xe}}{I_e} \tag{6}$$

where δ_{xe} is the displacement determined by an elastic analysis.

If the stability coefficient is larger than 1, an amplification factor should be introduced to account for the P-Delta influence in the design analyses. However, θ_{ASCE} should not exceed the θ_{max} defined in Equation (7).

$$\theta = \frac{0.5}{\beta \cdot C_d} \tag{7}$$

Where β can be assumed equal to 1 in a conservatively way.

3 INVESTIGATED STRUCTURES

3.1 Geometrical features

The influence of the second order effects were investigated by the design and verification of six MRFs varying the span length (6-8m) and the method to account for the P-Delta effects. To highlight the influence of the secondary effects' limitation on the design phase, all the

structures were designed according to current Eurocodes (i.e. both the EN1993-1-1 [20] and EN1998-1-1 [15]), with the sole exception of the P-Delta effects. In line with this purpose, cold formed partition walls were assumed, thus being able to separate the structural response from the infill system [21-24].

The first set of structures were designed according to the current EN1998-1-1 (i.e. EC8-C), the second set of structures were designed considering a modification of the actual EN1998-1-1 (i.e. EC8-M) and finally, in the last set of MRFs the P-Delta effects were accounted for according the ASCE7 approach.

All structures have a height of 22m with 6 floors and a constant value of storey height of 3.5m, except for the first level that is equal to 4.5m.

The plane has a rectangular shape, with five MRF bays in the X direction and three bays in the Y direction, with a concentric braced frame (CBF) system in the central bay (see Figure 1). The span length is equal in both directions and was alternatively set equal to 6m and 8m. Both the structural design and verifications were done on a planar MRF system that was extracted from the 3D structure.

The vertical dead load was assumed equal to 4.5kN/m2 and the live loads were set equal to 2kN/m^2. The response spectrum was evaluated considering a peak ground acceleration (PGA) equal to 0.25*g*, soil type B and a damping ratio equal to 2%. In accordance with the EN1998-1-1 riles for seismic design, the torsional effects were taken into account by means of the amplification factor δ, assumed equal to 1.3.

As damage limitation requirement, the maximum interstorey drift (ISD) ratio was fixed equal to 1%, thus assuming non-structural elements fixed in a way so as not to interfere with structural deformations.

The design forces have been calculated by means of response spectrum analyses (RSA), according to EN1998-1-1, where all the vibration modes that contribute significantly to the global response were accounted for.

Full strength extended stiffened end-plate joints, designed according to the procedure described by D'Aniello et al. [25], were adopted for all the investigated structures.

The results in terms of cross section, amplification factor (α), interstorey drift and the design overstrength (Ω_d), are reported in Table 1 and Table 2 for the structures with 6 and 8m span respectively.

Table 2: Design results of the MRFs with span equal to 8m

The influence of the adopted method to account for P-Delta effects can be directly recognised by comparing the design results. Indeed, the structures designed according to EC8-C are characterized by very large values of the magnification factor (α), which is equal to 1.25 in some cases. The EC8-M compliant structures have smaller values of the amplification factor (α), with a maximum value equal to the 1.14. On the contrary, in the cases designed according to the ASCE7 the P-Delta effects can be neglected.

The value of the amplification factor implies an important change in the dimensions of structural members and consequentially in the structural weight, as consistently showed in Figure 3.

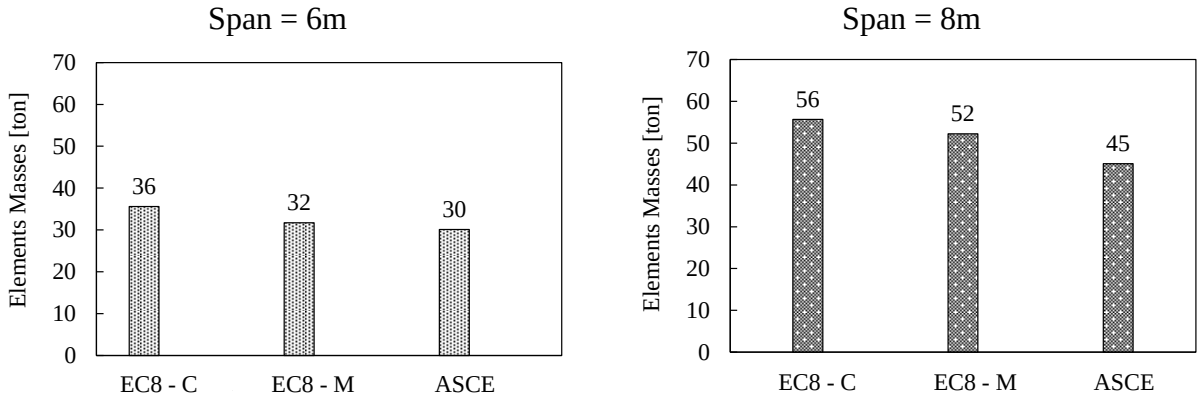

Figure 2 – *Structural weight (expressed in ton) for the frames with span equal to 6m and 8m*

3.2 FEM modelling

All the analyses were conducted on a 2D planar model build in Seismiostruct software [26]. As recommended by EN1998-1-1, the torsional effects were accounted for in the design phase by the introduction of δ (amplification factor), assumed equal to 1.3.

The slab's in-plane rigidity was simulated by the introduction of diaphragm constrains that connect all the MRF bays to the leaning column. The lumped masses at each floor and the concentrated forces, that model the gravity frame loads, are applied on the leaning column that has no lateral rigidity in order for it not to influence the structural lateral stiffness.

All the structural elements were modelled by a force-based (FB) distributed inelasticity elements. These elements account for distributed inelasticity through integration of material response over the cross section and integration of the section response along the length of the element. The cross-section behavior is reproduced by means of the fiber approach, assigning a uniaxial stress–strain relationship at each fiber. The Menegotto-Pinto [27] law was introduced to model the behavior of all steel elements, while the leaning column was modelled by an indefinitely elastic material.

Since their height seismic performance [28-31] extended stiffened joints were introduced in all the investigated structures; the real joint dimensions were modelled by the introduction of the rigid elements connected to the steel profiles by a lumped non-linear spring. that were properly calibrated against the experimental results obtained within the EQUALJOINTs research project (EQUALJOINTs [32], D'Aniello et al. [33]).

4 RESULTS

The pushover results are presented in terms of: elastic stiffness (K), the maximum resistance (V_{max}) and the overall overstrength factor (Ω), which are defined in Figure 3.

The V_{Ed} is the base shear at the design stage and V_y is the base shear at the formation of the first plastic hinge. For the sake of clarity, the overall overstrength factor (Ω) is given by the following ratio:

$$\Omega = \frac{V_{max}}{V_{Ed}} = \frac{V_y}{V_{Ed}} \cdot \frac{V_{max}}{V_y} \tag{8}$$

Where V_y/V_{Ed} is the ratio between force that corresponds to the formation of the first plastic hinge and the design force. The V_{max}/V_y ratio represents the overstrength due to the system redundancy (corresponding to α_u/α_1 the corresponding ratio in the EN1998-1-1).

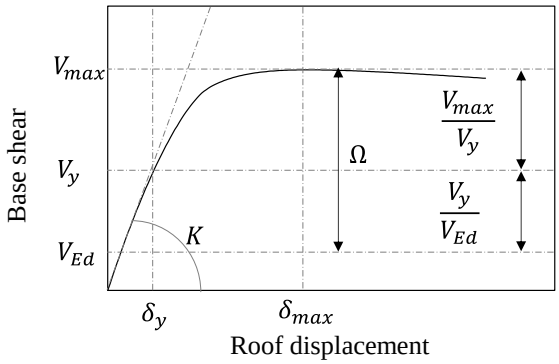

Figure 3: Monitored parameter in the pushover analysis

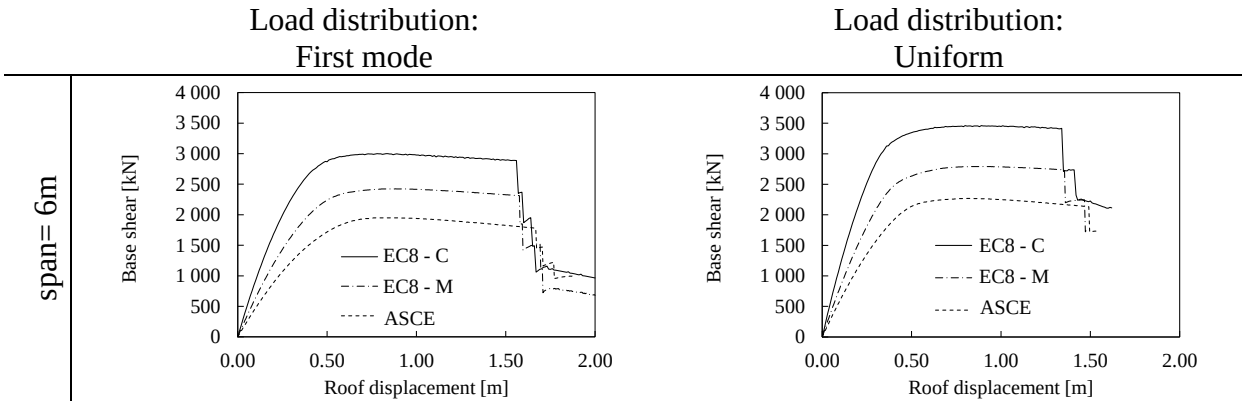
As a general consideration, it can be observed how, independently from the span length (6 or 8m) and the lateral force shape, the pushover results (see Figure 4) show that both the structural resistance and elastic stiffness are strongly influenced by the P-Delta effects limitation. The structures designed according to the current EN1998-1-1 are the stiffer and the more resistant, while, the MRF designed according to EC8-M have intermediate stiffness and resistance between the EC8-C and the ASCE compliant frames.

The shape of the response curves highlights that independently from the lateral force distribution the structures with 6m span exhibit the failure of the plastic hinges that corresponds to the drop in terms of strength and stiffness of the response curves. Contrariwise, most of the structures with span length equal to 8m show the formation of plastic hinges in the columns. In line with the design assumptions, the structures designed according to the current version of the EN1998-1-1 show the larger value of the V_y/V_{Ed} ratio. For instance, comparing the results of the structures with 6m of span subjected to a lateral force proportional to the masses, it can be recognized that the EC8-C structures have a V_y/V_{Ed} overstrength factor 1.22 and 1.58 times larger than the one of the EC8-M and ASCE structures, respectively. These differences are almost the same for all the investigated structures (see Figure 4). Contrariwise, independently from the design approach and the span length, the V_{max}/V_y overstregnth factors are comparable for all the investigated structures and vary in the range 2.10-2.80, values larger compared to the EN1998-1-1 recommendation of 1.3.



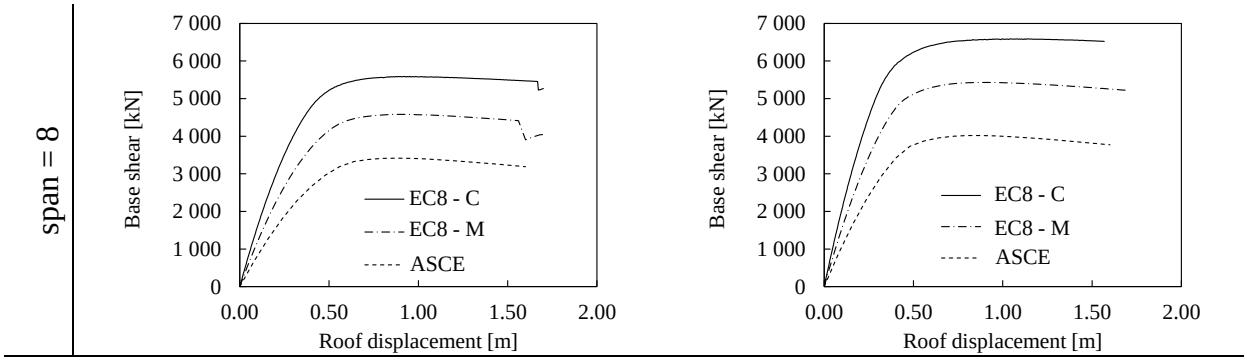


Figure 4: Push over results for both the 6 and 8m spam length structures

Moreover, the shape of the response curves highlights that independently from the lateral force distribution and the span length, the more deformable structures are more sensitive to the P-Delta effects, showing a more pronounced performance degradation.
Differently from the structures with a span length of 8m, where the plastic mechanism involves also the column of the first floor, all the structures with 6m span exhibit the failure of the plastic hinges that corresponds to the drop in terms of strength and stiffness of the response curves.
Regarding the overstrength factor, the structures designed according to the current version of the EN1998-1-1 show the larger values of the V_y/V_{Ed}. This result is consistent with the design assumptions.

5 CONCLUSIONS

- The design limitation on the P-Delta effects strongly influence the MRFs lateral stiffness; therefore, the structures designed according to the actual version of EN1998-1-1 are 1.13 and 1.2 times heavier than those designed according to the EC8-M and ASCE, respectively. This difference increases in the case of the frames with the longer spans (e.g. 8m).
- The pushover analysis confirms that, independently from the shape of the lateral loads and the span length, the structures compliant with EN1998-1-1 are the stiffer and the stronger among those examined. The EC8-C structures have overdesign factors ranging within 2.49-2.93 for 6m and 8m of span, respectively.
- Changing the evaluation method for the P-Delta effects leads to a strong variation of both the lateral stiffness and overstrength; therefore, the structures designed according to the EC8-M and ASCE have an overstrength factor varying in the ranges 1.88-2.40 and 1.58-1.85, respectively.

Abstract

Steel lattice towers are widely used by telecommunication companies to install radiowave dish antennas for the expansion of their network. They are tall highly-optimized structures for which severe weather conditions including low temperatures, snow and high winds are the governing loading conditions. Specifically, high winds in combination with accumulated ice on the members of the structure and the dishes are the leading causes of collapse. The focus is on a standardized model of a telecommunication tower used by major telecommunication companies in Greece. The model is designed according to European Standards for areas located at distances lower than 10km from the coastline. The tower is 48 meters tall, having a square cross-section whose dimensions generally reduce with height and it employs channel and angle steel sections. Non-linear dynamic analyses were performed in order to estimate the fragility of the structure to wind and/or icing conditions. Wind loads were simulated via a 3D wind field fully capturing the spatial and temporal variation of wind speed over the entire profile of the tower for different reference values of wind speed. The impact of ice was assessed by considering a range of different uniformly thick layers of ice that increase the weight as well as the cross-section area of all members and dishes. The ultimate goal of this work is to provide the fragility functions for every potential combination of wind and icing conditions that could be observed during the service life of the structure. Thus, by incorporating the corresponding climactic hazard surfaces, the risk of tower collapse is estimated over its entire projected lifetime, offering a useful decision support tool to telecommunication companies regarding the need to replace or upgrade their existing tower network on a case-by-case basis.

Keywords: Telecommunication Tower, Steel Lattice Structure, Wind, Ice, Fragility

1 INTRODUCTION

Rapid advances in data transmission technology and telecommunications introduce new engineering challenges affecting not only the electromechanical components (e.g. microwave dishes) of a telecommunication network but also the supporting structures. Supporting structures are usually tall highly-optimized steel lattice towers. These structures are vulnerable to weather hazards with wind, low temperatures and corresponding ice accretion being the most critical loading conditions.

Relevant experience, especially from power transmission networks, has shown that storm events may lead to significant damage of steel lattice towers of a network resulting in total collapses with adverse impact for the whole operation of the network, in most of the times associated with considerable long downtime in service and significant economic loss. The above effect of strong winds is further enhanced when ice has accumulated on the exposed members of the structure due to low temperature and/or precipitation (e.g. snow) [1-3]. Under this perspective, the development of a framework for performance based assessment [4] for lattice steel structures used in telecommunication or power transmission networks is essential. The first step towards this effort is the estimation of the fragility of those structures under weather hazards and especially wind and icing conditions [5].

The most critical part for a performance based analysis of steel lattice structures requires detailed and precise calculations of the wind forces acting on the structure. Methodologies for estimation of wind force at lattice structures proposed by current standards (e.g. EN1991-1-4) are mainly based on the solidity ratio of the structure. In cases of a telecommunication tower carrying microwave dish antennas, the shielding effects of the antennas should be taken into account. However, due to the lack of sound guidelines in standards, the estimation of the shielding effects is usually based on wind tunnel tests [6-8].

Considering the above, the purpose of this paper is to present a case study of a telecommunication tower carrying four microwave dish antennas, and designed for coastal areas of Greece according to European standards [9]. The ultimate goal is the estimation of the structure's fragility under possible combinations of wind speed and icing conditions. For this reason, a 3D model was developed in open-source software and a 3D simulation of the wind field was conducted capturing the spatial and temporal variation of wind speed over the entire profile of the structure. Moreover, the impact of ice was assessed by considering a range of various uniformly thick layers of accumulated ice on the exposed tower members and dishes. The estimation of the fragility was based on the processing of the results of a large number of non-linear dynamic analyses via probabilistic methods.

The results could be elaborated for performance-based design and analysis of telecommunication towers. Furthermore, if the fragilities are used in combination with climatic data from the site of installation a risk assessment of this particular type of structure would be possible. This assessment could be valuable to telecommunication companies as a useful decision support tool regarding their needs to replace or upgrade their existing tower network.

2 TOWER MODEL

2.1 Geometry

The main body of the lattice tower of the study is 48 meters tall and has a square cross section [9]. At the top of the tower though, a pyramid that holds the lightning rod is formed and ends at a height of 51m. A complete view of the tower is presented in Figure 1a. The view of the tower can be divided into two main sections. The first section is an inclined one, whose

square cross section reduces with height and runs from 0 to 24m. The second section is a vertical one, which runs from 24 to 48m and has no inclination since it is designed to carry the antennas. The tower has horizontal diaphragms every 3 meters along its height (Figure 1b). It also includes five working platforms at heights of 12, 24, 42 and 45m (Figure 1c). Finally, a ladder and a waveguide rack for the cables of the antennas run connecting the centers of the horizontal diaphragms.

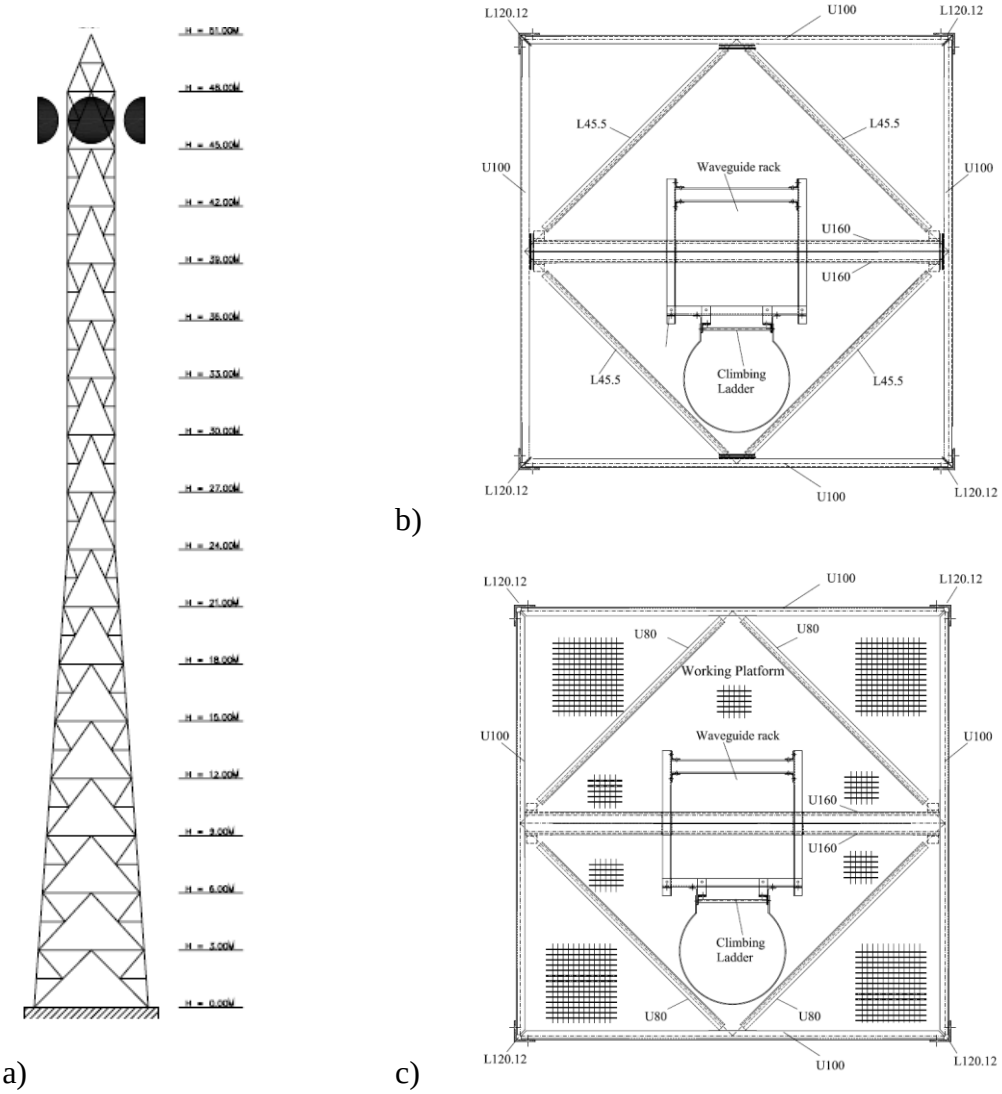

Figure 1: a) Complete view of the tower. b) Typical plan of a horizontal diaphragm. c) Typical plan of a working platform [9].

The structural members of the tower consist of channel and angle steel sections. The members could be characterized as (Figure 2): legs, (main) vertical diagonals/bracing members, secondary vertical bracing members, horizontals, horizontal diagonals and a central horizontal member at each diaphragm which carries the loads of the ladder, the waveguide rack and the cables.

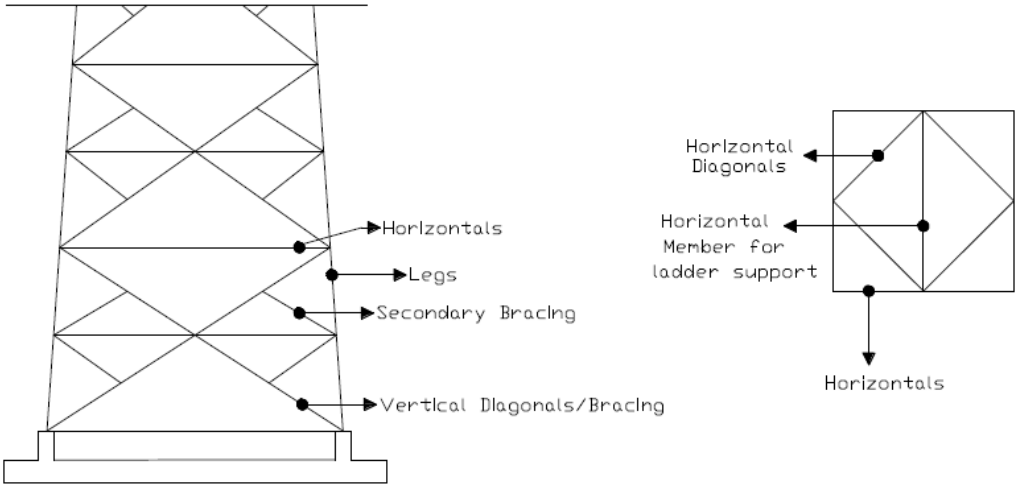

Figure 2: Designation of structural members [9].

As far as the legs are concerned, two types of angle sections were used. Specifically, the legs of the inclined section (height: 0-24m) were constructed from L160.15, while the legs of the vertical section (height: 24-48m) were constructed from L120.12. For the main vertical diagonals, an angle L70.7 section was used throughout the whole height of the structure, while for the secondary vertical diagonals a L45.5 section was used. The horizontal members of each diaphragm were constructed from a channel U100 section. For the horizontal diagonal members an angle L45.5 was used, except for the five levels of the working platforms where a channel U80 section was employed. On the other hand, the central horizontal member of each diaphragm was formed by 2 channel U160 sections welded on both edges. Finally, the members of the pyramid at the top of the tower (height: 48-51m) were made by L70.7.

2.2 Material

The structural steel grade was S355J2K2 for legs and S235J0JR for the rest of the members. At this point it should be noted that since the purpose of this work is not the design but a performance assessment for a lattice telecommunication tower, the real values of steel strength (as estimated by experimental work listed in the literature) were assumed in the analysis, instead of the nominal ones. Specifically, for steel grade S355J2K2, the (mean) yield strength f_y is equal to 454.90 MPa and the (mean) tensile strength f_u is equal to 546.84 MPa. On the other hand, for S235J0JR the corresponding values are 328.80 MPa and 435.41MPa, respectively [10]. The material stress-strain curve that was assumed in the analysis is presented in Figure 3. The value of E corresponds to steel Young's Modulus and is equal to 210 GPa, while the the buckling reduction factor χ was calculated for each structural member according to EN 1993-1-1 [11] to reduce its compression strength. Since the members of the tower have different properties according to their cross-section, the stress-strain curve is different for each member and thus Figure 3 presents only the general form of the stress-strain curve for all members.

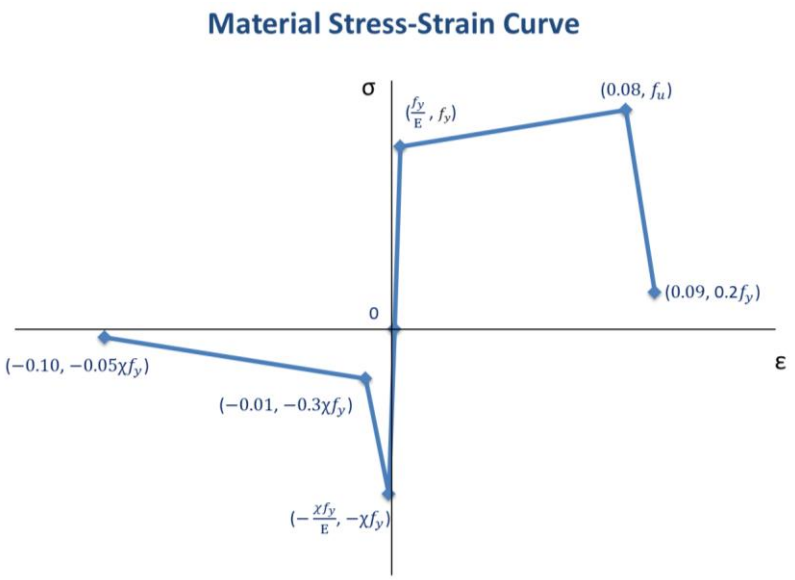

Figure 3: General form of a member stress-strain curve

2.3 Loads

2.3.1 Gravity loads

The unit weight of steel is equal to 78.50 kN/m^3. The weight of the climbing ladder is 15.30 kN and the weight of waveguide rack 14.60 kN. Four dish antennas are installed at the top (height 45-48m) of the tower. Each dish antenna has a weight of 2.30 kN. The weight of the cables is assumed to be 0.05 kN/m per dish. Finally, the weight of the five working platforms is 0.25 kN/m^2.The live load of the climbing ladder is 5.00 kN, while the live load at the working platforms is assumed to be 2.00 kN/m^2.

2.3.2 Wind loads

In the case of a telecommunication tower with dish antennas, the total wind force acting on the structure consists of two main components, namely the force acting on the tower (i.e. the structural members) and the force acting on the dish antennas [6,8,12]:

$$F_T = F_{tower} + F_{antennas} \quad (1)$$

Wind Force at the tower

The wind force acting on the tower is calculated by the Equation:

$$F_{tower} = qC_D A_{ref} \quad (2)$$

where: q is the dynamic pressure of the wind, C_D is the drag coefficient and A_{ref} is the area of the members projected normal to the level of the wind.

The dynamic pressure of the wind q depends on the air density ρ and the wind speed u and is estimated using the following Equation:

$$q = \frac{1}{2}\rho u^2 \quad (3)$$

Herein, ρ was assumed to be equal to 1.225 kg/m^3.

The drag coefficient C_D for lattice steel structures depends on the solidity ratio φ. According to EN1991-1-4 [13], the solidity ratio φ is the fraction of the sum of the projected area A

of the members of the structure's face normal to that face divided by the total enclosed area A_c by the face's boundaries projected normal to that face. Thus:

$$\varphi = \frac{A}{A_c} \tag{4}$$

In this work, the structure was divided into sixteen segments (every 3 m) along its height considering each horizontal diaphragm to be at the middle of the segment. For each segment the solidity ratio was calculated and the corresponding drag coefficient was estimated based on [13]. Finally, the forces of each segment were assigned to the level of the corresponding diaphragm.

Wind Force at the dish antennas

According to [12], the commonly used practice in the past for the estimation of the wind force on dish antennas was to calculate the drag coefficient of the isolated antenna, then the corresponding force, and finally adding the result to the force of the tower as calculated by Eq. (2). However, this practice would overestimate the total force since the antenna may shield part of the tower. This is also evident in case of multiple antennas installed on the tower. For this reason, except for the drag coefficient of the isolated antenna, an additional interference factor should be added in the estimation. Thus the wind force, in case of two identical in size antennas installed on the same height at the tower, is calculated as follows [6, 8]:

$$F_{antennas} = qA_a(C_{Da_1}f_{a_1} + C_{Da_2}f_{a_2}) \tag{5}$$

where: q is the dynamic pressure of the wind, A_α is the area of each antenna projected normal to the level of the wind, $C_{D\alpha 1}$ and $C_{D\alpha 2}$ are the drag coefficients for the two isolated antennas and $f_{\alpha 1}$ and $f_{\alpha 2}$ are the corresponding interference factors for each of the antennas.

The values of the drag coefficients and the interference factors of the antennas are mainly based on the wind angle and the solidity ratio. Those values are usually estimated experimentally [6-8]. Herein, in lack of experimental results for the tower and the antennas, proposed values by an experimental study of a similar case [8] for $C_{D\alpha 1}$, $C_{D\alpha 2}$, $f_{\alpha 1}$ and $f_{\alpha 2}$ were adopted.

2.3.3 Ice Loads

Apart from wind, another environmental hazard that should be taken into account is ice. In the case of a lattice telecommunication tower, ice accumulates on the surface of the structural members and the dish antennas. Ice accretion affects the loads of the structure in two major ways. First, the weight (i.e. dead load) of the members and the dish antennas increase and secondly, the projected area of the members and the antennas also increase. Following the previous section, where the estimation of the wind loads was discussed, it can be inferred that an increase in the projected area of the members affects the solidity ratio of the tower and the corresponding drag coefficients resulting in a larger wind force for the same wind speed value.

In this work, it was assumed that an ice layer of uniform thickness was formed on the surface of the exposed parts of the members and the dish antennas. In terms of the value of the ice thickness, three scenarios of different values were considered, namely 15mm, 30mm and 45mm. For each of those icing scenarios, the corresponding areas of the ice surface and the associated values of the affected parameters (e.g. weight, solidity ratio etc.) were estimated. Finally, it should be noted that the unit weight of ice was considered equal to 7.00 kN/m^3.

3 ANALYSIS

3.1 OpenSees model

For the analysis, the tower was modeled in OpenSees, an open-source software, provided by Pacific Earthquake Engineering (PEER) Center [14]. The final 3D model (Figure 3) was composed by 932 members, both trusses and beams. The members were also modeled as fiber sections sharing the same properties of the corresponding steel cross-sections used in the structure. In total, four different versions were analyzed, one for no icing conditions and one for each of the three different scenarios of ice thickness as presented in a previous section.

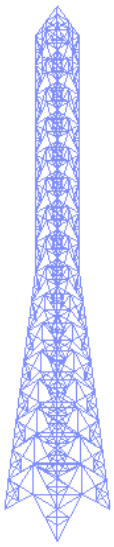

Figure 3: 3D model created in OpenSees.

The natural frequencies of the structure were determined by a modal analysis. The first two modes have the same period due to structure's and loads symmetry, although refer to different directions (X and Y). The third mode is torsional.

Modal analyses were also performed for each of the icing scenarios. Table 1 presents the periods of the first three modes for each scenario. The results show, as expected, that as the thickness of the ice layer increases, the corresponding periods increase. Certainly, this should be attributed to the increase of the tower (and dish antennas) mass.

Ice Thickness (mm)	T_1 (sec)	T_2 (sec)	T_3 (sec)
15	0.901	0.901	0.305
30	1.108	1.108	0.370
45	1.316	1.316	0.436

Table 1: Natural periods of the first three modes for the three icing scenarios considered.

3.2 Wind speed simulation

3.2.1 Wind speed profile

Wind speed increases with height following a specific pattern known as wind speed profile. Herein, a power law wind speed profile was considered. According to the power law profile, the value of wind speed at a height z is given by:

$$\frac{u}{u_{ref}} = \left(\frac{z}{z_{ref}}\right)^{a} \tag{6}$$

where: u is the wind speed at height z (in m/s), u_{ref} is the wind speed at a reference height z_{ref} (in m/s) and α is the power law exponent. In this work, a power law exponent α=0.20 was used, as proposed by IEC 61400-1 [15] for onshore structures. Eq. (6) gives the values of the wind speed along the height of the tower. Herein, the values of wind speed at the heights of the horizontal diaphragms and the center of the dish antennas were calculated. Based on these values, the wind force along the height of the tower is estimated by applying Eq. (1) and Eq. (2).

3.2.2 Wind field simulation

The simulation of the wind field where the tower is placed was performed in TurbSim software [16]. TurbSim has been developed by National Renewable Energy Laboratory of the USA and is mainly used in wind industry applications. The software simulates a 3D wind field. TurbSim can also generate timeseries of wind speed over a user-defined period (e.g. 10 min, 1 hour etc.) and for a specific wind speed value which is considered to be the mean wind speed (reference wind speed). The wind field is defined by a custom grid whose dimensions and resolution are specified by the user. The software finally outputs the corresponding timeseries of the values of the three wind speed components (for each of the three directions X, Y, Z) at the points of the grid of the wind field. For each of those components the corresponding wind force timeseries (mainly for the directions X and Y, since the component of direction Z is ignored in this study) were estimated by applying Eq. (2) for the wind force at the tower and Eq. (5) for the wind force at the antennas.

3.3 Pushover analysis

As a first step before the nonlinear dynamic analysis, a pushover (nonlinear static) analysis was performed in order to specify the failure mechanisms of the tower. The lateral load profile considered in the pushover was following the pattern of the wind force. Pushover analysis was conducted for no ice conditions and the three scenarios of icing. In all cases, the failure mechanism revealed a cascading effect shown in Figure 4. It is evident that the first member failure occurs at the point of the tower where the inclination of the legs changes to vertical, a change which also coincides with the change in the legs' cross-section from L160.15 to L120.12. The first element that fails could be either a leg or a main vertical bracing member (marked with a red circle in the figure). As lateral loads increase, the failure cascades to other elements resulting finally in a total collapse.

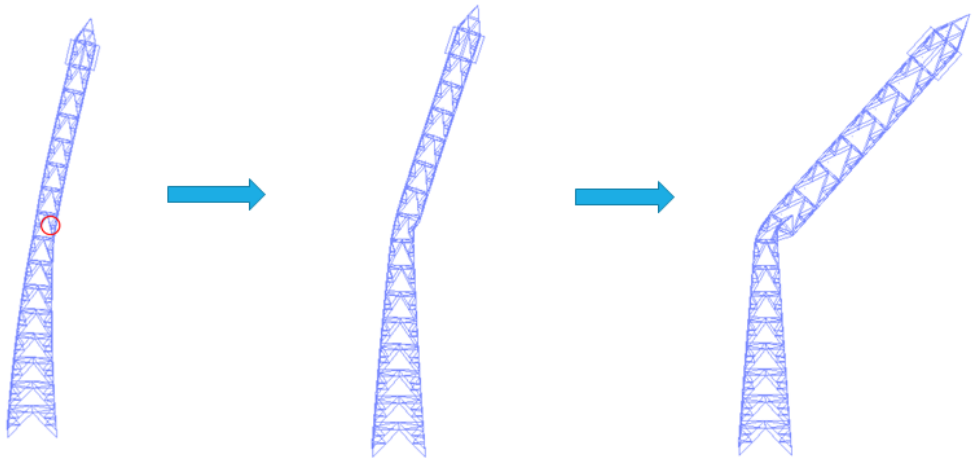

Figure 4: Failure mechanism as revealed by pushover analysis

Figure 5 presents the pushover curves for each of the four versions of tower (no ice and icing scenarios). The horizontal axis depicts the displacement of the top of the tower along the lateral loads direction, while the vertical axis depicts the shear force at the base of the tower. The curves show that the maximum shear force (i.e. the shear force when the first failure occurs) is approximately the same for the four versions and close to 470 kN. The corresponding displacement of the top (height 51m) at the time of the first failure is approximately 0.68 m in all versions.

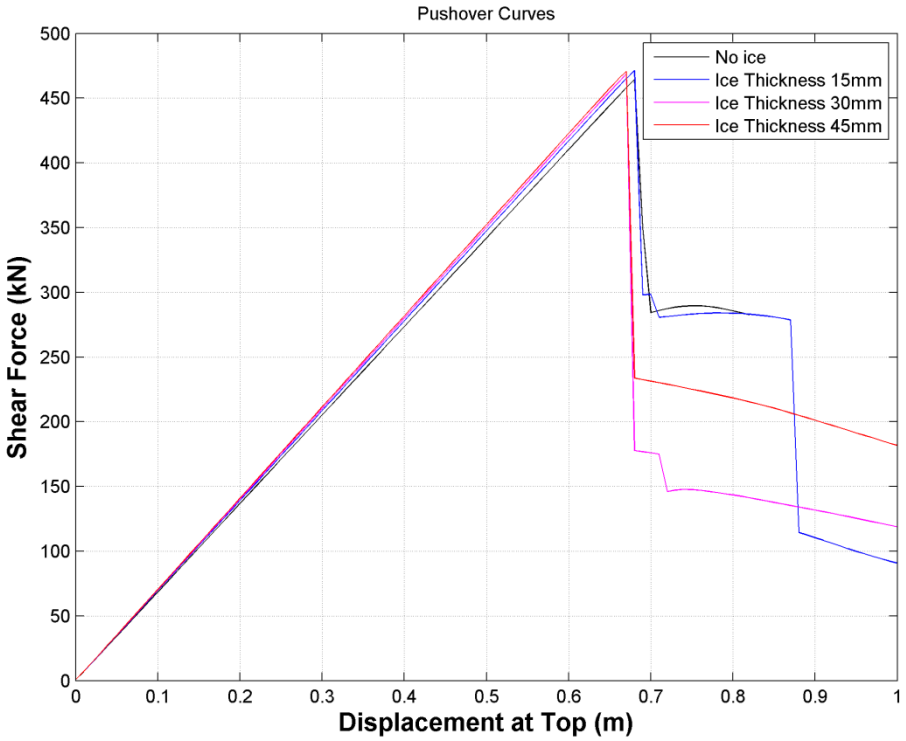

Figure 5: Pushover curves for each of the four versions of ice thickness considered.

3.4 Dynamic analysis

The main input for the nonlinear dynamic analysis was the timeseries of the wind speed created in TurbSim software as discussed above. Thus, the wind speed value (i.e. the wind speed profile) was estimated for specific points at the heights of the horizontal diaphragms of the tower. Figure 6 presents a typical form of the wind speed timeseries at the level of the top horizontal diaphragm (height 48m). The length of the timeseries was 1 hour (3600 seconds).

The next step of the analysis was to estimate the timeseries of wind force along the height of the tower (i.e. the wind force profile). The estimation was done by processing the results of the timeseries of wind speed and performing the necessary calculations by applying Eq. (1) along the two horizontal directions (X and Y). Thus, the wind force profile for the two horizontal directions was created. Those values constituted the inputs of the dynamic parameters for the OpenSees software where the dynamic analysis was performed.

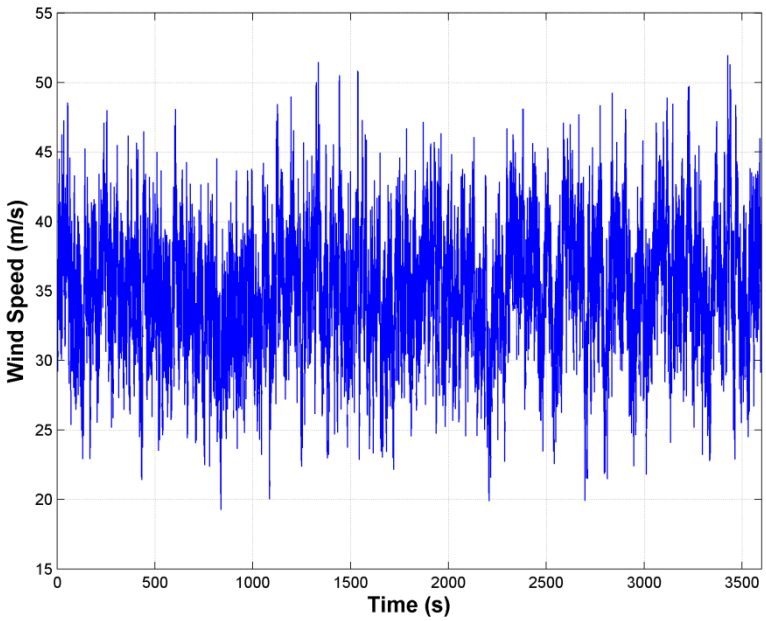

Figure 6: Typical form of 1hr wind speed timeseries (reference wind speed 35 m/s).

In an attempt to reduce computational effort and time, only five different values for wind speed with a horizontal angle of 0 degrees (i.e. parallel to X axis) were considered, namely 20, 25, 30, 35 and 40 m/s. Those values were actually the reference values of wind speed (constituting the inputs for TurbSim software) and their height was the height of the top horizontal diaphragm (height 48m). Moreover, for each of the above values, six timeseries were created resulting in a total of 5×6=30 different timeseries of wind speed. Consequently, 30 different wind dynamic analyses were performed in OpenSees software for each of the four tower versions (no ice conditions and the three icing scenarios) considered in this work. Finally, it should be noted that the same 30 timeseries of wind speed were used for the four versions in order the final results to be comparable. However, the resulting wind force timeseries were different since wind force is affected by ice thickness.

3.5 Fragility analysis

The ultimate goal of this work was to estimate the fragility of the tower to wind and/or icing conditions. Fragility could be defined as the probability of failure for a given intensity measure (*IM*), herein the value of wind speed. The results of such an analysis are reported in the form of fragility curves. The estimation of the fragility functions and corresponding curves is based on the probability of failure for the various values of the *IM*, i.e. the wind speed in this case. A common assumption is that the fragility curve is defined by a lognormal cumulative function (CDF) with the following mathematical expression [17]:

$$P(C|IM = x) = \Phi\left(\frac{ln(x/\theta)}{\beta}\right) \tag{7}$$

where: $P(C|IM=x)$ is the probability that a value of the *IM* (e.g. the wind speed) equal to x will cause a failure of the structure, $\Phi(\ )$ is the standard normal cumulative distribution function (CDF), θ is the median of the fragility function which corresponds to the value of *IM* with 50% probability of failure and β is the standard deviation of *lnIM*, sometimes referred to as dispersion of *IM*.

A simple method to estimate fragility is by performing stripe analysis. Stripe analysis is mainly applied when discrete values of *IM* are used, as in the case of this work. The first step of the process is to perform a number of dynamic analyses for each value of the *IM*, namely the wind speed, and then estimate the number of cases where a failure was occurred. Then for each wind speed the fraction of analyses causing failure could be estimated by simply dividing by the total number of analyses. This fraction is actually an estimator of the probability of failure for the corresponding value of the *IM*.

In this work, six dynamic analyses were performed for each of the five different reference values of wind speed based on the wind speed timeseries discussed in a previous section and for each of the four versions of tower considered. Finally, a failure was assumed that occurs in two ways. First, when the mean value of the inter-story drift during the first 10 minutes of the analysis is different from the corresponding mean value of the last 10 minutes of the analysis. Secondly, if the dynamic analysis was failed (i.e. it was incomplete) due to non-convergence of the algorithm used by the OpenSees software.

Figure 7 shows the stripe analysis results for no ice conditions. A blue circle denotes a non-failure result of the dynamic analysis. A red triangle denotes a failure result of a converged dynamic analysis, while a black asterisk denotes a non-converged dynamic analysis. Following the results of Figure 7, the estimation of the probability of failure for each combination of wind speed and ice thickness can be estimated by simply calculating the fraction of analyses causing failure, as presented in Table 2.

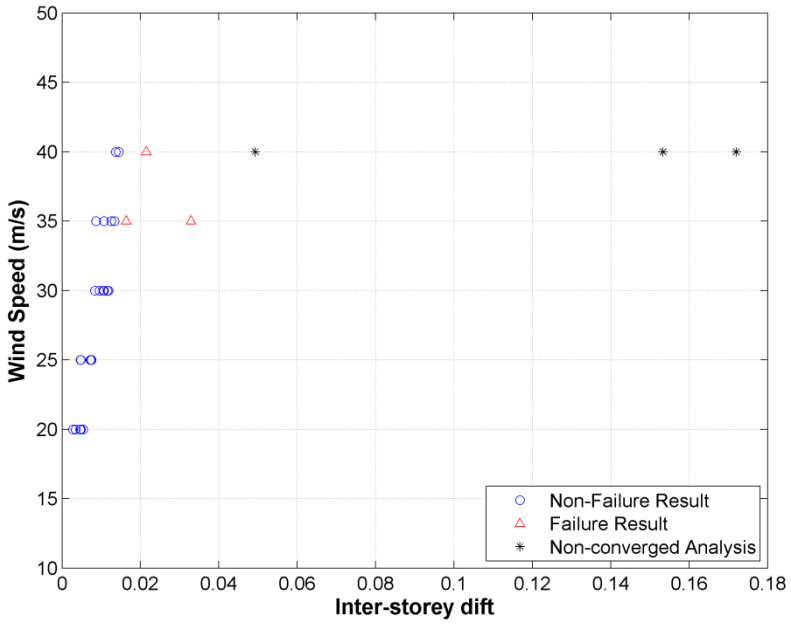

Figure 7: Stripe analysis for no ice conditions.

Wind Speed (m/s)	No Ice	Ice thickness 15 mm	Ice thickness 30 mm	Ice thickness 45 mm
20	0.00	0.00	0.00	0.00
25	0.00	0.00	0.00	0.17
30	0.00	0.33	0.50	0.33
35	0.33	0.67	0.67	1.00
40	0.67	1.00	1.00	1.00

Table 2: Fraction of analyses causing failure for combinations of wind speed and ice thickness

The next step is to fit a lognormal cumulative function (Eq. (7)) to the values listed in Table 2. The parameters θ and β can be easily estimated by maximum likelihood estimation method as in [17].

Results show that for no ice conditions, the median wind speed (θ) of the fragility function is 37.62 m/s. On the other hand, for ice thicknesses of 15mm, 30mm and 45mm, the corresponding values are 32.28 m/s, 31.48 m/s and 29.55 m/s, respectively. This means that as ice accumulates on the tower, the median wind speed of failure decreases. At the same time, the probability of failure increases, as the thickness of the ice layer increases. The last is also evident if the four fragility curves are plotted on the same graph as in Figure 8. It is obvious that the position of the fragility curve moves to the left as ice thickness increases. This finding should be attributed to the impact that ice has on the structure by increasing both the dead loads and the wind force for the same wind speed.

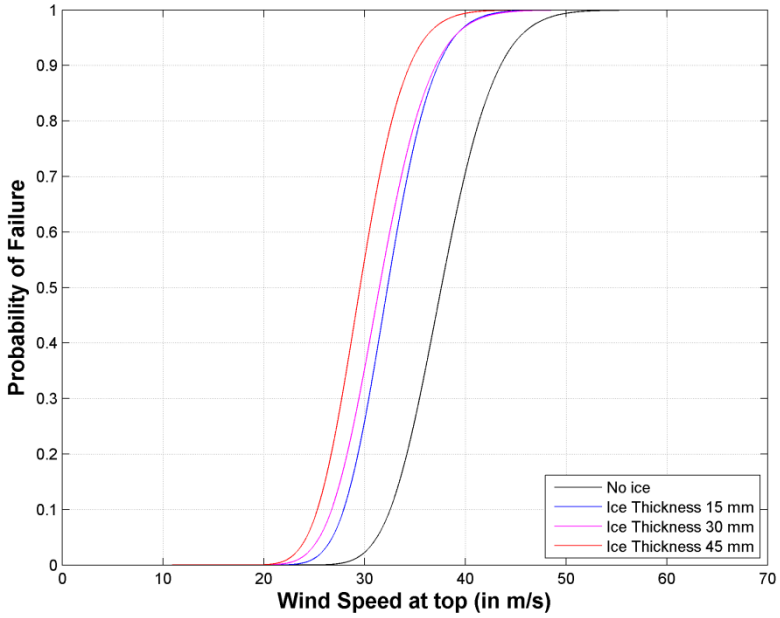

Figure 8: Fragility curves for wind speed and ice thickness combinations

4 CONCLUSIONS

Telecommunication towers are tall steel lattice structures vulnerable to weather hazards. In this paper, a case study of a telecommunication tower carrying four dish antennas and designed for coastal areas of Greece was presented. For the analysis of the tower a 3D model was developed in an open-source software.

A number of nonlinear dynamic analyses of the 3D model of the tower were performed in order to estimate the fragility of the tower to wind and icing conditions. For those analyses, timeseries of wind speed and corresponding force at the structure were created based on a detailed 3D simulation of the wind field along the entire profile of the tower. Furthermore, four different cases of icing conditions were examined by developing the corresponding models. Finally, the fragility of the structure for every combination of wind and icing conditions was estimated and the corresponding fragility curves were created following a probabilistic methodology.

The results confirm the significant effect of wind on steel lattice structures, especially when it is combined with ice accretion. Specifically, the probability of failure (and probably collapse) tends to increase as ice accumulates on the structure for the same wind speed value in comparison with no ice conditions. This finding is in accordance with related literature.

At the end, the elaboration of climatic data from the site of the structure could be proposed as an extension of this work. Based on climatic data, the probabilities of occurrence of all wind and icing combinations over a specified period (e.g. service life of structure) could be estimated. By incorporating these probabilities along with the fragility curves presented herein, one could estimate the risk of the structure over its projected lifetime. This risk estimation could be used as a useful decision tool by telecommunication companies in upgrading and/or expanding their network.

Abstract

Automated Rack Supported Warehouses (ARSW) are the state of the art in storage technology, as they provide substantial savings in terms of cost, space and energy with respect to traditional solutions. Despite their lightness, ARSWs carry very high live loads, by far higher than their self-weight, in contrast to what happens in typical civil engineering structures. Thus, standard design approaches are not applicable, especially when one considers lateral loading, i.e. seismic and wind loading.
In the frame of the STEELWAR project, the behavior factor (q) as well as the seismic fragility shall be assessed for a number of archetype warehouses. FEM modelling for such structures is a tedious task; they consist of hundreds or thousands steel members and nodes connected to each other through simple and semirigid joints. Modern computers accompanied with efficient computational algorithms can handle linear systems with ease and thus, linear analysis can be performed by including all structural components in the analysis model. Problems arise when one considers nonlinear phenomena i.e. material and geometric nonlinearity. Simulations that take into account all ARSW members and their nonlinear response may lead to prohibitive computational costs, while introducing convergence and numerical stability problems. As a direct remedy, a reduced-order physical model is proposed that enables accurate assessment of nonlinear behavior without compromising convergence performance.

Keywords: Simplified models, steel racks, pallet racking systems, automated rack supported warehouses, nonlinear analysis.

1 INTRODUCTION

Pallet rack is a material handling storage aid system designed to store materials on pallets (or "skids"). Although there are many varieties of pallet racking, all types allow for the storage of palletized materials in horizontal rows with multiple levels. Forklift trucks are usually an integral part of any pallet rack system as they are usually required to place the loaded pallets onto the racks for storage.

1.1 Structural Components

The structural design of a warehouse (geometry, materials, cross-sections etc.) varies depending on the material handling system, the designer's preferences and the owner's requirements. However, the following structural components are commonly considered:

a) Upright frame

Also known as built-up column, this component is in-plane with the cross-aisle direction of the warehouse (Figure 1). It consists of two or three vertical elements known as uprights, which are usually made of cold-formed open cross-section. The uprights are connected with diagonal and horizontal bracings typically made of "C" cross-sections, which transfer shear forces by uniaxial compression-tension mechanism. Their assembly strategy defines different upright frame types (D, Z, K, X etc. [1]).

b) Beam

Similarly to steel frames, beams carry the pallet loads and transfer them to the upright frames (Figure 1). Usually, the have connecting claws that ensure a decent connection to the frames without the use of bolts or screws. They are made of hollowed cross-section of high bending resistance and thus, their weakest point is the beam-to-upright connection.

c) Down-aisle vertical bracing

In many cases the loose connection between uprights and beams is not capable to resist the lateral loads and a bracing system is assembled in down-aisle direction. Purpose of this system is to prevent soft-story collapse mechanism [2] and limit the displacements induced by earthquake excitations.

1.2 Automated Rack Supported Warehouses

At present, Automated Rack Supported Warehouses (ARSW) or clad rack warehouses are usually built by manufacturers specialized in structural systems for logistics with the same or similar cold formed profiles used for warehouse storage pallet racks although in the case of ARSW the rack forms the load bearing structure of the whole building by itself.

The research made up to now is mainly limited to steel storage racks which are a much smaller scale of automated warehouses ([3], [4]). Automated storage systems, which will probably be the future of the warehouse sector, have not been investigated to such an extent so far. Moreover, in Europe (and in the world) there is no official reference document specific for the design of Automated high-rise warehouses. Designers are obliged to work with a total lack of specific references and of commonly accepted design rules and procedures. As a result, these structures are vulnerable in extreme load scenarios, such as high wind speeds and seismic actions (Figure 2).

The aforementioned lack of knowledge and bibliography raises the demand for further research. Today, a variety of methods (Pushover, IDA etc.) exist to determine the nonlinear characteristics (overstrength, ductility, energy dissipation) of a structure, which require computationally expensive numerical analyses. By examining the FEA model of an ARSW, it is obvious that a nonlinear simulation of the whole structure is nearly impossible. Objective of

the present paper is to develop simplified models for the representation of complete warehouses in order to check their nonlinear response to seismic motion.

Figure 2: Configuration of a racking system: portal frame (left), upright frame's components (right)

2 MODEL SIMPLIFICATION PROCEDURE

As mentioned before, the full simulation of an Automated Rack Supported Warehouse consists of hundreds of thousands of elements and nodes yielding to an extremely computationally cumbersome model, which is not only hard to be designed in a CAD program, but also nearly impossible to be solved nonlinearly. These problems motivate the search for an equivalent model which will be computationally efficient but also respect the behavior of the real structure. The solution suggested in the present papers is to substitute the built-up columns and the roof for simple beam elements whose degrees of freedom will be way lesser.

2.1 Elastic Properties of equivalent beam element in Cross-Aisle direction

The stiffness matrix of a prismatic homogeneous two-dimensional beam element with doubly symmetric cross-section depends on the material properties (i.e. E and G), length, cross-section area, moment of inertia and shear area. It is worth mentioning that shear deformation is usually neglected because in beams with typical lengths and cross sections this phenomenon is insignificant. However, in the case of upright frames, the "cross section" does not

remain perpendicular to the neutral axis [5] and so shear must be considered (Figure 3). If one neglects the effects of shear deformation, the equivalent element may be 10 to 30% more stiff, depending on the characteristics of the structure and the distribution of loads. Moreover, compatibility of deformations leads to fixed restraints on the equivalent beam.

Obviously, the equivalent element is made of the same material and has the same length, thus:

$$\begin{aligned} E_{eq} &= E \\ G_{eq} &= G \\ L_{eq} &= L \end{aligned} \tag{1}$$

Cross-section area of the simplified column is equal to the sum of upright's cross-section areas:

$$A_{eq} = \sum_{i=1}^{N} A_i \tag{2}$$

, where N is the total number of uprights and A_i is the cross-section area of i-upright.

In general, the equivalent moment of inertia of a built-up column consisted of N uprights is given by:

$$I_{eq} = \sum_{i=1}^{N} A_i \cdot h_i^2 \tag{3}$$

, where h_i is i-upright's distance from the center of gravity. For example, the upright frame shown in Figure 4 has moment of inertia equal to:

$$I_{eq} = A_c \left(-\frac{h_0}{2} \right)^2 + A_c \cdot 0 + A_c \left(\frac{h_0}{2} \right)^2 = A_c \frac{h_0^2}{2}$$

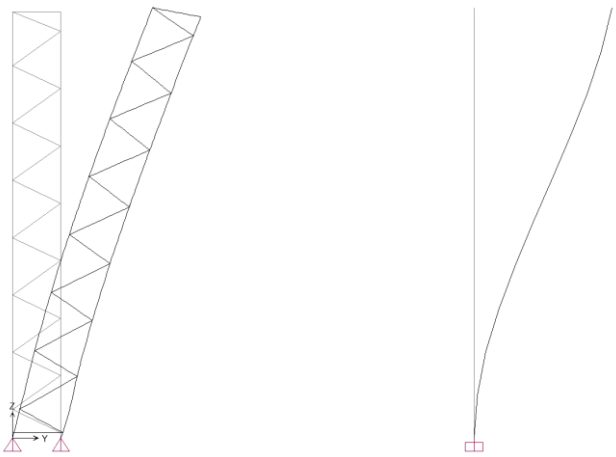

Figure 3: In built-up columns (left) "cross sections" do not remain perpendicular to the neutral axis. This effect must be considered when assigning equivalent element's properties (right)

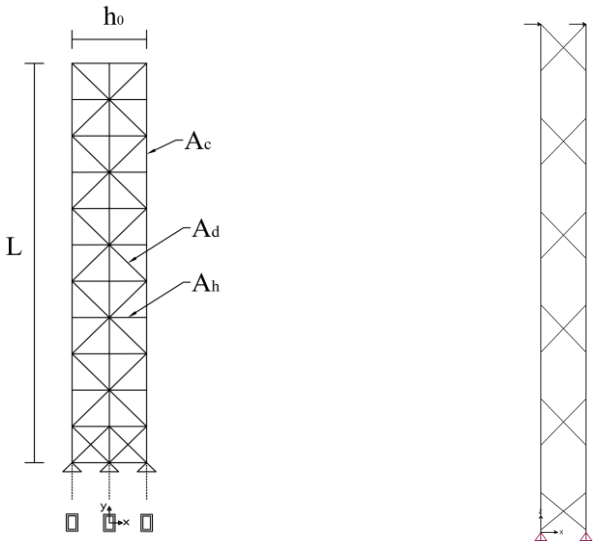

Figure 4: Example of a X-type column with 3 uprights (left) and an upright frame with arbitrary bracing (right)

Finally, shear area depends on the geometry and the type of the upright frame (X, D, Z and K systems. Closed form solutions can be easily derived for common systems, by considering a segment of the upright frame and enforce static equilibrium [6]. However, in the case of arbitrary bracing configuration like the one shown in Figure 4, no formula exists for the calculation of shear area. In order to overcome this difficulty, the following approximate procedure is introduced:

1. Isolate the column under consideration and pin the nodes at one end.
2. Apply a point load at the free end. If P is the applied load, then the corresponding displacement of the free end δ_{tot} is given by:

$$P=\frac{12}{4+\Phi}\frac{EI_{eq}}{L^3}\delta_{tot} \tag{4}$$

, where $\Phi=\frac{12EI_{eq}}{GA_{eff}L^2}$

3. Solve Eq. (4) for A_{eff} :

$$A_{eff}=\frac{P(3EI)L}{(3EI)\delta-PL^3}/G \tag{5}$$

2.2 Elastic Properties of equivalent beam element in Down-Aisle direction

In down-aisle direction the uprights of an upright frame are independent and thus they behave as springs in parallel. This assumption is valid as the bracings are commonly pinned to the uprights. As a result, we aggregate the moment of inertias of all uprights:

$$I_{eq,DA}=\sum_{i=1}^{N} I_{i,DA} \tag{6}$$

, where $I_{i,DA}$ is i-th's upright moment of inertia in down-aisle direction. Moreover, if the uprights are assumed partially fixed to the base plate by employing rotational springs, the sum of their stiffnesses has to be applied on equivalent beam's restrained end.

	Z-COLUMN SINGLE	**Z-COLUMN DOUBLE A**	**Z-COLUMN DOUBLE B**
			Nº uprights	2	3	3
A_{eq}	$2A_c$	$3A_c$	$3A_c$
I_{eq}	$A_c \frac{h_0^2}{2}$	$2A_c h_0^2$	$2A_c h_0^2$
A_{eff}	$\frac{\frac{EA_d}{G}\frac{h_0^2}{d^2}\frac{a}{d}}{1+\frac{h_0^3}{d^3}\frac{A_d}{A_h}}$	$\frac{\frac{EA_d}{G}\frac{h_0^2}{d^2}\frac{a}{d}}{1+\frac{h_0^3}{d^3}\frac{A_d}{A_h}}$	$2\cdot\frac{\frac{EA_d}{G}\frac{h_0^2}{d^2}\frac{a}{d}}{1+\frac{h_0^3}{d^3}\frac{A_d}{A_h}}$

Table 1: Equivalent properties of X-type columns

2.3 Nonlinear behavior of equivalent beam element

The nonlinear behavior of an upright frame can be distinguished in three main categories:

1. *Axial Failure*. This type of failure refers to flexural, local, distortional and lateral torsional buckling of the uprights [7]. It is common in rack-system technology to perform laboratory tests to evaluate uprights' compression resistance and thus, $N_{rd,upright}$ is usually a known value.
2. *Bending Failure*. Loads are not primarily carried by bending mechanisms, as bracings are considered to be pinned and uprights are usually simply supported to the foundation. However, when vertical bracing system is missing in down-aisle direction, horizontal loading may lead to development of bending moments in the uprights. However, their contribution is usually small with respect to the axial loads.
3. *Shear Failure*. Shear forces are transferred via axial tension-compression mechanism by bracings, which may fail due to buckling or tensile yielding.

The equivalent element must take into consideration all these failure mechanisms. For instance, open-source software OpenSees [8] provides the Two Node Link Elements (aka Link Elements, see Figure 5) with the capability to assign axial, rotational and shear springs.

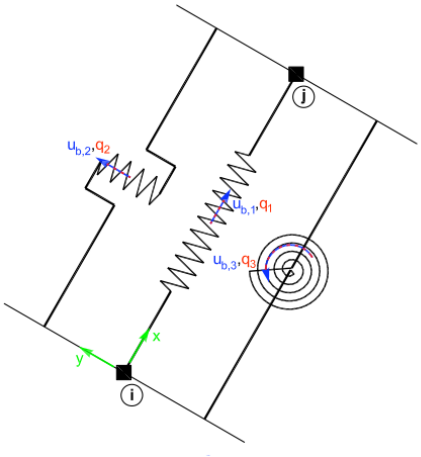

Figure 5: Concept of Two Node Link Element

One important characteristic of the equivalent element is the coupled behavior of the axial and rotational spring. Equivalent element's bending moment M_{eq} is linked to a set of axial forces N_b on the uprights, of opposite direction. As an example, for the Z-type upright frame shown in Figure 6 the following relation holds:

$$M_{eq} = N_b \cdot h_0 \tag{7}$$

On the other hand, equivalent axial force N_{eq} is related to a set of axial forces $N_{eq}/2$ on the uprights, of the same direction. Summing all together, if $N_{rd,upright}$ is upright's compression resistance and N, M the axial force and the bending moment acting on the equivalent element respectively, then the condition for axial failure is (same formulae can be derived for any number of uprights):

$$N_{rd,upright} = \frac{N_{eq}}{2} + \frac{M_{eq}}{h_0} \tag{8}$$

Eq. (8) indicates a linear interaction between moment and axial force of the equivalent element, which is conceptually illustrated in Figure 7.

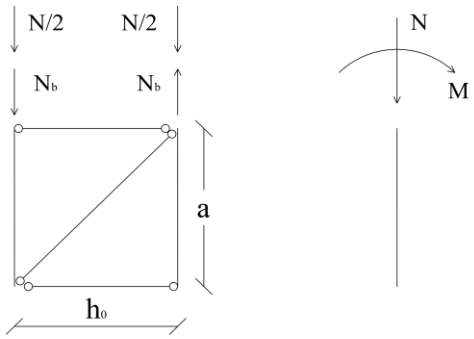

Figure 6: Relation between axial forces and bending moments of the two models

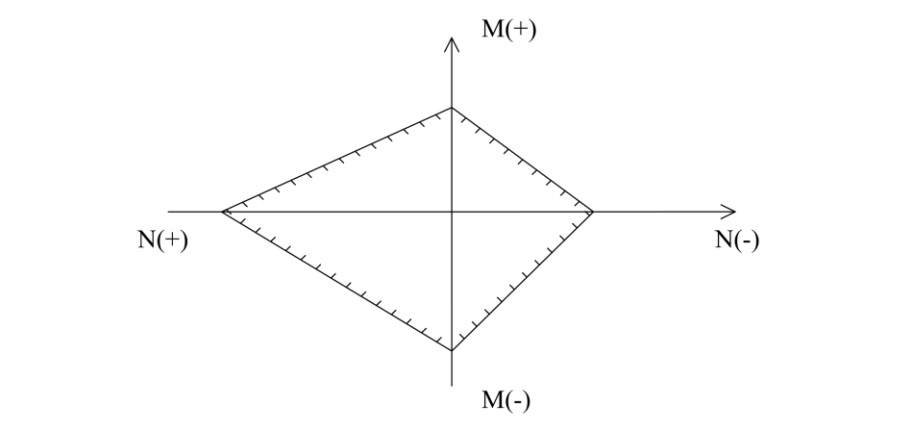

Figure 7: Interaction between the bending moment and axial force of the equivalent element

An important factor that dominates the nonlinear behavior of an upright frame in seismic loading is bracings' failure, as indicated in [9]. These structural components are responsible for the transfer of seismic shear forces to structure's foundation. If V_{eq} is equivalent element's shear force and $N_{rd,bracing}$ the axial resistance of the diagonal bracing shown in Figure 6, then failure occurs when:

$$N_{rd,upright} = \frac{V_{eq}}{\cos\varphi} \tag{9}$$

, where $\cos\varphi$ is the angle between upright and bracing. Eq. (9) holds for Z-type upright frames with two uprights, but it can be extended for any system.

Concluding, the substitution of an upright frame for simple beam elements does not reduce model's capabilities to simulate any type of structural failure. OpenSees' Link Elements comprise of two rigid linear segments and three or six springs in the center for 2D and 3D analysis respectively. These springs have to produce the same stiffness matrix as the classic finite beam elements. Table 2 shows the stiffness of each spring for the 2D case.

Type of beam	**EULER-BERNOULLI**	**TIMOSHENKO**
Axial Spring	$\frac{EA}{L}$	$\frac{EA}{L}$
Shear Spring	$\frac{12EI}{L^3}$	$\frac{1}{1+\Phi}\cdot\frac{12EI}{L^3}$
Bending Spring	$\frac{EI}{L}$	$\frac{EI}{L}$
P-delta input value (OpenSees users)	-0.1	$\frac{-0.1}{(1+\Phi)^2}$

3 ANALYSIS OF AN ARSW FRAME WITH SHEAR FAILURE

The nonlinear behavior of a single ARSW frame is examined in static and dynamic analysis. The uprights are class 1 steel sections and thus not expected to participate in structure's failure mechanism. This test case focuses solely to shear failure of the simplified model or equivalently to bracings' failure.

3.1 Configuration of test case and structural characteristics

The ARSW frame under consideration (geometry illustrated in Figure 8) consists of 2 external single X-type upright frames and 4 internal double X-type upright frames connected to a "truss" roof. The section and the material of the uprights and diagonal bracings vary in height while the horizontal bracing has constant properties (see Table 3 for more details). The roof is comprised of double angle sections 45x45x4 with steel grade S355.

Regarding the connections, it was assumed that the base plates do not offer additional stiffness and thus the uprights were simulated as pinned to the foundation and the roof. Horizontal and diagonal bracings were also assumed pinned as they are commonly connected to the uprights by 1 or 2 bolts. A common practice in the design of pallet racking systems is to reduce diagonal bracings' cross-section area to take into account the looseness of their connection. The magnitude of this reduction can be quite significant (e.g. 80%) and is verified by experimental shear tests. However, for this particular test case the existence of class 1 uprights and diagonals may lead to the safe assumption that this reduction is negligible and thus it was not considered.

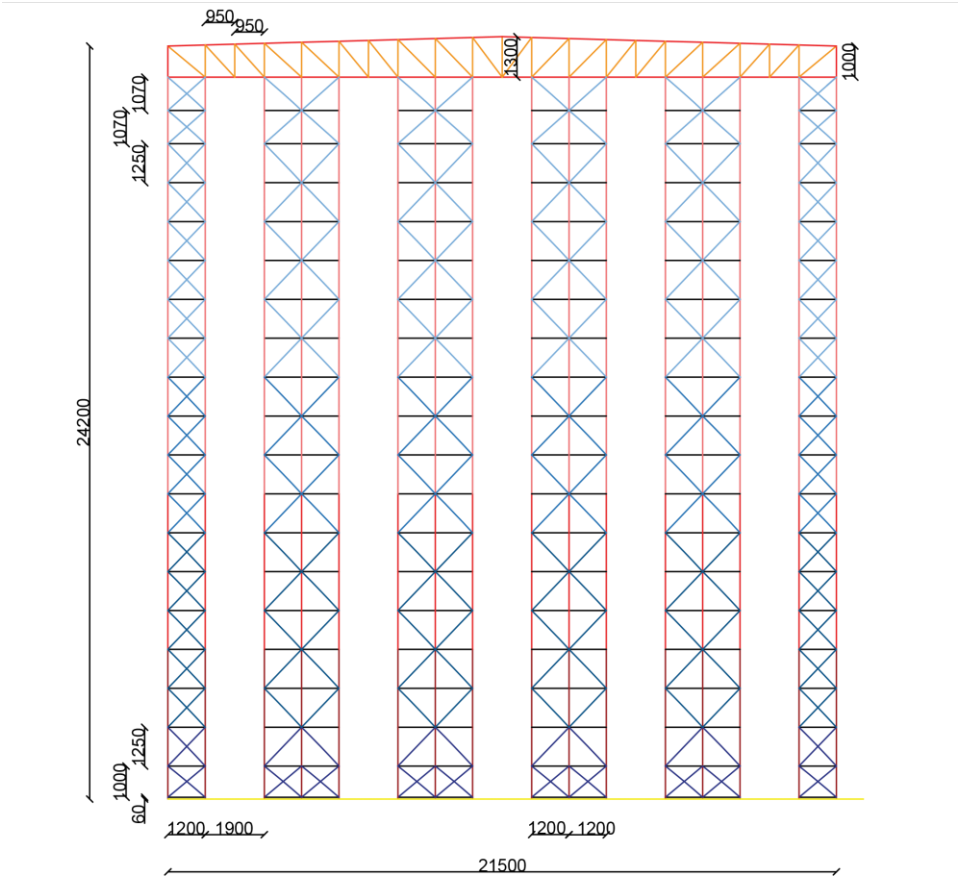

Figure 8: Configuration and geometric properties of ARSW frame test case (units in mm)

Table 3: Cross sections of upright frames. (RHS: Rectangular Hollowed Section, L: Angle, DC: Double Channel)

3.2 Reduced order models

Three models of decreasing accuracy will be examined:

1. *Fiber Model:* All structural members suspected to participate in structure's failure mechanism (i.e. uprights, diagonal and horizontal bracings) are simulated as force-based fiber elements [10] with 3 integration points. Especially for the diagonal bracings in compression, an imperfection L/200 is assumed, where L is the length of the element. For the rest elements classic Euler-Bernoulli beams where used.
2. *Truss Model:* In this case, uprights are assumed to behave linearly (class 1 sections), while the bracings are simulated by nonlinear truss elements. Their material law can be derived by EN1993 formulae or by isolating each bracing, simulate it by fiber elements, perform compression and tension arithmetic tests and use them to find an equivalent stress-strain diagram. For the rest elements classic Euler-Bernoulli beams where used.
3. *Link Model:* Here, an entire upright frame is substituted for a Two Node Link Element that includes shear failure. As mentioned before, Link Elements include axial, rotational and shear springs which may have nonlinear material laws. Here we will mainly focus on the characteristics of the shear spring.

To determine the elastic properties of the Link Elements first we have to substitute the upright frames for elastic Timoshenko Elements, using Eq (1) to Eq (6). Afterwards, spring's elastic stiffnesses can be readily evaluated using Table 2.

Next, the nonlinear behavior of the shear spring will be approximated. In initial configuration (Figure 9), shear forces are transferred through the diagonal bracings, while the horizontal bracing is unstressed due to symmetry. We define $N_{(+)}$, $N_{(-)}$ diagonal bracing's strength in tension and compression respectively and N_h buckling resistance of the horizontal bracing. The following relations hold:

- $N_{(+)} > N_{(-)}$, as in compression buckling phenomena are witnessed.

- $N_h > N_{(-)}$, as $h_0 < d$ and taking into account that horizontal bracing commonly is comprised of equal or even heavier section than the diagonal.

Thus, the first member exceeding its ultimate strength will be the diagonal bracing in compression, which corresponds to a *"yield shear strength"*:

$$V_y = 2N_{(-)} \frac{h_0}{d} \tag{10}$$

Figure 10 shows the failure mechanism of a X-type upright frame. One can claim that the system has transformed from X-type to Z-type and thus the shear area has changed. This will be referred as *"shear degradation"*. Link element's reduced shear stiffness after the degradation will be:

$$k_{y,shear} = \frac{12EI}{\left(1+\Phi_y\right)L^3} \tag{11}$$

, where Φ_y is calculated using the shear stiffness formula for the Z-type columns given in Table 1. Shear spring's *"yield deformation"* is derived by combining Eq (10), Eq (11) and:

$$\delta_y = \frac{V_y}{k_{y,shear}} \tag{12}$$

The upright frame has transformed from a X-type to a Z-type and thus, horizontal bracing is now compressed. The next structural member that will fail depends on their tensile and compressive strength. If $N_h < \cos\varphi N_{(+)} = \frac{h_0}{d} N_{(+)}$, the horizontal bracing in compression will fail first, otherwise the diagonal bracing in tension. Following a similar to Eq. (10), (11) and (12) procedure the complete force-displacement diagram can be calculated for each spring.

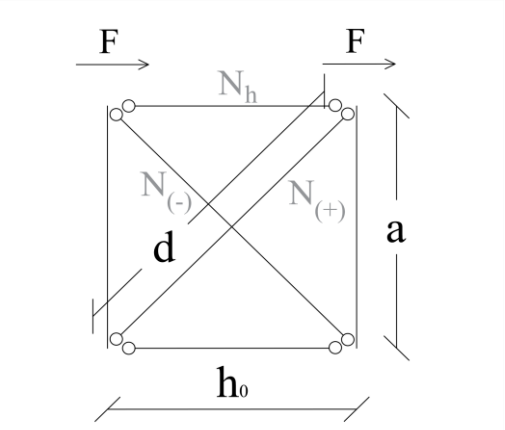

Figure 9: Shear transfer mechanism in initial configuration

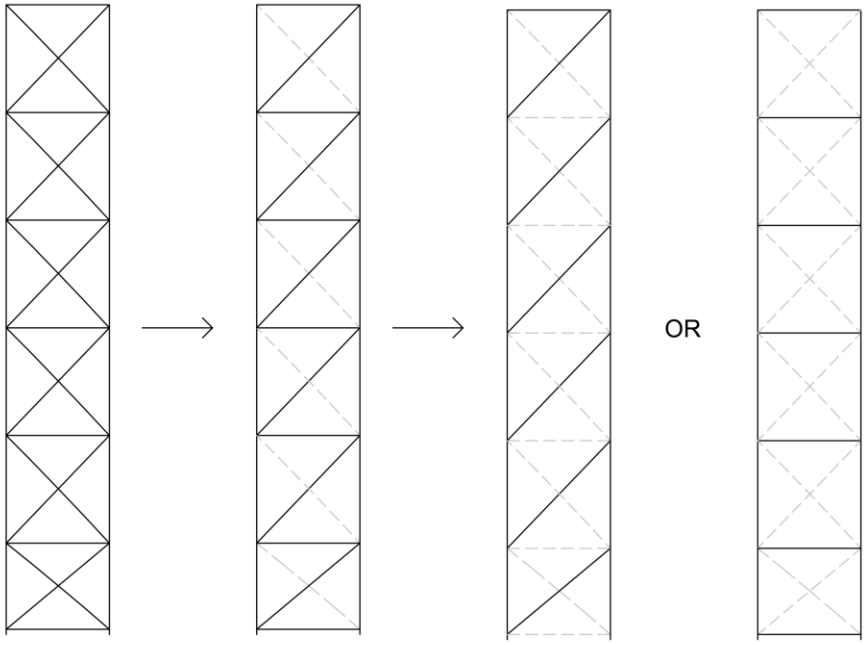

Figure 10: Failure sequence of X-type upright frame's bracing

3.3 Modal Analysis

First, Modal Analysis is performed to validate the Link Model in the elastic region. The masses are assumed to be lumped, of magnitude 10 kN at each level. The results for the five first eigenmodes are shown in Figure 11 and Figure 12. As it is observed, the Link Model predicts well even the higher modes of the system, and so, it is expected to give accurate results in linear dynamic analysis.

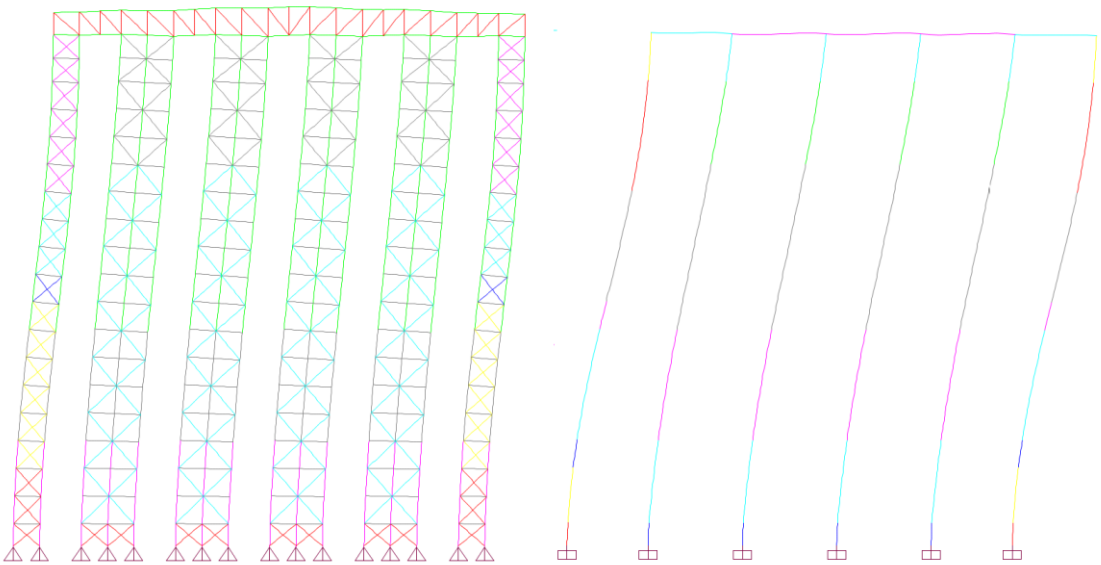

Figure 11: First Eigenmode of Full Model (T1,1=0.775 sec) and Link Model (T1,2=0.784 sec)

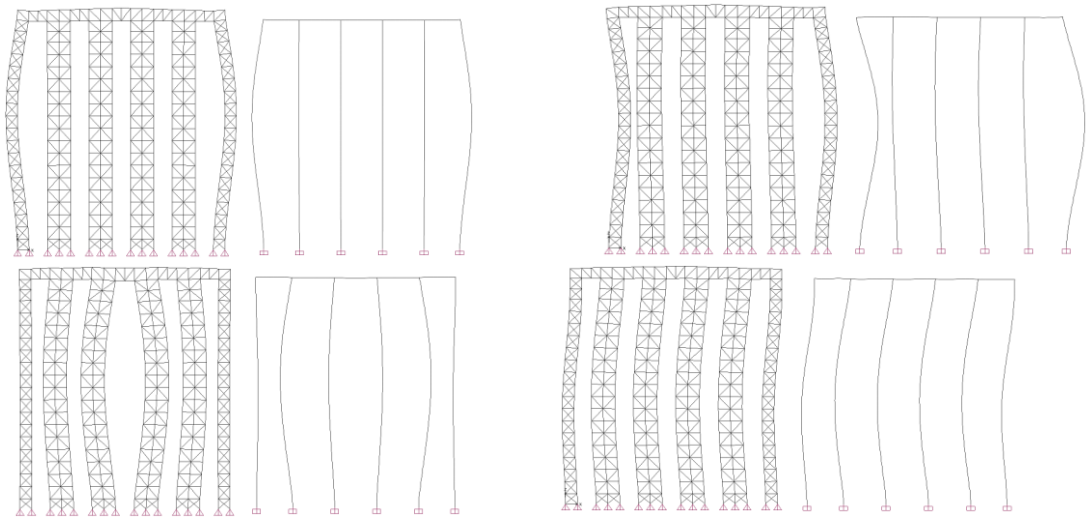

Figure 12: 2nd, 3rd, 4th and 5th mode shapes. 5% maximum relative error

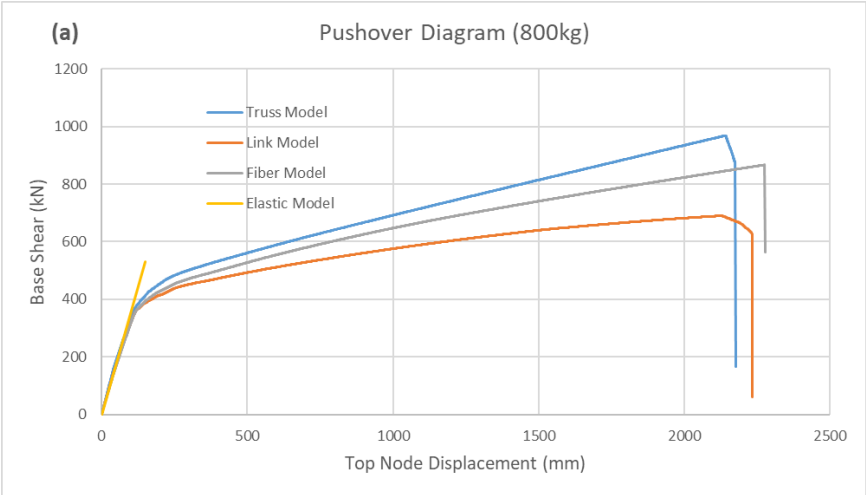
3.4 Pushover Analysis

Next, Static Pushover Analyses were performed for the three models, assuming triangular distribution for the lateral loads. The analyses were executed until the system reached 10% roof drift or stability and non-convergence problems occurred. The Base-Shear vs Top Node Displacement diagrams are illustrated in Figure 13a and Figure 13b for 800 kg and 2000 kg pallet load respectively.

All models respond linearly and elastic until a roof displacement approximately equal to 150 mm is achieved. After this "limit state" is exceeded, the structure is highly nonlinear, and Pushover's slope decreases exponentially. This behavior was attributed to the successive failure of the diagonal bracings in tension. At about 500mm the slope has dropped to 7.2% of the elastic branch for the Link Model, 5.5% for the Truss Model and 7.7% for the Fiber Model. It is mentioned that steel's strain hardening was chosen equal to 5% which is roughly Pushover's residual slope.

Pallet load scenarios 800 and 2000 kg have a vast difference in post-capping behavior. In latter, P-delta phenomena are of major importance and the structure is not able to achieve high ductility and overstrength.



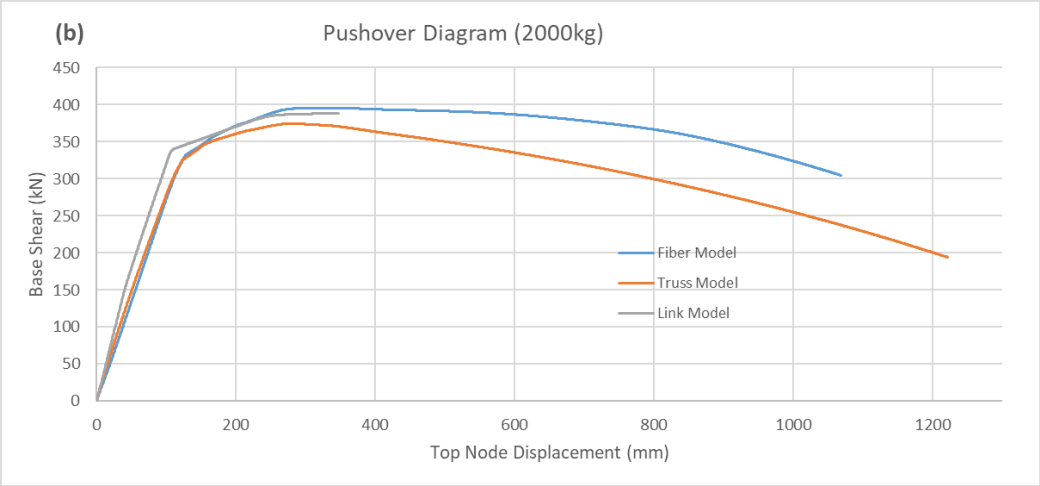


Figure 13: Base Shear vs Top Node Displacement of Pushover Analysis for the three models under examination; (a) 800 kg pallet load and (b) 2000 kg pallet load

3.5 Pushover Analysis

Nonlinear dynamic analyses were executed for the Truss and Link Model, and the time-history results are displayed in Figure 14a to 14d. Structural properties, geometry and distribution of masses were the same as in Pushover Analysis of 800 kg pallet load. In addition, both systems were assumed undamped, and thus residual oscillations are expected. It was observed that the Link Model was encouraging accurate, as it was able to predict adequately well the maximum displacement of the system.

4 CONCLUSIONS

The simplified method developed in present thesis was tested on a 2D Automated Rack Supported Warehouse frame for linear, nonlinear static and nonlinear dynamic analyses. In elastic region, the reduced-order model can predict extremely well even the higher eigenmodes of the real structure. A question remains about Linear Buckling Analysis, as upright's local buckling between bracings cannot be considered.

Concerning nonlinear analyses, the introduced model uses Two Node Link Elements to simulate the nonlinear response of upright frames and Timoshenko Beam Elements for the roof. In this specific test case, uprights were considerably stiff, so they did not participate in structure's plastic mechanism. Thus, we concentrated on bracings' compression and tension failure, which corresponds to shear degradation for the equivalent link element. As it was observed, X-column was "transformed" to Z-type after buckling of the diagonal bracing occurs and the system loses shear stiffness.

Abstract

The application of Fiber Reinforced Polymer (FRP) strips is common for rehabilitation and strengthening of concrete structures. Still, the strengthening of steel profiles with FRPs has received little attention so far. In this direction, three tests were performed on steel plates strengthened with Carbon Fiber Reinforced Polymers (CFRP) at the Institute of Steel Structures, NTUA. They comprised one tensile and two four-point bending tests on composite specimens that consisted of one 3mm thick steel plate and one 1.2mm thick CFRP plate bonded together in order to make a preliminary estimation of the CFRP strengthening effect. The first four-point bending test was performed with the CFRP on the tension side, while the second test employed the CFRP on the compression side of the specimen. Analytical approaches as well as numerical nonlinear analyses using finite elements were employed to gain intuition and further substantiate the results. In conclusion, CFRP strengthening was found to be an effective strengthening method, which enhances ductility, tensile and bending capacity of the steel plate by almost five times, regardless of whether the CFRP is used under tension or compression. Notably, the CFRP plates, despite their slenderness were found to offer considerable resistance to compression stresses.

1 INTRODUCTION

The application of fiber-reinforced polymers (FRP) has been long established in teaching, research, design and regulation for strengthening and repair of concrete structures [1] – [4]. However, such an activity for steel structures is relatively new although strengthening of steel structures by means of FRPs has gained attention in recent times [5]. The main application fields refer to enhancing the moment capacity of steel or composite girders in building/bridge applications [6], [7], increasing the local buckling resistance of thin-walled compression elements [8], repair through crack-patching of fatigue prone details [9], or increase strength and ductility by means of confinement of steel or concrete filled steel tubes [10], [11]. It is therefore not surprising that, at least in Europe, there is a lack of regulations on the subject, except probably an Italian guideline [12], while the European seismic code for assessment and retrofitting of buildings [2] provides information for FRP-interventions in reinforced concrete structures only and not for steel or composite structures.

The potential for structural interventions in steel structures by means of FRPs is high, at least in some areas, despite the fact that conventional interventions with steel for steel structures are easier to implement than with concrete for concrete structures. Indeed, it is simpler to remove and repair damaged steel parts or entire structural members and easier to attach for strengthening purposes new to existing steel through welding or bolting, than remove, repair or strengthen through jacketing existing concrete members. An area where FRP composites might be applied with big advantages is for strengthening of masts and towers, like for telecommunication towers that are often in need of strengthening due to their occupation with more and larger antennas. Indeed, the classical method for strengthening tower legs where a second angle profile is added in a star battened configuration may be substituted by adhesive bonding of FRP plates to the existing angle profile. This leads to a smaller attack area of the strengthened member for the wind and a smaller periphery for the snow loading, leading to increased resistance and less loading, while the conventional method leads to increased resistance and higher loading. In addition, the operation could be handled easier due to less weight to be lifted, less space needed and, probably, lower susceptibility to environmental influences. Another area of potential beneficial application is for buildings in seismic areas where FRP plates could be attached to the beam flanges near the beam-to-column joints, in order to move the plastic hinges away from the joints, or added panel zones to increase their shear capacity. The interest for such research at European level appears to attract attention and is funded by the Research Fund for Coal and Steel (RFCS) in the ANGELHY project [13] and the German Academic Exchange Service (DAAD) in a project of hybrid strengthening methods [14].

Characteristic for these applications is that FRP composites are added in both tension and compression zones of elements, as well as in zones subjected to both compression and tension. Indeed, tower legs or bracing members may be subjected to compression or tension forces depending on the wind direction, flanges of beams in building frames in seismic areas are subjected alternatively to compression and tension, depending on the direction of the seismic excitation and the same happens to the applied shear forces of panel zones.

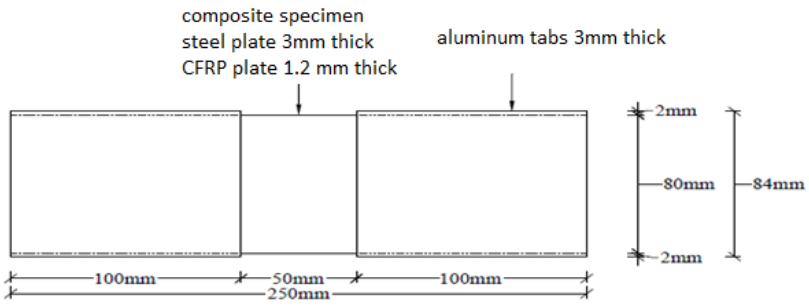
Design for FRP strengthening of steel elements is currently based on the nominal FRP material properties as supplied by the fabricators. These material properties, such as modulus of elasticity, tensile strength or elongation at fracture, refer exclusively to tension. Indeed, international test specifications for FRP material refer only to tensile testing, [15] to [18], obviously due to the fact that FRP material is predominantly used for tension and too thin to be directly tested for compression. The tension properties are also used, unchanged, in analytical formulae proposals for the prediction of the global or local buckling resistance of compression

members [8]. However, this approach may be questioned due to the fact that the compression resistance of FRPs is expected to be lower than the resistance to tension. It would be therefore beneficial to test the material under compression and check whether the compression properties are the same as for tension. Unfortunately, there is no international specification providing a test method, but for such a test the FRP material should be obviously attached to another element from the material that is intended to strengthen. Another issue, unspecified yet, is whether compression originates in the test from axial force or bending. For the current research it was accordingly considered necessary to investigate prior to the full-scale tests on angle leg columns, complete towers or beam-to-column joints, as planned in the relevant projects, the compression and tension behavior of FRP stripes bonded to steel plates. This would help the determination of the relevant properties and the correct design of the interventions.

This paper presents experimental, analytical and numerical investigations on the behavior of composite steel-CFRP specimens subjected to a tension and two four-point bending tests, one with the CFRP material on the tension side, the other on the compression side. The purpose was to determine the properties of FRP plates in tension separately from whether the tension arises from external axial forces or bending moments, and in compression arising from bending moments. Carbon fiber-reinforced polymer (CFRP) was used as composite material due to its high elastic modulus and tensile strength. The research was carried out in the frame of the MSc-Theses of the two first authors [19], [20].

2 GENERAL SPECIFICATIONS

The test specimens were constructed by the partner of the DAAD project [14] at the Brandenburg University of Technology (BTU) in Germany. They had the same dimensions and were made by the same materials. Each one was consisted by two parts, a 3mm thick steel plate with dimensions 80x250mm and a 1.2mm thick CFRP plate with the same dimensions (80x250mm). The two parts were bonded with a structural adhesive along their whole surface, with measured thicknesses of 1.3, 1.1 and 1.1 mm for the specimens 1, 2 and 3 respectively. Two aluminum tabs with dimensions 84x100x3mm were also used at the specimen's ends on the side of the CFRP plate, in order to protect the fibers and avoid a local failure or a fibers' break at the sections that are attached in the machine's grips in the tensile test or at the points of load application in bending tests. The side and plan view of the specimens are shown in Fig. 1, while Fig. 2 shows pictures of the specimens before testing.



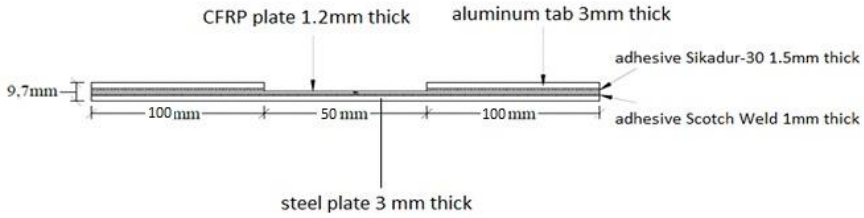


Figure 1: Plan and side view of the specimens

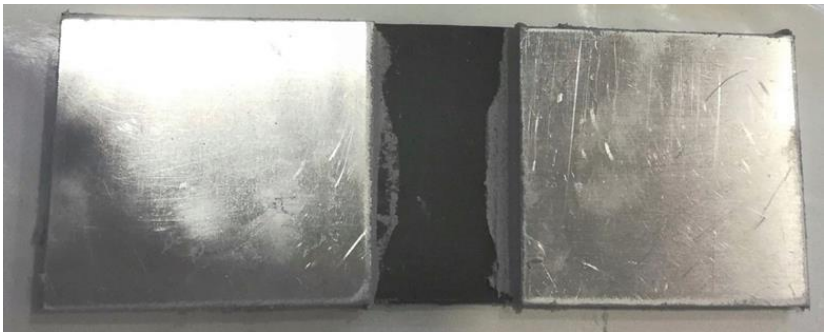

Figure 2: Picture of the specimen before testing

The mechanical properties of the constituent materials have been determined experimentally by tensile testing, carried out in an INSTRON 300XL universal machine with 300kN capacity. Steel has been tested by two tests in accordance with [21]. The resulting σ-ε-curve is shown in Fig. 3, the mechanical properties, as average from the two tests, in Table 1.

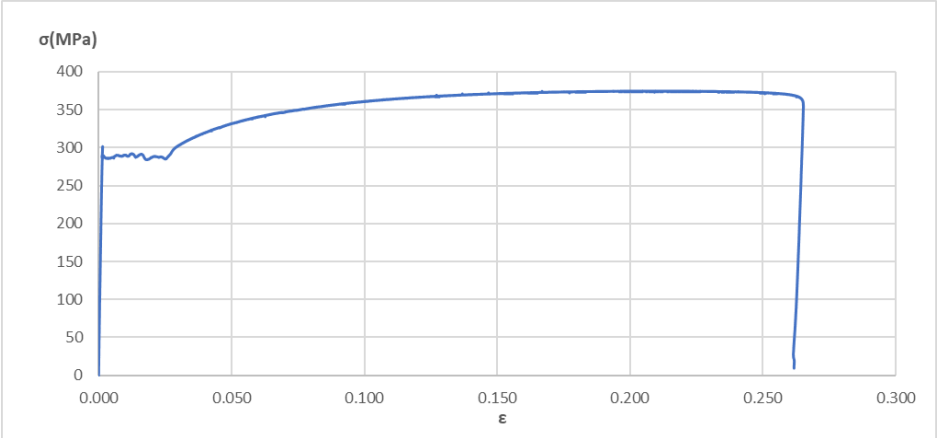

Figure 3: Experimental stress-strain curve for steel

E (MPa)	Yield stress σ_y (MPa)	Yield strain ε_y (%)	Hardening stress σ_R (MPa)	Hardening strain ε_R (%)	Ultimate stress σ_{max} (MPa)	Ultimate strain ε_{max} (%)
210000	287.5	0.1364	291	2.886	375	39.818

Table 1: Material properties of steel

The CFRP plates were made by MC Brauchemie and are considered as “low strength” plates. Their designation is 160/2400, i.e. the nominal modulus of elasticity is 160 GPa and the ultimate strength 2400 MPa. The plates were made using unidirectional fibers along the longitudinal axis of the plate. The actual mechanical properties have been determined by tensile tests on seven (7) specimens according to EN ISO 527-4 [16] and ASTM D638 -03 [17], D3039 [18]. The dimensions of the specimens were 300x25x1.5 mm, with their ends protected from the jaws of the machine by aluminum end tabs of dimensions 105x30x3 mm, as proposed by [16]. The loading speed was 1mm/min, lower than as specified in [16], in order to allow taking pictures by a thermic camera Flir B360 that was used to investigate if temperature changes take place in the material during the loading process. Strains were measured by both extensometer and strain gage. The material behaved linear elastic up to failure which was brittle and was due to the breakage of the carbon fibers, Fig. 4. Fig. 5 shows the resulting σ-ε-curves as derived from the extensometer and the strain gage measurements. The former indicates that slippage occurs between the extensometer and the specimen distorting the results. Accordingly, mechanical properties were determined on the basis of the strain gage measurements. The modulus of elasticity was determined by two methods: (a) as the slope of the curve between two predefined points with strains ε1 = 0,05% and ε2 = 0,25% proposed in [16] and (b) as the linear trendline of the σ-ε-curve from the origin up to failure. The average value from the tests was for method (a) ≈130 GPa, while for method (b) ≈141 GPa. Both methods delivered lower value than the nominal value provided by the producer, possibly due to the fact that only one strain gage was used on one side of the specimen so that effects of eccentricity were present. The average values for the ultimate stress was 2734 MPa, i.e. higher than the nominal value, as expected, and for the ultimate strain 1.91%.

Figure 4: CFRP specimens at failure

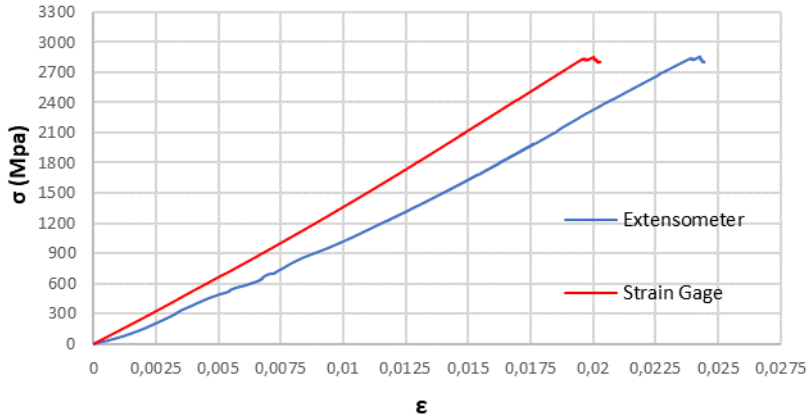

Figure 5: Experimental stress-strain curve for CFRP

The structural epoxy resin Scotch WeldTM DP 490 was used as adhesive to bond steel and CFRP plate, which is characterized by its simple and easy application and therefore recommended by its producer as appropriate for steel sections. Its ultimate shear stress τ_k and normal stress σ_k are estimated based on [5] and are shown in Table 2.

E_k (MPa)	Shear strength τ_k (MPa)	Shear modulus G_k (MPa)
3036	3.76	308.9

Table 2: Material properties of adhesive, average values

This adhesive was not strong enough to bond the aluminium tabs at the specimen's ends to the CFRP plates, so that Sikadur 30 from SIKA with nominal shear strength of 20 MPa was used instead.

As mentioned before, the specimens were fabricated at the Brandenburg University of Technology, Germany, following a specific procedure. Firstly, a special treatment using a hard brush was implemented to the steel surface, to increase the surface roughness in order to have better application of the adhesive. Then the surfaces of both steel and CFRP plates were cleaned with acetone. The adhesive was added using a special equipment, Fig. 6, to allow a uniform application of the adhesive with a thickness of approximately 0.2mm over the entire surface. For this purpose, small beads with diameter 0.105-0.20 mm made from glass were placed between the two surfaces as seen in Fig. 6. The two bonded plates remained under constant pressure for seven days until the adhesive reached its total strength. However, after this procedure the adhesive's thickness was measured, as well as possible, and was estimated to be 1.3, 1.1 and 1.1 mm for specimens 1,2, and 3 respectively.

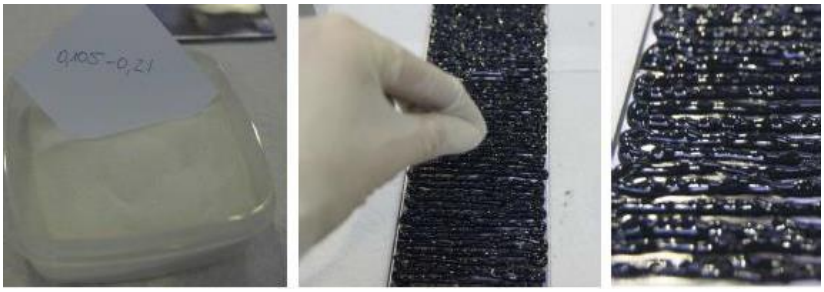

Figure 6: Application of the adhesive using special equipment

Subsequently, two aluminum tabs were also bonded on the CFRP side to protect it from the jaws of the machine. A different adhesive, Sikadur 30, was used to bond the aluminum plates to the CFRP plate**.** After that the three specimens remained seven more days under some heating lamps at a constant temperature of 33-36ºC, so that adhesive reaches its maximum strength.

3 TENSILE TEST

The tension test was carried out in the INSTRON 300XL machine. The specimen was loaded via displacement control at a testing speed of 0.2 mm/min, up to the maximum load capacity of the test machine, 300 kN, which is lower than its nominal failure load. Besides the load and the total elongation measured by the machine, strains on both the steel and the CFRP were measured by two strain gauges. The test set-up is shown in Fig. 7.

Figure 7: Test set-up for the tension test

The experimental force – displacement curve is shown in Fig. 8. The applied force is divided between the steel and the CFRP plates as in Fig. 9. It may be seen that steel behaves in the elastic-plastic, while CFRP purely in the elastic range. The force is distributed according to the stiffness of the constitutive parts as long as steel behaves elastic. When steel enters into the plastic region, it transfers only its yield force the other part transferred by the CFRP. This is because steel did not enter into the strain hardening region, as the strains measurements showed.

Assuming uniform strain distribution in the two materials, i.e. both materials are subjected to pure tension, the total force may be determined analytically and expressed by equations (1)

and (2). This assumption, which will be checked later, leads to acceptable results. This is shown in Fig. 8 where the simplified analytical curve is compared to the experimental curve.

$\varepsilon_s \leq \varepsilon_y$: $$P_{an} = E_s \cdot \varepsilon_s \cdot A_s + E_{cfrp} \cdot \varepsilon_{cfrp} \cdot A_{cfrp} \quad (1)$$

$\varepsilon_s > \varepsilon_y$: $$P_{an} = f_y + E_{cfrp} \cdot \varepsilon_{cfrp} \cdot A_{cfrp} \quad (2)$$

where:

E_s , E_{cfrp} are the modulus of elasticity of steel or correspondingly CFRP

ε_s, ε_{cfrp} are the, measured, strains of steel or correspondingly CFRP

A_s , A_{cfrp} are the cross-section areas of steel or correspondingly CFRP

ε_y, f_y are the actual yield strain and yield stress of steel

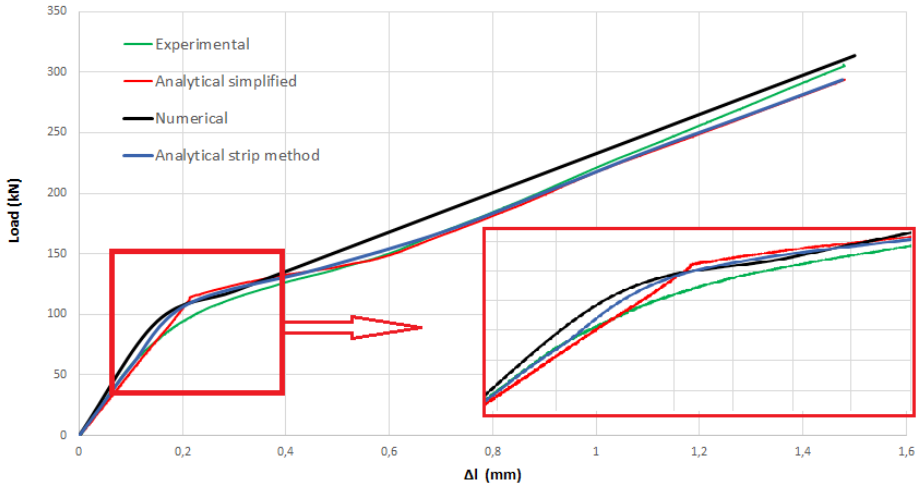

Figure 8: Experimental, analytical and numerical force – displacement curve

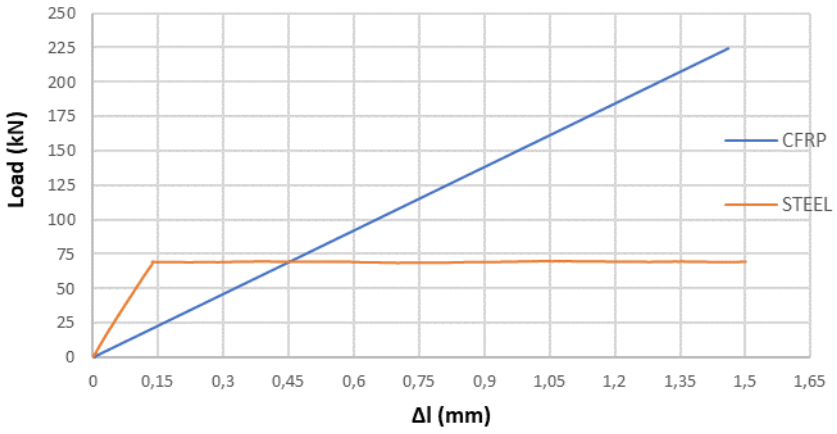

Figure 9: Partial forces transferred by the steel and CFRP plates

The specimen didn't reach failure at maximum load due to the limited capacity of the machine. However, the specimen exhibited a large permanent bow deformation after unloading as shown in Fig. 10, due to the fact that steel entered into the plastic range and exhibited a permanent tensile deformation. The corresponding plastic strain at unloading was measured by the strain gages as ε_{per} = 1,3%. This value is confirmed by appropriate geometrical measurements after the test and application of eq. (3).

$$\varepsilon_{perm} = \frac{1}{1-\frac{1}{\left(\frac{L/2}{f}\right)^2+1}} - 1 \quad (3)$$

where, Fig. 10:
f is the, measured, sagitta of the chord and
L is the, measured, chord length of the specimen.

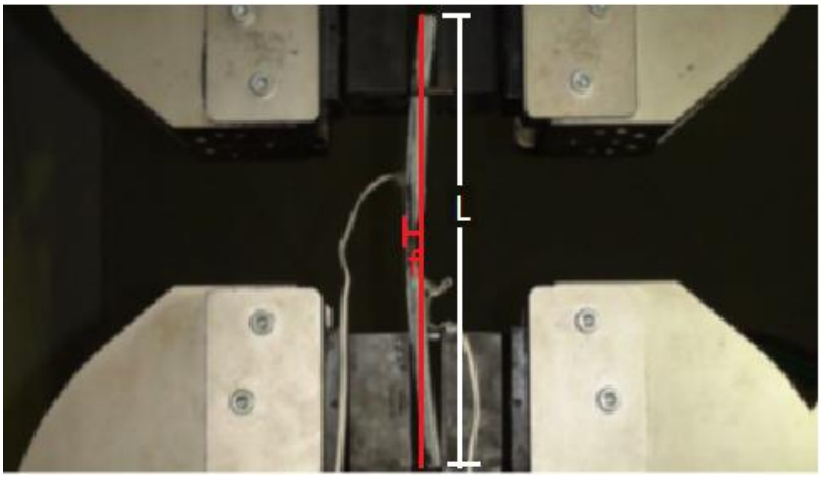

Figure 10: Permanent bow deformation after unloading. Steel on the tension (convex) side

The tension test was in addition investigated numerically using the ABAQUS Code [22]. Steel was modelled by application of solid elements of type C3D8R (Continuum solid element, 8-node linear brick, Reduced integration with hourglass control), while CFRP with shell elements of type S4R (Shell, 4-node double curved thick shell). The thickness of the shell was determined through the *Composite Layup*, by entering the number of carbon layers from which the CFRP is composed. Such a model is necessary when the orientation of the individual layers differs. In our case the same result could be achieved by a single layer with the total thickness. The end tabs and the epoxy resin were not included in the model. The interaction between steel and CFRP was introduced by connection of the two contact surfaces by means of tie constraints so that the two parts are rigidly connected with no slip between them.

The material properties of steel were introduced to follow the measured σ-ε-curve shown in Fig. 3. For the composite material the material properties were given separately for the fibers, type Graphite IM6 with modulus of elasticity E_f = 275.6 GPA, Poisson's ratio v = 0.2, ratio v_f = 51% and the matrix, type Epoxy 9310/9360 with E_m = 3.12 GPA, v_m = 0.38 and ratio v_m = 49%. The modulus of elasticity of the composite material in the longitudinal, 1, transverse, 2, and through thickness, 3, direction and the shear moduli are determined from eqs. (4) to (8) correspondingly [23]:

$$E_1 = E_f \cdot v_f + E_m \cdot v_m \quad (4)$$

$$E_2 = \frac{E_f \cdot E_m}{E_f \cdot v_f + E_m \cdot v_m} \quad (5)$$

$$E_3 = E_m \quad (6)$$

$$G_{12} = G_{13} = \frac{G_f \cdot G_m}{G_m \cdot v_f + G_f \cdot v_m} \quad (7)$$

$$G_{23} = G_m \quad (8)$$

where:

v_f, v_m are the fibers ratio and the matrix ration correspondingly and
$G = E / [2 \cdot (1+\nu)]$ for the fibers, f, and the matrix, m.
The Poisson's ratio of the composite material may be determined from:

$$\nu_{12} = \nu_{13} = \nu_f \cdot \nu_f + \nu_m \cdot \nu_m \quad (9)$$

$$\nu_{23} = \nu_m \quad (10)$$

The numerical model included the specimen over its entire length, but at the end regions where the jaws are acting the relevant displacements were restrained so that one end is fixed and the other can move freely in direction of the load application. The force – displacement curve of the numerical model is illustrated in Fig. 8, together with the experimental and analytical curves. The comparison shows a quite good agreement with the experimental and analytical results, indicating that the adopted input material parameters and the assumption of no slip between the two materials are acceptable.

However, the numerical model allows the determination of the strain and stress state separately in the two material as shown in Fig. 11 and 12. It may be seen that the stresses, and strains, at the external and internal surfaces of steel are not identical. Strains therefore vary through the specimen's thickness as shown in Fig. 13. The actual strains measured during the test were ε_{so} and ε_{cfrp} at the specimen's surface, which are similar but not identical to the strains at the centroids of the corresponding materials. The corresponding stress distribution gives rise to an internal moment that was calculated analytically by the strip method and numerically with ABAQUS and is shown in Fig. 14. This moment is in equilibrium with the external moment, calculated as the product between the applied force and the eccentricity between this force and the centroid of the composite section, calculated from eq. (11). The external moment is also illustrated in Fig. 14. There is a discrepancy between the curves of the external and internal moment that is due to the approximations made in the calculations of both. More specifically, the calculations for the internal moment assume pure axial tension with no moment in the initial loading steps, while moments arise later due to plasticity. On the other side, the external moment starts to develop from the beginning and is affine to the applied force since the eccentricity is considered unchanged during the test.

Besides the moment, the strip method was applied to calculate the axial force by integration of the axial forces in the individual strips. The relevant analytical curve is shown in Fig. 8. The comparison with the experimental curve indicates that the strip method is more accurate to the simplified one in the elastic region, while the two converge at larger strains in the plastic region of steel.

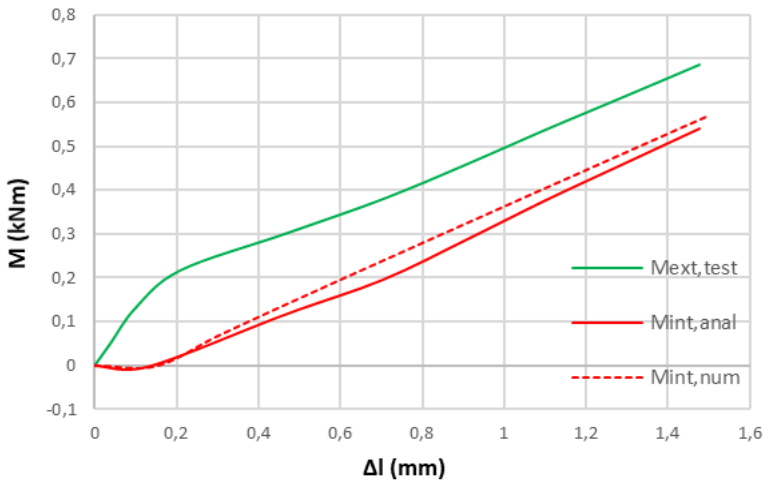

Figure 14: Moment – displacement curve of the specimen

4 FOUR-POINT BENDING TEST – FRP ON THE TENSION SIDE

The test set-up for the 4-point bending test, which was carried out in the INSTRON 300XL machine, is shown in Fig. 15. The specimen was loaded via displacement control at a testing speed of 0.42 mm/min. The recordings included the applied load, the deflection at mid-span, both measured from the machine recordings, and the strains of the steel and the FRP-plate at midspan, measured by two strain gauges. At late loading stages no steel's strain data were available because the strain gauge at the compression side was disconnected due to very high strains. Small slips also occurred at certain times during the test.

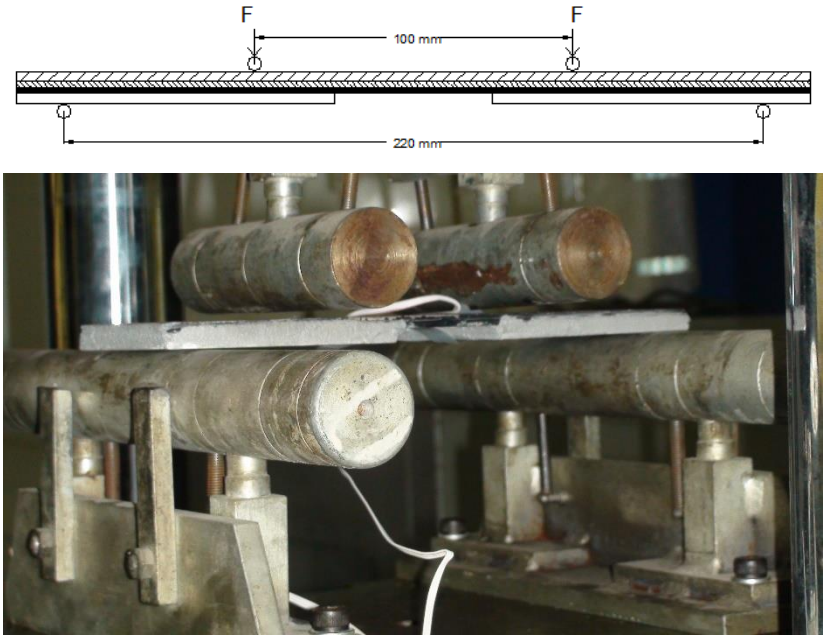

Figure 15: Test set-up for the 4-point bending test – CFRP in tension

The experimental force – deflection curve is shown in Fig. 16. At some points the load drops indicating small slips between the specimen and the supports. The experimental test was accompanied by analytical and numerical calculations. For the former two methods were adopted.

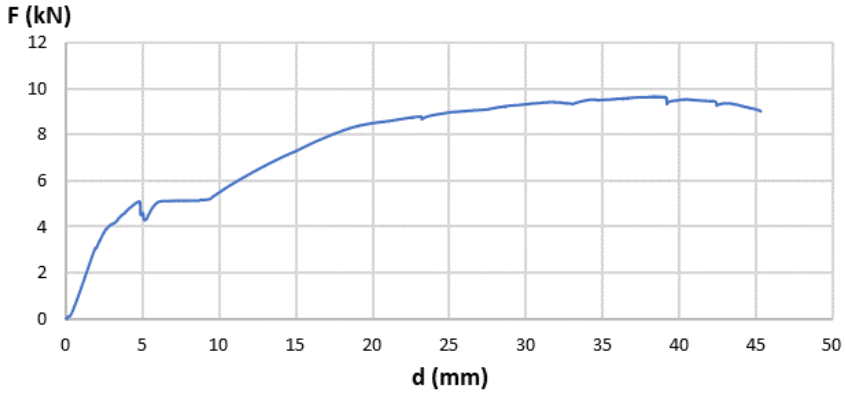

Figure 16: Experimental force – mid-span deflection curve

- Analytical Method 1

This is based on the Bernoulli-Euler beam theory for linear strain distribution over the cross section, Fig. 17. The centroid of the cross section, distance from the top side, is calculated from eq. (11):

$$zc = \frac{zs*As+(z_{res}*\frac{A_{res}}{n_{res}})+(z_{CFRP}*\frac{A_{CFRP}}{n_{CFRP}})}{As+\frac{A_{res}}{n_{res}}+\frac{A_{CFRP}}{n_{CFRP}}} \quad (11)$$

where:
z_s, z_{res}, z_{cfrp} are the centroids of steel, resin or CFRP correspondingly
A_s, A_{res}, A_{cfrp} are the cross-section areas of steel, resin or CFRP correspondingly
E_s, E_{res}, E_{cfrp} are the moduli of elasticity of steel, resin or CFRP correspondingly
$n_{res} = E_s/E_{res}$ is the modular ratio of the resin
$n_{cfrp} = E_s/E_{cfrp}$ is the modular ratio of the CFRP

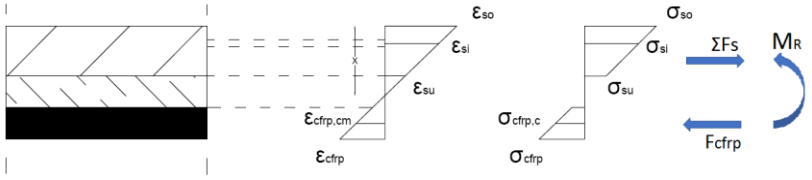

Figure 17: Calculation procedure for the internal moment – Analytical method 1

Starting from the strains as measured during the test, the internal moment is determined by the strip method as indicated in Fig. 17 neglecting the contribution of the resin. The analytical moment – deflection curve is illustrated in Fig. 18 and compared with the experimental one. The disadvantage of the analytical method 1 is that no experimental strain data are available at the late loading steps so that the moment can be calculated up to a certain point (up to a deflection 25 mm in Fig. 18).

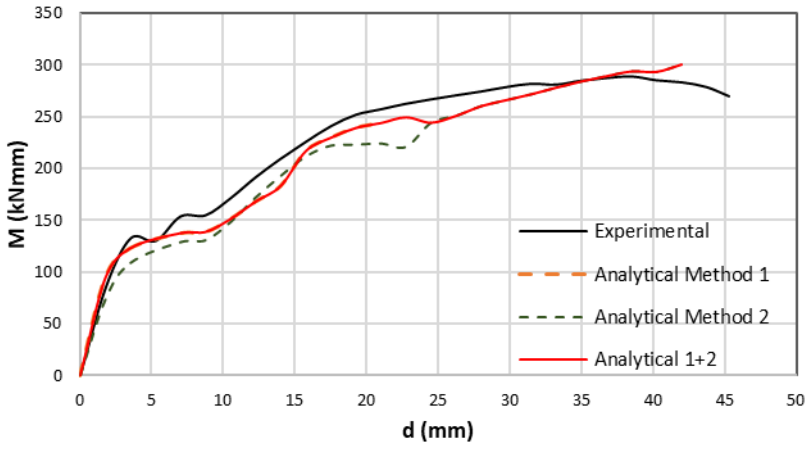

Figure 18: Experimental and analytical moment – deflection curves

- Analytical Method 2

In this method the computation process is reversed. The tension force in the CFRP, acting at its centroid, is determined from eq. (12):

$$F_{cfrp} = E_{cfrp} \cdot \varepsilon_{cfrp} \cdot A_{cfrp} \quad (12)$$

where:

ε_{cfrp} is the strain at the CFRP centroid of the CFRP. It is taken as ½ of the measured CFRP strain, since the plastic neutral axis of the composite section is considered to be within the adhesive.

The tension force in the CFRP is equal for equilibrium reasons to the compression force in steel, Fig. 19. The stress distribution in steel is assumed uniform across its thickness. The steel stress is determined from measurements as long as strain data for steel are available. After it, the steel stresses are estimated under consideration of strain hardening. The so calculated moments are shown in Fig. 18.

It may be seen that despite the missing strain measurements, method 2 is appropriate for the late loading steps at large strains where steel is yielding and strain hardening, while method 1 fits better for the early loading steps. Fig 18 shows that the combination of the two methods may provide a good estimate of the specimen's response.

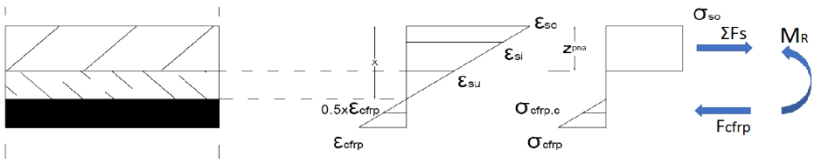

Figure 19: Calculation procedure for the internal moment – Analytical method 2

The bending test was also investigated numerically with the same modelling using the ABAQUS Code as previously described. Fig. 20 shows the test specimen in its deformed shape, together with the corresponding numerical model.

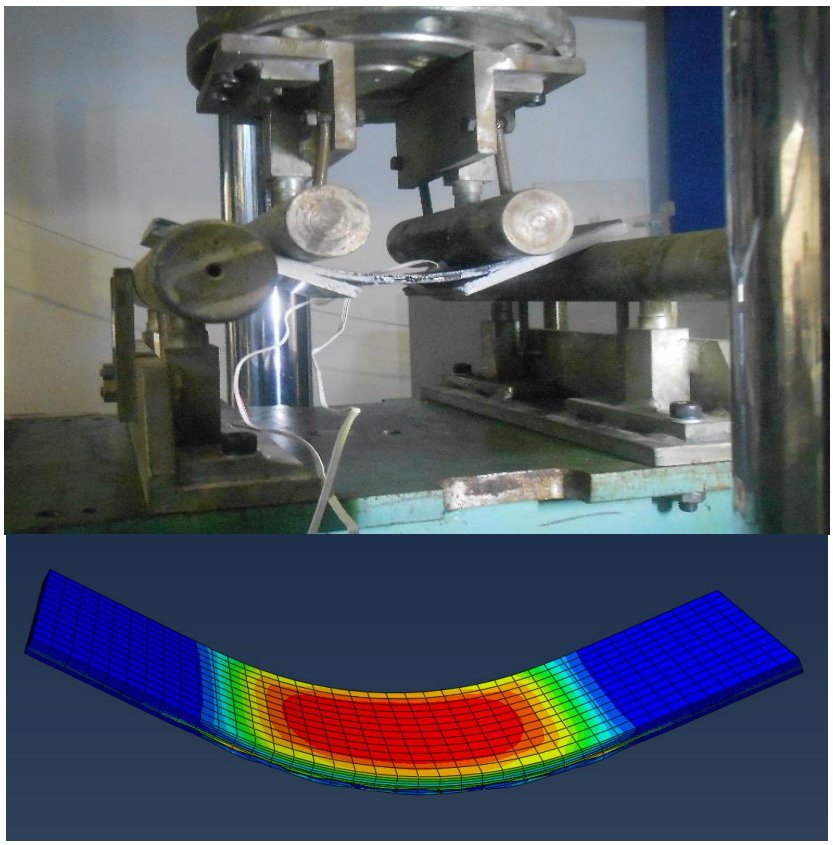

Figure 20: Experimental and numerical model at its deformed state

The calculations included MNA and GMNA analyses, where in the former only the material non-linearity and in the latter the geometric and material non-linearity were considered. Fig 21 shows the experimental and numerical results. It may be seen that the numerical results fit well with the experimental ones, especially when the effects of slip are removed from the experimental ones. The numerical models, especially the GMNA analysis, predict a smaller capacity due to the neglect of any contribution of the adhesive. However, the initial stiffness is very close to the experimental one.

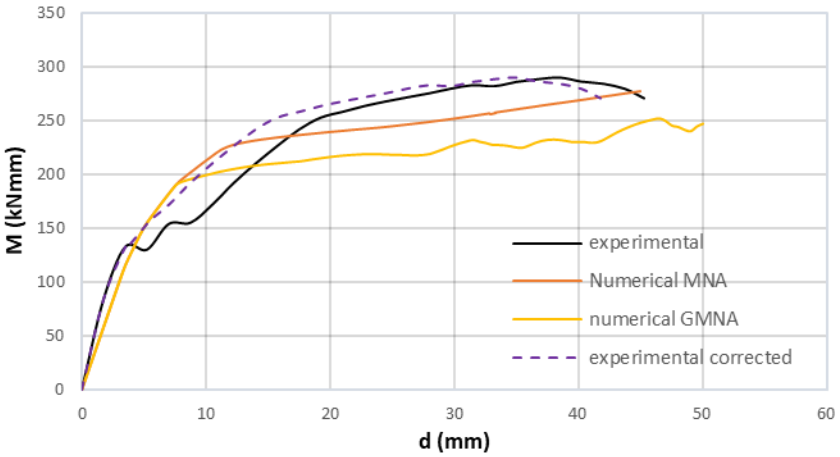

Figure 21: Experimental and numerical moment – deflection curves

5 FOUR-POINT BENDING TEST – FRP ON THE COMPRESSION SIDE

The test set-up, the measurements and all other data are the same as before, except that the specimen is put upside down, so that the CFRP is on the compression side, Fig. 22. For the same reasons as before, at late loading stages no CFRP strain data were available because the strain gauge was disconnected at the compression side due to very high strains.

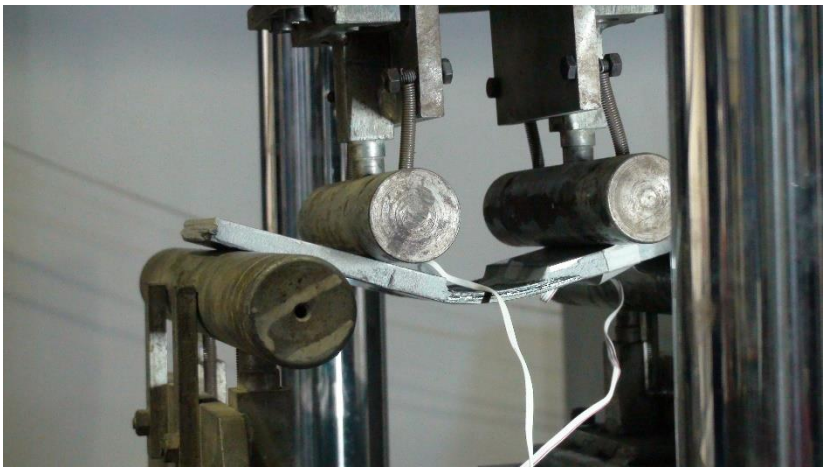

Figure 22: Test set-up for the 4-point bending test – CFRP in compression

Fig. 23 shows the experimental and analytical moment – deflection curves. The analytical curves were determined by the two methods described before. It may be seen that the combination of methods 1 and 2 provides acceptable results, even if the contribution of the resin

was neglected. Based on the analytical calculations, the compression strength of the CFRP is estimated to be 640 MPa.

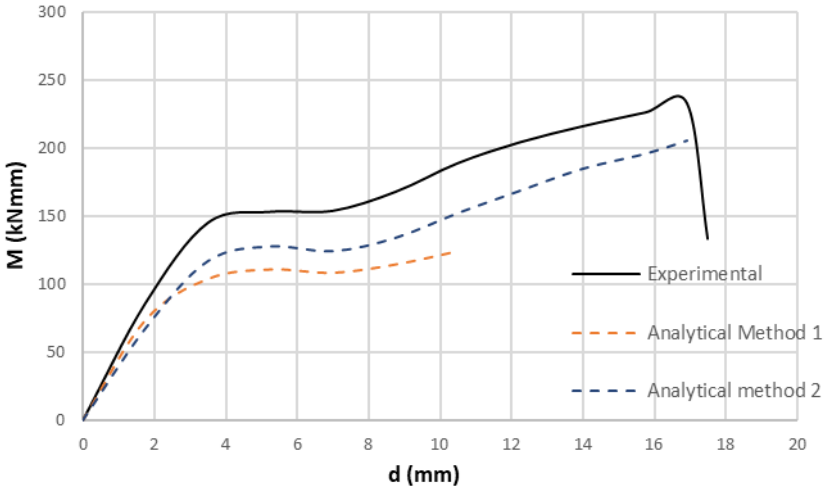

Figure 23: Experimental and analytical moment – deflection curves

This test was also studied numerically using the same model as in the other tests. Especially, the material properties of the CFRP were taken as those for tension. Both MNA and GMNA analyses were performed. The deformed shape of the model for the GMNA analysis is shown in Fig. 24 and may be compared to the deformed shape of the experimental model shown in Fig. 22.

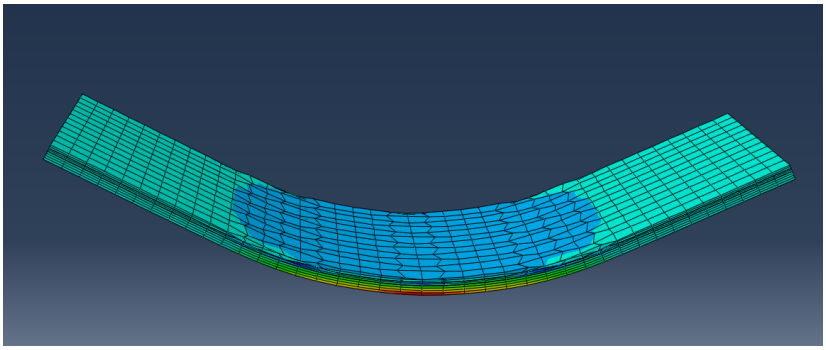

Figure 24: Deformed shape of the numerical model by GMNA analysis

Fig. 25 shows the experimental and numerical moment - deflection curves. It may be seen that for this test the GMNA analysis provides better results. However, the numerical analyses cannot predict the moment capacity due to the fact that for the CFRP material the linear elastic tension properties were introduced. Accordingly, the large deflections predicted numerically are not realistic if the tension properties of the material are adopted. Based on the stresses of the numerical model at the maximal deflections of the experiment, the compression strength of the CFRP is estimated as 700 MPa, which is similar to 640 MPa as determined with the analytical model. This is around 30% of the nominal tension strength. However, it should be noted that no local buckling occurred in this test.

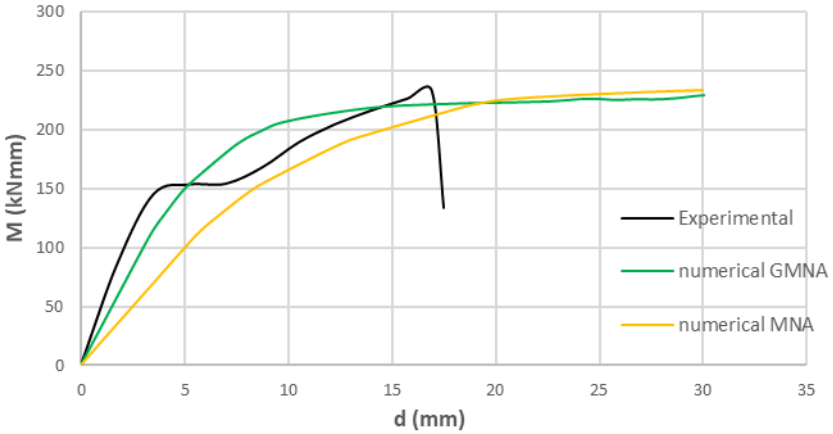

Figure 25: Experimental and analytical moment – deflection curves

The numerical model was further on used to calculate the 4-point bending response of the steel plate alone without any CFRP strengthening. Fig. 26 compares the derived curve in comparison with the experimental curves of the same steel plate strengthened with CFRP on the tension or the compression side. It may be seen that the bending capacity of the steel plate increased almost 6 times by strengthening it with CFRP in the tension side. When the CFRP was placed on the compression side this increase was less, around 4.6 times, confirming the lower strength of CFRP when it is used for compression. However, the stiffness of the strengthened specimens was equal indicating that the same modulus of elasticity may be used for the CFRP either in compression or tension. Important is that the ductility of the composite specimen is exhausted when the CFRP material is reaching its compression capacity.

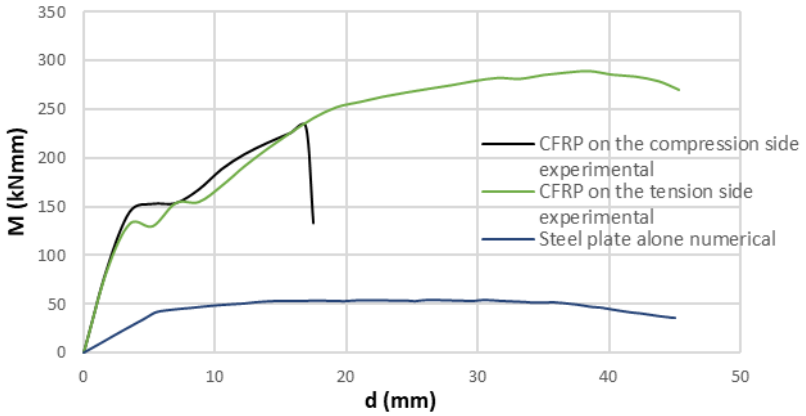

Figure 26: Moment – deflection curves for steel plates with and without CFRP reinforcement subjected to 4-point bending

6 CONCLUSIONS

The behavior of steel plates reinforced in one side with carbon fiber reinforced polymer (CFRP) has been studied experimentally, analytically and numerically. The properties of the source material have been determined experimentally. Subsequently, the composite material has been subjected to tension tests and four-point bending tests with the reinforcement on the tension and the compression side. The test material has been prepared in BTU Cottbus, Germany, while the tests have been executed in NTUA, Athens, Greece. Analytical relations have been derived on the basis of the Bernoulli assumption of linear strain distribution in the cross

section and numerical investigations with application of the FEM have been performed. From the studies carried out following conclusions may be drawn:

1. One-sided strengthened steel plates subjected to axial tension forces exhibit permanent bow deformations after unloading due to irreversible plastic deformations of steel.
2. Existing analytical relations for defining the properties of the CFRP plates in relation to the properties of the two constituent materials, the carbon fibers and the matrix, have been confirmed.
3. The modulus of elasticity of CFRP was equal, whether the CFRP was in the tension or in the compression side.
4. The strength of the CFRP was different for compression and tension, the former being a fraction of the latter.
5. The assumption of a composite section from two different materials, the Bernoulli assumption of linear strain distribution in the cross-section and the assumption of no slip between the two constituent materials are valid for this type of strengthening, provided that appropriate adhesives are used and their application follows the relevant specifications for their connection.
6. Design for CFRP strengthening of steel elements where the CFRP is in the tension side may be based on the nominal material properties of CFRP as determined by the specified tensile testing.
7. For CFRP strengthening of steel elements where the CFRP is in the compression side, only the modulus of elasticity of CFRP as determined by the tensile testing may be used, while its strength must be reduced
8. Four-point bending tests of the composite material with no local buckling as outlined here, where the CFRP is in the compression side are appropriate to define the properties of the CFRP material to compression.

Abstract

This paper illustrates the effect of architectural non-structural components on the variation of dynamic properties and lateral seismic behaviour of Cold-Formed steel (CFS) buildings, using shake-table tests and numerical modelling. The seismic behaviour of a two-storey gypsum-sheathed building was investigated as a part of European project ELISSA. Shake-table tests were carried-out on this building under two different configurations: with and without architectural non-structural components. Dynamic properties, such as fundamental period and damping ratio, of both building configurations were evaluated and compared. Numerical models considering all the architectural non-structural components were developed in Opensees environment. Results highlight the importance of considering the contribution of architectural non-structural components, such as finishing materials of shear and gravity walls, partition walls and internal counter walls, in the process of structural analysis and modelling of CFS buildings.

Keywords: CFS structures, Shake-table test, Non-Structural Components, OpenSees modelling.

1 INTRODUCTION

Nowadays, Cold-Formed Steel (CFS) structures are often preferred to the traditional constructions as low-rise buildings in seismic areas due to their light weightiness and good seismic performance [1]. In fact, in the last decades numerous studies on elements [2–4], components [5–12] or whole buildings [13–15] have evaluated their seismic response. Although structural behaviour has been deeply investigated, only few experimental and numerical works have been carried out for the evaluation of the influence of architectural non-structural components on the global seismic response [16,17]. As demonstrated, the presence of non-structural architectural components offers a big contribution to the lateral resistance and stiffness of structure, but the current seismic design of CFS buildings does not take into account that contribution. To overcome this lack, as a part of European project ELISSA, the main task of University of Naples "Federico II" was the design and the execution of shake-table tests on full-scale two-storey CFS building in two different construction phases, which differ for the presence of architectural non-structural components. The influence of finishing material and other non-structural architectural components, i.e. partition walls and internal counter walls, on the dynamic properties of the structure (fundamental period of vibration and damping) has been evaluated, through the experimental results and numerical modelling. This paper summarises the experimental campaign and 3D building models developed in Opensees [18] software, focusing on the effect produced by non-structural architectural components on the seismic response.

2 EXPERIMENTAL CAMPAIGN

2.1 General

An experimental campaign aimed to deepen the knowledge of structural behaviour of CFS constructions, subjected to seismic excitations, was carried out at the Department of Structures for Engineering and Architecture of University of Naples "Federico II". In particular, the influence of architectural non-structural components on the seismic behaviour was investigated through cyclic tests and shake-table tests. The cyclic tests were carried out on two full-scale gypsum-sheathed shear wall configurations, which differ only for the presence of finishing and insulating materials, whereas shake-table tests were carried out on a full-scale 3D building mock-up with and without architectural non-structural components. In particular, the wall specimen without finishing and insulating materials is named as B wall Configuration, while the specimen wall with finishing and insulating materials is named as C wall Configuration. Equally, the building mock-up without architectural non-structural components is named as B mock-up Configuration, while the building mock-up in which the architectural non-structural components were added is named as C mock-up Configuration. The B and C wall Configurations were representative of the shear walls used in the B and C mock-up Configurations, respectively. More details about the research project are available in Landolfo et al. [19].

2.2 Shear wall testing

The effect of the presence of finishing materials was evaluated through cyclic tests. The wall specimens had a dimension of 2.4 × 2.3 m (length x height). The two wall configurations are shown in Fig.1. The steel frame of specimens was mainly composed of intermediate and chord studs and tracks. The studs had 147×50×10×1.5 mm (outside-to-outside web depth × flange size × lip size × thickness) lipped channel (C) sections mainly spaced at 625 mm on the centre. Tracks had 150×40×1.5 mm (outside-to-outside web depth × flange size × thickness)

unlipped channel (U) sections. All the steel members were made of S320GD+Z steel (characteristic yield strength: 320 MPa, characteristic ultimate tensile strength: 390 MPa). The steel frame was sheathed with 15.0 mm thick impact resistant gypsum board on both sides. In order to withstand the axial force due to overturning phenomena, back-to-back coupled studs and ad-hoc designed hold-down devices were placed at the wall ends. For the second test (C wall Configuration), the wall specimen was completed with insulation mineral wool, inserted among steel studs. The internal face was completed with an internal counter wall made of 20 mm thick vacuum insulated panel attached to the structural wall, 50×50×0.6 mm C vertical profiles spaced at about 600 mm, 50×40×0.6 mm U horizontal tracks, 50 mm thick insulation mineral wool. The steel frame of the internal counter wall was sheathed with double layer of 15 mm thick impact resistant gypsum board panels. The external face was completed with a ventilated façade made of a water proof membrane, 25×100 (outside-to-outside web depth × outside-to-outside flange size) slotted Ω horizontal profiles spaced at about 400 mm on the centre, sheathed with 12.5 mm thick cement-based outdoor board panels and finished with fibreglass mesh and cement plaster. Tests on wall specimens were conducted under displacement control in the reversed cyclic regime. The CUREE protocol, developed by Krawinkler et al. [20], was used.

Results are presented in the form of a comparison of cyclic behaviour obtained for the B and C Configurations walls (Fig. 2). Test results are shown in Table 1 in term of peak resistance per unit length (F_{max}/L), elastic resistance per unit length (F_e/L), which is the 40% of maximum resistance, drift corresponding to F_e (d_e/H), ultimate drift corresponding to a load equal to $0.80 \cdot F_{max}$ on the post-peak branch of the response curve (d_u/H) and conventional elastic stiffness per unit length (k_e/L) assumed equal to F_e / (L d_e). For both specimens the wall collapse was mainly governed by the tilting and pull-out of sheathing-to-frame connections. At global level, the steel frame deformed as a parallelogram with a consequent rigid rotation of the sheathing panels. In the case of C wall Configuration, the detachment of the sheathing panel, together with the wall lining of the internal face was also occurred for inter-storey drift ratios (IDR) higher than 4%. The presence of the finishing gave an increase in average of 48% for the wall strength and 39% for wall stiffness. Further details are available in Macillo et al. [21].

2.3 Mock-up testing

A 3D building mock-up was tested on shaking table in two different construction phases: bare structure (B mock-up Configuration), consisting only of structural elements; and complete construction (C mock-up Configuration), in which architectural non-structural components were added. The mock-up was a 2.5×4.5×5.4 m (length x width x height) two storey building. The seismic resistant elements were made of CFS shear walls laterally braced by gypsum panels. A white noise signal was applied to the building (Random tests) in B and C Configurations in order to assess the main dynamic characteristics, i.e. first period of vibration and damping, while a natural ground motion record scaled by 5 to 150% (Earthquake tests) was applied only to C mock-up Configuration to evaluate its seismic response. Indeed, the experimental seismic response under an earthquake input is available only for the C mock-up Configuration.

The B mock-up Configuration consisted mainly of shear walls and gravity walls without finishing parts, internal partition walls, floors and roof. Shear walls had the same structure of the B wall Configuration tested under quasi-static cyclic regime (see Section 2.2). Gravity and partition walls had the same structural elements of shear walls. The main difference between shear and gravity walls was the presence of hold-down. In fact, in order to withstand the axial force due to overturning phenomena, ad hoc designed hold-down devices were placed only at the ends of shear walls. Internal partition walls, instead, were not designed to carry gravity loads. Floors and roof were made of back-to-back 197×50×10×2.0 mm C joists with a spacing of about 500 mm on the centre, connected at their end with 200×40×1.5 mm U floor tracks. The steel frame of the floors was sheathed on the top side with 28 mm thick high-density gyp-

sum fibre board panels. The bottom side of steel frame of second floor and roof was sheathed with 15 mm thick impact resistant gypsum board panels.

The C mock-up Configuration was completed with architectural non-structural components, which mainly consisted of internal counter walls and finishing parts of shear walls, gravity walls, and finishing parts of floors and roof. In particular, shear walls had the same structure of the C wall Configuration tested under quasi-static cyclic regime and gravity walls were completed in the same way of the shear walls (see Section 2.2), however certainly without the hold down devices. Top sides of first and second floors were sheathed with additional gypsum fibre board panels, while bottom sides of second floor and roof were completed with a ceiling. The seismic weight of the B mock-up Configuration was evaluated to be approximately 24 kN for the second floor and 14 kN for the roof, while for the C mock-up Configuration they were approximately 50 kN and 26 kN, respectively. More details about mock-up are available in Fiorino et al. [22].

Random test results are presented in term of fundamental period of vibration and damping ratio for B and C mock-up Configurations, while the Earthquake test results are presented in term of peak and residual inter-storey drifts for C mock-up Configuration. The fundamental period for the B mock-up Configuration was greater than that recorded for the C mock-up Configuration. In particular, the fundamental period of the B mock-up Configuration was about 0.13 s, while for C mock-up Configuration it was about 0.10 s. As far as the measurement of damping ratio is concerned, it resulted in the range from 1.4% to 3.1% for the B mock-up Configuration and from 1.2% to 2.0% for the C mock-up Configuration. As concerned the peaks of the inter-storey drift ratio (PIDR) measured during earthquake tests carried out on the C mock-up Configuration, the PIDRs were 0.80% for 1st storey and 0.52% for 2nd storey. All the PIDRs corresponded to the earthquake with maximum intensity (scale factor equal to 150%). In addition, the residual inter-storey drift ratios (RIDRs) were very small (under 0.05%) and the observed damage was limited to architectural non-structural components, i.e. presence of gypsum dust and small detachment of cover paper at some corner joints on the inner faces of internal counter walls.

2.4 Effect of architectural non-structural components based on experimental results

Non-structural components explicitly considered in this study included insulating and finishing materials of shear and gravity walls, partition walls and internal counter walls. On the bases of experimental results, the effect of architectural non-structural components can be evaluated both on subsystem (shear wall) and whole building (mock-up). The evaluation of this effect for the shear walls can be done in term of stiffness, strength and collapse mechanisms, i.e. the cyclic tests on the shear walls were carried out up to the collapse on both shear walls without (B wall Configuration) and with architectural non-structural components (C wall Configuration). In contrast to shear walls, for the mock-up the effect of architectural non-structural components can be evaluated only in term of first period of vibration and stiffness, because the experimental seismic response under earthquake inputs is only available for mock-up with architectural non-structural components (C mock-up Configuration). Moreover, the partition walls are present in both B and C mock-up Configurations, therefore a rigorous comparison between B and C mock-up Configurations focused to assess the effect of non-structural components is affected by this circumstance. A further evaluation of the effect of architectural non-structural components was carried out through numerical modelling (see Section 3.6).

As experimental results showed, the increasing in stiffness due to the effect of non-structural components on the single shear wall was estimated equal to about 1.4 times, while the increasing in resistance was estimated equal to about 1.5 times, by comparing the lateral

response of B and C wall Configurations. For the mock-up, the influence of non-structural components implied a global decreasing of the fundamental period of about 1.3 times from B to C mock-up configuration. Note that the variation of fundamental period of the mock-up was also affected by the variation of the mass, because the mass of the B mock-up Configuration was about one half than that of the C mock-up Configuration. Therefore, for the mock-up an increase of the estimated lateral stiffness equal to about 3 times can be associated to the decrease of the fundamental period. It is evident that the increase of lateral stiffness was greater for the mock-up than for the shear wall. This result confirms the important role of all architectural non-structural components, together with the box building behaviour, which increase significantly the lateral stiffness.

3 NUMERICAL MODELLING

3.1 General

Numerical models representative of B and C mock-up Configurations were developed in Opensees environment in order to capture their dynamic behaviour and seismic response. In particular, B Models are representative of the B mock-up Configuration and include shear walls (SW_B) and gravity walls (GW_B) without architectural non-structural components and partition walls, while C Models are representative of the C mock-up Configuration and include shear walls (SW_C) and gravity walls (GW_C) with non-structural finishing materials, partition walls (PW) and internal counter walls (ICW). Several modelling options were explored to deepen the knowledge of contribution offered by different structural and architectural non-structural components on the seismic response of the mock-up. They ranged from very simple models with only shear walls to more complex models, in which all the structural and architectural non-structural components were included. The effect of two different modelling choices for diaphragm was also evaluated. Diaphragm was either modelled as a rigid diaphragm constraint across all the nodes at floor or roof level, or as each joist (J) being modelled as a separate element without any constraint. Different modelling options are summarised in Table 2.

Mock-up Configuration	**Model**	**Structural***				**Non-structural***			
		SW_B	**IS**	**GW_B**	**J**	**PW**	**SW_C**	**GW_C**	**ICW**
B	**B1**	Yes	No	No	No	No	No	No	No
	B2	Yes	Yes	No	No	No	No	No	No
	B3	Yes	Yes	Yes	No	No	No	No	No
	B4	Yes	Yes	Yes	Yes	No	No	No	No
	B5	Yes	Yes	Yes	Yes	Yes	No	No	No
C	**C1**	Yes	Yes	Yes	Yes	Yes	Yes	No	No
	C2	Yes	Yes	Yes	Yes	Yes	Yes	Yes	No
	C3	Yes	Yes	Yes	Yes	Yes	Yes	Yes	Yes

*SW_B= shear wall without finishing materials, IS= intermediate studs, GW_B= gravity wall without finishing materials, J= floor joists, PW= partition walls, SW_C= shear wall with finishing materials, GW_C= gravity wall with finishing materials, ICW= internal counter wall

Table 2 Modelling options

3.2 Shear walls

The shear walls were modelled by a pair of diagonal trusses elements with a Pinching4 material, calibrated based on quasi static cyclic test response of the walls, as explained in the

Section 2.2. Pinching4 material is a material model, which represents a pinched load-deformation response and can exhibit degradation under cyclic loading, using the definition of the backbone envelope and the parameters governing the cyclic behaviour. In order to define the best-fit Pinching4 material for the shear walls, the force-displacement backbone curves assigned to diagonals were individuated first using the cyclic test results from the experiments, then the cyclic parameters were calibrated to best match the experimental response.

The shear wall models were subjected to the same loading protocol used in the cyclic tests. A parametrical analysis was performed to better match the cyclic behaviour of the walls through a quantitative comparison based on the energy dissipation per single cycle and cumulative cyclic energy. Figure 3 shows the comparison between experimental and numerical response in terms of load vs. displacement cyclic behaviour and cumulative dissipated energy. Hold-downs present at the ends of shear walls were modelled as ZeroLength elements with stiffness of 37kN/mm. The chord studs were modelled as truss elements with physical and mechanical properties representative of chord studs used in tested mock-up (147×50×1.5 mm C back-to-back sections), while the tracks were modelled as infinitely rigid truss elements. More details are available in Fiorino et al. [23]. Intermediate studs were neglected in the shear wall models as they are pin connected to their ends and do not contribute to the shear wall response.

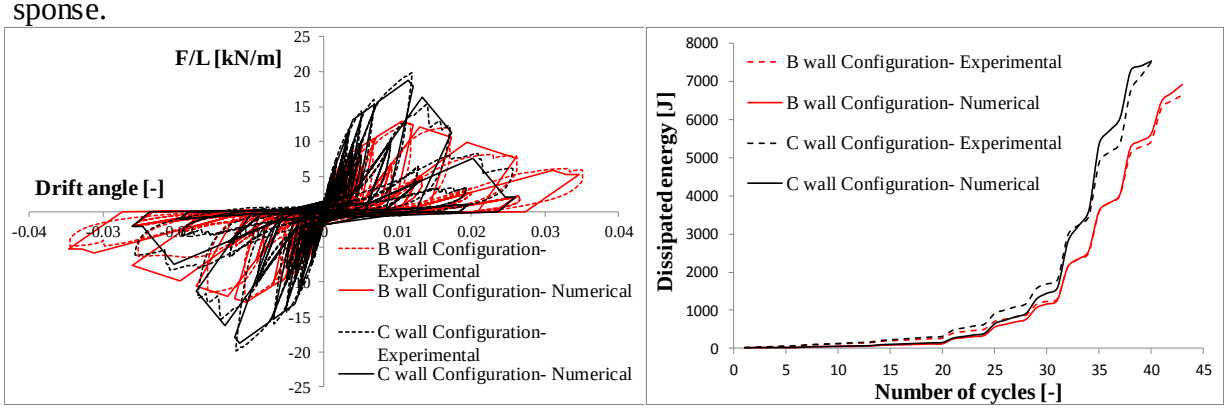

Figure 3: Experimental vs. numerical response in terms of load vs. displacement cyclic behaviour and cumulative dissipated energy

3.3 Other structural components

Apart from shear walls, other structural elements and components contribute to the seismic behaviour of the mock-up, i.e. intermediate studs, gravity walls, floors and roof. The intermediate studs were modelled as truss elements, with physical and mechanical properties representative of studs used in tested mock-up (147×50×1.5 mm C sections). The behaviour of gravity walls was also idealized as a pair of diagonal truss elements with Pinching4 material. The main difference between gravity and shear walls is the absence of hold-downs in gravity walls and the presence of hold down in shear walls. To reproduce the experimental rigid behaviour of the floors (ASCE 7-10), two different approaches were followed: rigid diaphragm or floor joists explicitly modelled. In the first approach the diaphragm was simulated by infinite rigid vertical and horizontal truss elements and in-plane X trusses applied at both floor intrados and extrados. In the second approach, joists were modelled as elastic beam column elements pin connected to the floor track elements, with the same properties of joists used in the mock-up (197×50×10×2.0 mm C back-to-back section. For further details see Campiche et al. [24].

3.4 Architectural non-structural components

Main architectural non-structural components present in the C mock-up Configuration were: finishing materials of shear walls and gravity walls, partition walls and internal counter walls. Finishing materials of shear and gravity walls were included directly in wall models, by using models representative of the walls with architectural non-structural components, i.e. model of shear wall with finishing materials (SW_C) and model of gravity wall with finishing materials (GW_C). The model of the partition walls was the same model used for the gravity walls. Since partition walls did not have present finishing materials, only test data of the B wall Configuration were used to calibrate the *Pinching4* material. The lateral force contribution provided by the double layer of impact resistant gypsum boards in counter walls was already lumped in the model of shear and gravity walls with finishing parts. Therefore, only the studs of internal counter walls were modelled as a truss element with their position in model and, the physical and mechanical properties being the representative of profiles used in tested mock-up (60×27×0.6 mm C sections). The end nodes of these studs were linked to the rigid truss elements of floors and they were constrained by the same rigid Diaphragm used to reproduce the rigid behaviour of the floor.

3.5 Numerical vs. Experimental response

In order to validate the numerical results, a comparison in term of dynamic properties (fundamental period of vibration) for B and C mock-up Configurations and seismic performance for C mock-up Configuration was performed. For each model, the fundamental period of vibration was evaluated via modal analysis (T_{NUM}) and was compared with the values evaluated on the bases of the experimental results (T_{EXP}), through the ratio $\Delta T = (T_{NUM} - T_{EXP})/T_{EXP}$ (Table 3) The models which gave the most accurate estimation of the fundamental period for the B and C mock-up Configurations were the B2 and C2 Models, respectively. They exhibited a fundamental period of vibration of about 0.12 s and 0.11 s, corresponding to a ΔT equal to about 3% and 7%, respectively.

For C Models, the peak inter-storey drifts were evaluated via non-linear time history analysis ($PIDR_{NUM}$) and were compared with the values obtained experimentally ($PIDR_{EXP}$), through the ratio $\Delta PIDR = (PIDR_{NUM} - PIDR_{EXP})/PIDR_{EXP}$. Moreover, experimental and numerical inter-storey drift time histories were compared. The model which gave the most accurate estimation of peak inter-storey drifts and better reproduced the experimental time history (Fig.4) was the C3 Model. It exhibited a PIDR equal to about 0.61% and 0.53% for the first and second storeys, corresponding to a $\Delta PIDR$ equal to about 24% and 2%, respectively.

Model	T_{NUM} [s]	T_{EXP} [s]	ΔT [%]
B1	0.143	0.130	13
B2	0.123		3
B3	0.118		7
B4	0.117		8
B5	0.100		21
C1	0.107	0.100	7
C2	0.095		5
C3	0.082		18

Table 3 Comparison between experimental and numerical fundamental period of vibration

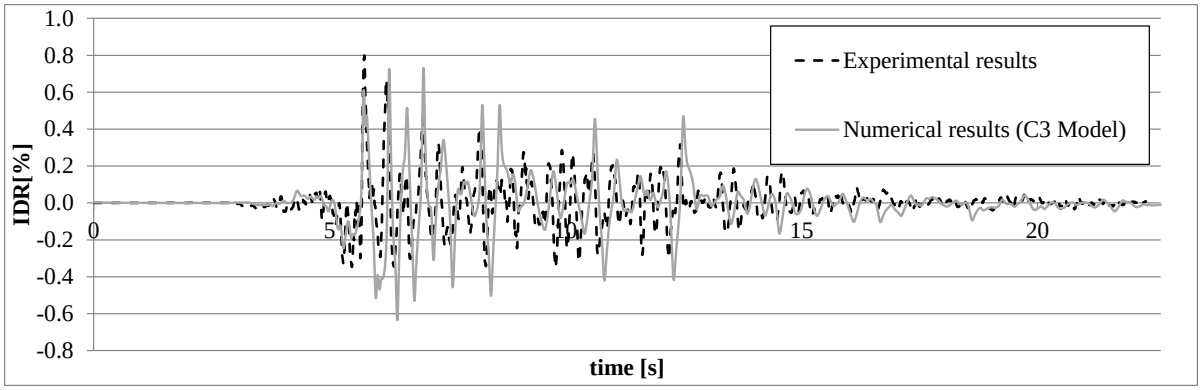

Figure 4: Comparison between experimental and numerical (C3 Model) IDR time history for the first storey

3.6 Effect of architectural non-structural components based on numerical results

Since the experimental data for the seismic response under earthquake input are not available for the B mock-up Configuration and partition walls were present in both B and C mock-up Configurations, the effect of architectural non-structural components on the seismic response of the mock-up was investigated numerically. The B4 Model, in which only all the structural components are modelled, and C3 Model, i.e. the model including all structural and non-structural components, were subjected to non-linear time history analysis and the results, in terms of IDR time history (Fig. 5), PIDR and residual inter-storey drift ratio (RIDR) were compared. PIDRs were 1.24% and 0.61%, while RIDRs were equal to 0.058% and 0.024% for B4 and C3 Models, respectively. The comparison of earthquake response of B4 and C3 Models shows the decreasing of the PIDR in C3 Model due to the effect of non-structural components on the whole building equal to about 2.0 times, while the decreasing of RIDR was estimated equal to about 2.4 times. Obviously, due to the non-linear response of the building under the earthquakes with higher intensity, the influence of the non-structural components in terms of PIDR reduction becomes lower in comparison with their effect on the increasing of initial lateral stiffness (see Section 2.4). However, also results in terms of earthquake response confirm the important role of all architectural non-structural components, which can significantly reduce peak and residual inter-storey drifts.

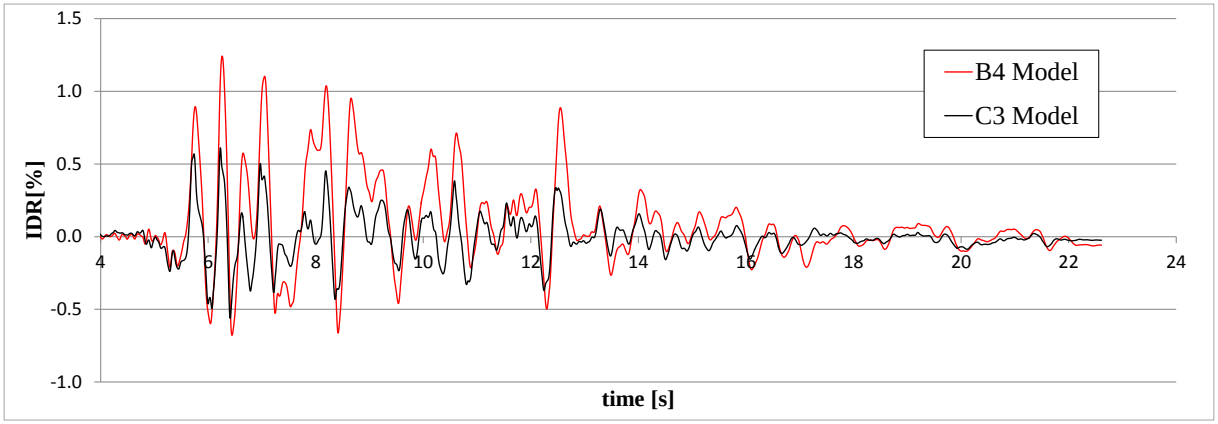

Figure 5: Inter-storey drift time history for B4 and C3 models

4 CONCLUSIONS

The present paper summarises the study on the effect of architectural non-structural components on the seismic behaviour of CFS structures, through the experimental test results and numerical modelling. Cyclic tests on full-scale gypsum sheathed shear walls with and without finishing materials and shake-table tests on full-scale two-storey CFS building with and without the architectural non-structural components and finishing materials were carried out. On the basis of the experimental results different numerical models of the building were developed in Opensees software, considering architectural non-structural components.

Based on the experimental results, the increasing in lateral stiffness and resistance due to the effect of non-structural components on the single shear wall was estimated equal to about 1.4 and 1.5 times, respectively; while for the building the effect of non-structural components, together with the box building behaviour, increased the lateral stiffness of about 3 times. Based on the numerical results, the decreasing of the inter-storey drift due to the effect of non-structural components was estimated equal to about 2.0 in terms of peak value and 2.4 times in terms of residual value.

Therefore, both experimental and numerical results confirm the important role of all architectural non-structural components, together with the box building behaviour, which significantly increase lateral stiffness and strength and reduce peak and residual inter-storey drifts.

Abstract

Recent experimental tests have shown that RBS connections incorporating Jumbo specimens meet the current seismic design qualification protocols, allowing to further extend the current seismic provisions for prequalified steel connections with possible applications of heavy steel sections beyond their current use in ultra-tall buildings. The experimental results and observations described in this paper enabled a better understanding of the structural behaviour of RBS connections made of heavy structural sections for application in seismic regions. However, the results indicate that geometrical and material effects need to be carefully considered when designing welded RBS connections incorporating large steel profiles. To better interpret the experimental results, extensive detailed non-linear finite element simulations are conducted on the entire series of tests, comprising of three large-scale specimens with distinct sizes. The analyses intend to clarify the scale effects that influence the performance of these connections, both at material and geometric level, and particularly to understand the balance in deformation between the column panel zones and the reduced beam section and level of stress within the main connection components. It is shown that the numerical models for all three specimens reproduce accurately the overall load-deformation and moment-rotation time history.

Keywords: reduced beam sections; steel connections; welded connections; seismic design; non-linear modelling.

1 INTRODUCTION

Structural members with long uninterrupted spanning and large loading capacity are needed in the design of tall buildings, convention centres, sport arenas and airport concourses. The latest product developments made by ArcelorMittal permits the use of large jumbo steel profiles as W920x420x1377 (W36×925) with steel of 450 MPa in grades like S460 and HISTAR 460, available both on the US and European market. When such profiles are used in areas of high seismicity, the welded connection design requires a careful development from welding performance specifications (WPS) point to ensure that the required rotational capacities to reach interstudy drifts of 4% can be developed. One technique used to control the flexural demand from the beam is to utilize reduced beam sections (RBS), which effectively limit the demands at the beam-column interface (Figure 1).

The RBS concept was proposed initially by Plumier [1] in the late 1990s to alleviate problems encountered in the 1994 Northridge Earthquake with conventional welded connections. Following, different shapes of RBS have been studied along the time. For example, Iwankiw and Carter [2] studied the first polygonal cut and observed initial yielding in the column panel zone (PZ) followed by diagonal yield lines in the beam flanges. Englehart [3] observed that a higher performance goal might be achieved by changing the shape from constant to a radius cut dogbone. Moreover, Zekioglu et al [4] showed that the application of large plastic rotation capacities, without considering the strength degradation or rotation demand range, to justify a particular moment frame system, would not be a rational approach.

Popov et al. [5] showed in tests that the triaxial loading makes steel at a connection fail without exhibiting yielding ductile behaviour due to the state of stress and not because of material property. Later, Uang et al [6] used a database of 55 cyclically full-scale RBS moment connection tests to study the cyclic instability of such connections. They observed that the slenderness ratio for web local buckling affects the plastic rotation. Ultimately, Zhang and Ricles [7,8] investigated the RBS moment connections to a deep wide flange column and observed that thee composite floor can significantly reduce the lateral displacement of the beam bottom flange in the RBS and the amount of twist developed in the column.

The current AISC Provisions for Steel Buildings (AISC 360-16) [9], Seismic Provisions (AISC 341-16) [10] and the Provisions for Prequalified Connections for Special and Intermediate Steel Moment Frames (AISC 358-16) allow the use of these connections but only for sections up to 900 mm in depth and 450 kg/m in weight [11]. To extend the coverage of these specifications to much larger sections, a joint experimental and analytical program was undertaken by Virginia Tech and ArcelorMittal [12]. It is worth noting, that codified prequalification procedures for seismic steel connections are under development in Europe as a result of the recently completed Equaljoints research project [13].

In this paper, results and observations from an experimental program on three RBS connections provided with large section are reported. Complementary numerical studies are also undertaken using nonlinear finite element procedures which are validated against the experimental results from this study. Comparative assessments are also presented, including stiffness and strength as well as ductility and energy dissipation are examined.

2 EXPERIMENTAL AND NUMERICAL METHODOLOGY

2.1 Testing arrangement and specimen details

The experimental campaign is based on a trial design to determine the realistic member size in buildings with high seismicity area [12]. The study consisted of a square office building tower with fifteen stories and a large open atrium at the 1st floor. Special Moment Frames

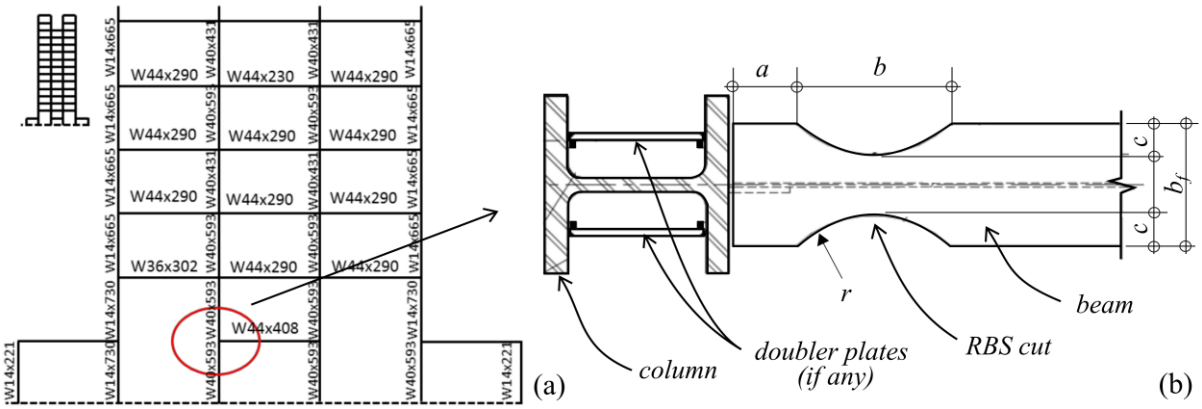

Figure 1: a) Sections at the lower storeys of the Case study building, b) Plan detail of the examined beam-column connections with doubler plates.

Spec.	Beam	Column	Doubler plate	RBS cut			Cont. plates
				A mm (in)	B mm (in)	C mm (in)	
SP2	W 44x408	W 14x873	None	200.5 (7.9)	708.5 (27.89)	68 (2.69)	None
SP3	W 36x925	W 14x873	5/8	236.5 (9.31)	710.5 (27.97)	99 (3.91)	None
SP4	W 44x408	W 40x503	None	305 (12.00)	950 (37.40)	85 (3.36)	None

Table 1: Specimen details

with RBS connections were considered exclusively for the seismic-load-resisting system. These frames are located at the perimeter and are typically three bays wide, except at the lower levels as shown in Figure 1a. From these typical frames, sample connections were extracted as possible test specimens. Table 1 presents the chosen configurations for the testing, whilst Figure 1b depicts the schematic of a specimen. Each specimen exceeds the size limitation outlined in the AISC 358-16 [11] in at least one regard.

The specimens were secured within a rigid frame that is affixed to the strong floor laboratory as illustrated in Figure 2 and the schematic representation in Figure 3a. The pieces in red indicates where the frame was being fixed to the strong floor. The frame connects to the strong floor in two different ways. The first set of connections to the strong floor is made up of eight stiffened W33×291 members. These eight members take load in the longitudinal direction (parallel to both the actuators and the W members embedded within the strong floor). Each of the members is secured to the W members embedded within the strong floor (depicted as grey strips in Figure 3a) with 42 × one-inch (25.4 mm) A490 bolts in slip-critical connection (achieved with pre-tensioning). The second set of connections to the strong floor involves two large steel wedge shape blocks, designed to take the load in the lateral direction.

As observed, the specimens were tested in the horizontal orientation in displacement control with the actuators reacting to the testing frame. The specimens were subjected to the loading protocol described in AISC 341-16 [10], as illustrated in Figure 3b. After two cycles at a story drift angle of 0.04 rad, the story drift increases by 0.01 rad increments every two cycles until failure. Due to stroke limitations in the actuators, the maximum achievable story drift during these tests was 0.06 rad, hence, the specimens were cycled at 0.06 rad until failure. Specimen instrumetation included a combination of linear and string potentiometers, strain gauges and rosettes, and an in-house imaging system (OJOS) in order to capture all pertinent measurements for analyzing the system as a whole. Results from these devices are later used for the numerical validation descriBed later.

Figure 2 Specimen in testing orientation with two actuators

Is is worth noting that besides the extension of prequalification limits in the AISC codes, another main objective of the experimental programme was to determine an acceptable balance between the deformation obtained from flexural yielding of the RBS and shear yielding of the column web PZ [12]

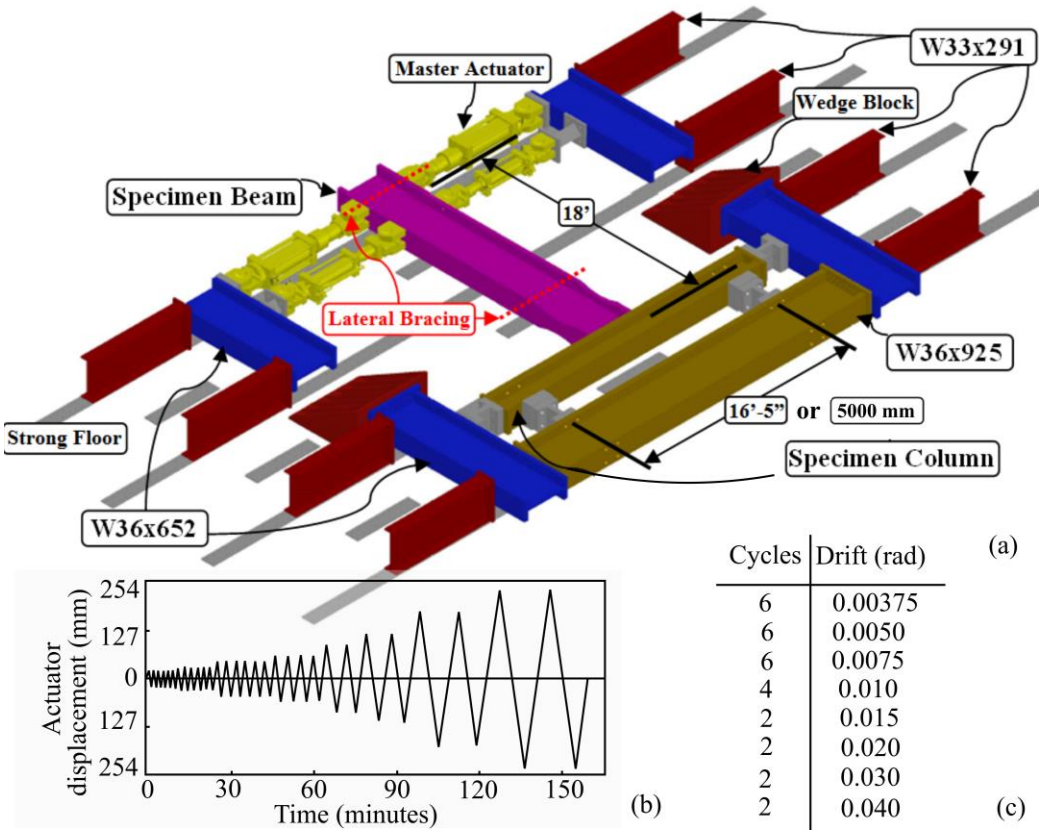

Figure 3 a) Test setup with four actuators, b) Loading protocol – AISC 2010..

2.2 Numerical procedures

The numerical simulations described in this paper were carried out using the non-linear finite element (FE) program ABAQUS [14]. Tri-dimensional (3D) models of RBS connections adopt eight node brick elements (C3D8R). Extruded solid elements from heavy W sections representing the column were connected to the beams using tie constraints. Special attention was given to the characteristics of the RBS region and the column PZ by considering the exact dimensions taken from the experimental specimens (Table 2). Initial studies indicated that the experimental stiffness of specimens with the largest cross-sections (SP3) differed from analytical assessments [12]. To address the potential influence from the test rig, two modelling approaches were considered. Firstly, the specimens, including the four stub elements made of W sections used as boundary conditions were modelled together. Multi-point constraints connected to reference points assigned with pinned boundary conditions to the exterior face of the W profile, whilst surface-to-surface interactions were assigned to the interface between the column element of the specimens and stub elements. Secondly, the specimens described in Section 2.1 were modelled along with the complete testing arrangement as illustrated in Figure 3a. Similarly, pinned boundary conditions were assigned to reference points that were connected through multi-points constraints to the rig elements. All contacts between specimens and rig elements were modelled using surface-to-surface interactions.

Cyclic displacements were applied to reference points that are connected to beam tips through constraints and transfer plates simulating firmly the experimental time history. Mesh sensitivity studies were undertaken assess the element size influence on the hysteretic response. These indicate that a relatively coarse mesh restricts a reliable inelastic strain propagation within the RBS and local buckling effects are not captured. On the other hand, a fine mesh within the RBS and column PZ ($l_m \approx$15-20 mm), combined with $l_m \approx$30-40 mm outside of the critical regions offer reliable deformations and strains, as described in the subsequent sections. A minimum of two mesh rows per flange thickness offer a good balance in terms of computational time and reliability of the results, whilst a much larger number of rows significantly increase the analysis time and reduce the ability of the model to capture local effects, primarily due to hourglass effects [15]. The Newton-Raphson approach was adopted for the numerical integration procedure. The steel material properties were modelled using a plastic multilinear kinematic hardening [14] constitutive representation in which the materials properties obtained from coupon testing, separately for webs and flanges, were accounted for. The yield strength varied between f_y=440-477 MPa and the ultimate strength varied between f_u=609-702 MPa.

3 TEST RESULTS AND NUMERICAL VALIDATION

A reliable failure mode of RBS connections is triggered by yielding at the RBS, followed by limited yielding of the PZ and ultimately local flange buckling at the RBS. The latter is an important mechanism as controls the connection behaviour acting as limit to hardening in flexurally governed yielding responses [12]. Close inspection on the slenderness parameters of the section showed that SP2 and SP4 were susceptible to such sequence of yielding and failure. As the slenderness of both web and flanges are relatively low for SP3, local buckling is unlikely to develop. As expected, SP2 and SP4, failed by flexural yielding and inelastic local buckling, and achieved the desired deformation capacity [12] as illustrated Figure 4a,c. The load-displacement curves for these specimens indicate typical, yielding post-buckling softening after maximum capacity was reached. In contrast, SP3, with significantly higher sections reached flexural yielding, failing relatively sudden without any evidence of softening (Figure 4b). This behaviour was attributed to the extreme demands on the very thick welds,

for which the conventional design procedures may substantially underestimate the local strain demands under cyclic displacements [12].

Non-linear numerical validation of the experimental results of Specimens SP2, SP3 and SP4 were undertaken by accounting for the procedures described in Section 2.2. Figures 4d-e present the relationship between load versus beam tip deflection of the above. The results indicate reliable prediction in terms of elastic stiffness, yielding characteristics, deformations and relatively good predictions of the hysteretic response for Specimen SP2. Remarkably, the model can closely capture the initiation of flange buckling and plastic development in the RBS region and PZ. It is worth noting that the numerical model of SP2 showed slightly larger deformations at RBS and slightly lower deformations at the PZ, recorded as displacement reaction from beam flanges in the column, in comparison to the test response.

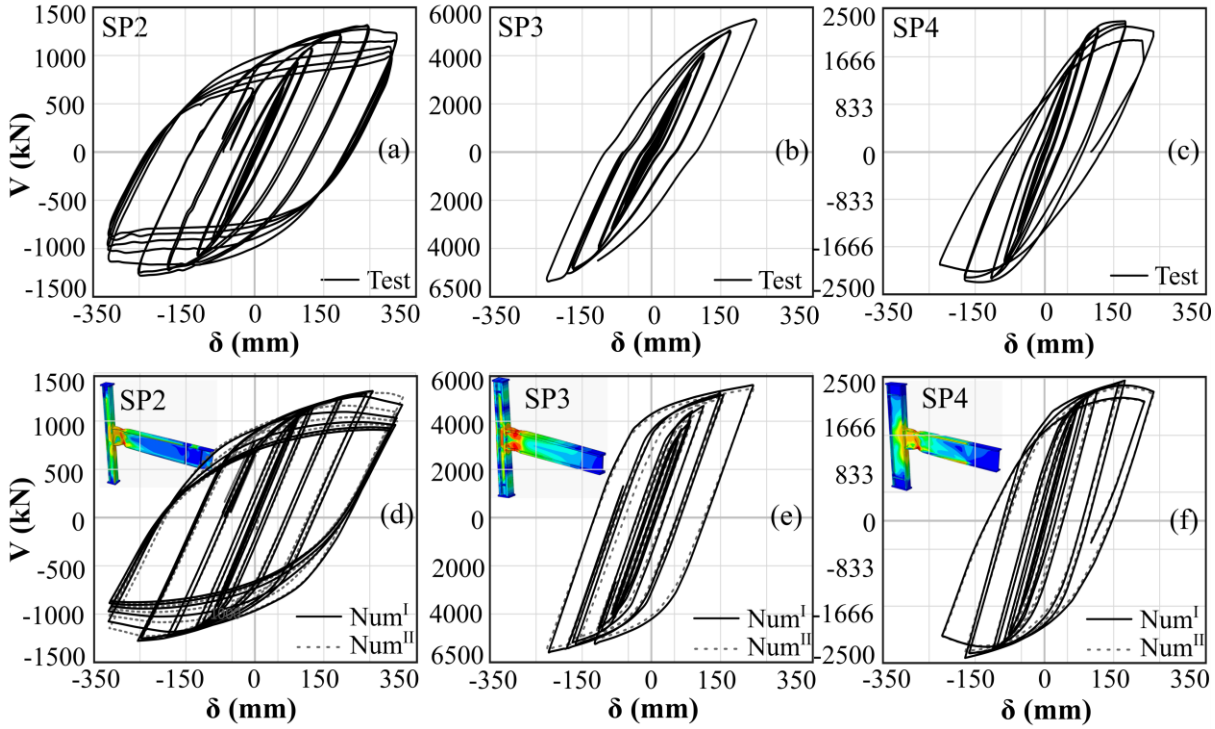

Figure 4: Test force – deflection (V-δ) a) SP2, b) SP3, c) SP4; Numerical validation d) SP2, e) SP3, f) SP4

On the other hand, the behaviour of SP3 was predicted well only in terms of capacity and corresponding displacement, with the numerical stiffness being more rigid in comparison to the experimental stiffness. The test load-displacement of SP3 shows some pinching and change in the unloading stiffness at load reversal, which is not captured with the adopted modelling approach, primarily since all connections between rig elements are modelled with tie constraints, whilst in tests these were rather discrete at the bolted connections. Simulation results of Specimen SP4 show good agreement in terms of stiffness, capacity and degradation, yet the energy dissipation, considered as the area enclosed under the hysteretic loops, is over-estimated. For this specimen the numerical displacements at RBS in tension is identical with the test response, whilst the compression is slightly over-estimated. This is however compensated by a decrease in the deformation at the PZ at which the numerical displacement is about 35% less than the test displacement (Figure 5).

The direct comparison between the models with and without testing rig allowed for an improved understanding of the rig compliance to the load-displacement response. Except the

post-buckling softening response, for SP2 and SP4, the test and numerical curves in Figures 4d,f are virtually identical in terms of key structural parameters and hysteretic response. For SP3, which had significantly larger section sizes in comparison to SP2 and SP4, there is some deviation in the elastic stiffness, primarily due to higher reactions at the boundary conditions of the specimen. Also, the numerical results indicated that the webs of the stub elements that connected the SP3 column to the reaction stubs developed inelastic strains. Additional modelling of the slip between elements fixed to the strong floor and connected rig elements, r by transducers, reduced the stiffness of SP3, being closer to the experimental stiffness, yet more rigid.

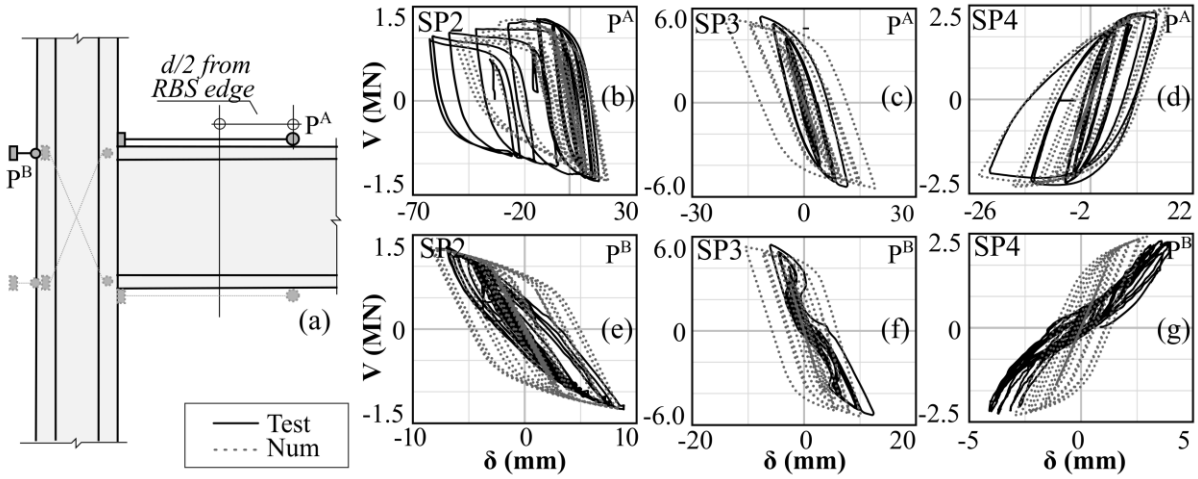

Figure 5 a) Instrumentation extract; Comparison of deformations at RBS b) SP2, c) SP3, d) SP4; at column flange due to force introduction from beam flanges e) SP2, f) SP3, g) SP4.

Observations from models indicate that although the welds were not explicitly modelled, the inelastic strain maps obtained from the SP3 model showed initiation of yielding in the beam at the column face and further in the web column panel, with lower stresses in the RBS flanges than in its web. Also, the direct comparison between the test hysteretic responses of SP2 and SP4 versus SP3 indicate a relatively distinct response. The latter depicts a less ductile behaviour with a lower amount of energy dissipated through the loops. These observations combined with test and numerical results from literature on RBS beam-to-column connections [5] with relatively large sections suggest a possible size effect in cyclic response of large size steel connections. As material models employed in numerical simulations are typically validated against tests on relatively small samples, at significant inelastic strains, these may not reliably represent the structural response when plastic strains develop on large areas.

4 COMPARATIVE ASSESSMENTS

This section describes a detailed analysis of the response of the connections investigated in terms of moment-rotation envelopes, ductility, energy dissipation and stiffness. Bending moments M were assessed at the face of the column from actuator loads in case of experiments and reaction forces at reference points for numerical models. For the global behaviour, chord rotations θ are assessed from beam tip displacements. Figure 6a depicts both test and numerical M-θ envelope curves determined from the V-δ from Figure 4. Besides M-θ curves, the yield moment M_y at the RBS, using assessed material strengths, for each specimen is presented. As observed, the yield moment, represented by a change in member stiffness for both test and numerical models intersects with the analytical assessments, marked with dashed lines.

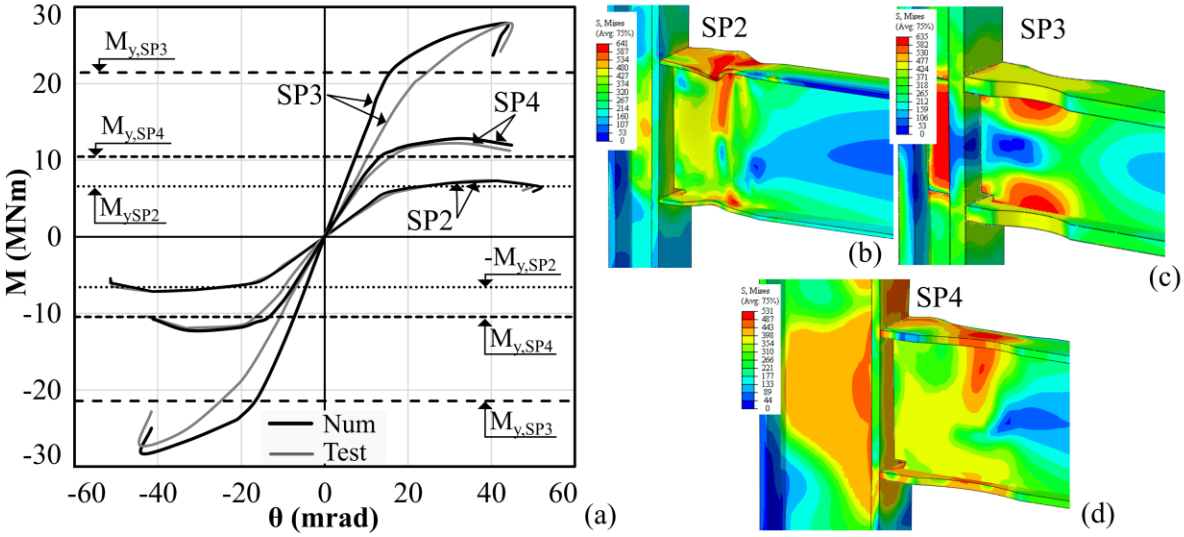

Figure 6 a) Moment – rotation envelopes; stress fields at peak displacement for b) SP2, c) SP3, d) SP4

All specimens exhibited acceptable levels of ductility at ultimate with values above 40 mrad. Specimens SP2 and SP4 had higher ductility and enhanced hysteretic response in comparison to SP3, as also described in previous sections. This is also highlighted by a direct comparison between the test and numerical M-θ curves. For SP2 and SP4 there is a very good agreement in terms of stiffness, yield moment M_y, hardening, ultimate moment M_u and softening. On the other hand, although the yield and capacity of SP3 are well captured by the numerical simulations, the test stiffness is lower than its numerical counterpart. It is worth noting that the size of SP3 was significantly higher than of the SP2 and SP4, hence the M_u at the column face for SP3 was in the range of 27.9 MNm, which is 2.3 × M_u of SP4 and 3.8 × M_u of SP2.

Figures 6b-d illustrate the Mises stress fields at the last cycle of the peak displacement applied. The stress distributions indicate (i) flange buckling at RBS for SP2 with a lower damage at the PZ (Figure 6b), (ii) concentration of stresses at PZ and beam web with lower stress levels at the RBS flanges at SP3 (Figure 6c), and (iii) non-symmetric stress distribution at RBS and PZ with out-of-plane column rotation for SP4 (Figure 6d). It is suggested that the cyclic degradation of SP2 resulted from buckling at the RBS, whilst at SP4 the initiation of buckling was combined with column twist and column web buckling. In contrast, as the RBS flanges of SP3 had lower stress levels than the remaining connection components, there was no degradation at RBS, yet significant column web panel distortion occurred.

The contributions of the RBS and column web PZ obtained from numerical simulations are depicted in Figures 7a-c. The rotation at RBS was assessed from the relative displacements of the top and bottom RBS cuts, and divided by the beam depths. The web column rotation was determined from the relative web displacements resulted from force induction by beam flanges and relative vertical panel displacements [16]. As indicated in the figure, SP2 an SP4, dissipated large energy proportions through the RBS, with the PZ contributing in the range of 15-25%; hence a stronger PZ. On the other hand, SP3 had a relatively even contribution of the two components indicating a relatively balanced behaviour. A close inspection on an identical model of SP3 without double plates showed a contribution of the web column panel of about 70% to the connection rotation, resulting in excessive distortional demands leading to unreliable performance of the components [17,18].

Figures 7d-e indicate the cumulative energy dissipation, integrated from the hysteretic loops converted in M-θ from Figure 4, and the decrease in secant stiffness in relation with θ. As described before, SP2 had stable hysteretic loops and a ductile response with θ_u=50.5 mrad. This is captured by the cumulative energy curve whose stiffness increases with rotation. Additionally, as the numerical response was in good agreement with the test curves, the test and numerical E_d curves of SP2 nearly overlap. On the other hand, SP3 and SP4 reached lower E_d indicating poorer hysteretic response in comparison to SP2 yet reaching reliable ductility levels (θ_u≈mrad). More importantly, considering that the yield rotation was around θ_y=15 mrad for all members, the plastic rotation θ_p=30-35 mrad indicating that these connections developed reliable response for connections in seismic resistant structures with θ_p being between the minimum requirements for ductility class medium ($\theta_{p,M}$=25 mrad) and for ductility class high ($\theta_{p,M}$=35 mrad) [19].

5 CONCLUSIONS

The performance of reduced beam section (RBS) beam-to-column connections incorporating large jumbo steel profiles subjected to cyclic loading was investigated in this study. The experimental and numerical results showed that the strength, stiffness, ductility, hysteretic response and failure mode of such connections are largely dependent on the beam and column section sizes. The results indicated that RBS beam sections with relatively high depth-to-web thickness slenderness ratios develop reliable failure modes characterised by extensive yielding at the RBS, followed by yielding at the panel zone (PZ) and ultimately, flange buckling at RBS. Also, for relatively deep columns, force induction from beam flanges, combined with RBS flange buckling, could produce out-of-plane column rotation. These connections

developed responses characterised by stable hysteretic response, a relatively strong PZ and reliable ductility levels.

In contrast, compact sections with relatively low depth-to-web thickness ratios may develop unreliable response with yielding developing almost concomitantly and at RBS and PZ, having a relatively equal contribution to the total connection deformation. Numerical simulations showed that for connections with relatively compact sections, a higher concentration of stresses may occur at the PZ and at the beam, web with lower stress levels developing at the RBS flanges. These observations indicate the need for an alternative design procedure of RBS for connections incorporating large compact sections. More importantly, the connections investigated in this paper reached reliable rotational capacities, that correspond to inter-story drifts of 4% as a minimum required by North American prequalification standards. This corresponds to plastic rotations of above 25 mrad, indicating that these steel connections conform with the minimum European requirements for ductility class medium. Ultimately, the numerical models were able to capture the local effects, as well as the key structural response characteristics indicating that the modelling procedures can be employed for further extensive parametric investigations.

Abstract

Many existing steel multi-storey frames in Europe were designed prior to the provisions of modern seismic design codes; therefore, they often exhibit low resistance to earthquakes due to their insufficient energy dissipation capacity. However, the current framework for assessing existing structures in EC8-3 is inadequate and should be reviewed. Particular attention should be paid to the contribution from masonry infill walls as they significantly affect the modal properties and the lateral stiffness of structures. To this end, two 3D models of a two-storey steel moment-resisting frame were developed to assess the applicability of the current framework in EC8-3 to the infilled structures under multiple earthquakes through nonlinear analyses. The modelling of masonry infill walls was achieved through a macro-model using equivalent diagonal struts. The ground motions utilised during the analyses took the records of the recent 2016 Central Italy earthquake sequence. As part of the project HITFRAMES, this paper serves as a preparation for the experiment to be conducted in Greece.

Keywords: Existing steel frames, Assessment, Pseudo-dynamic testing, Seismic response, Modal calibration.

1 INTRODUCTION

Nowadays, modern seismic design codes have recognised the importance of the inelastic behaviour of structures during earthquake and provided guidelines for designing ductile structures with sufficient capability of dissipating energy. However, numerous existing steel frames were designed prior to the provisions of model seismic design codes and were designed to gravity loading only. Those frames are often characterised by inadequate energy dissipation capacity due to their non-ductile connections and slender beams and columns [1], and therefore, high vulnerability to earthquakes. Global collapse and severe local damage have been observed in such frames in the aftermath of the 2016 Amatrice earthquake in Central Italy. Public attention has been attracted to the urgent need of a rigorous framework of assessing the seismic vulnerability of existing steel frames [1, 2].

Many code-based procedures for assessing and retrofitting existing steel frames has been developed so far, such as EC8-3 in Europe [3] and ASCE41-13 in the US [4]. Those codified assessment procedures generally adopt the concept of performance-based earthquake engineering and allow both linear and nonlinear analysis of frame models to be carried out, though with some restrictions on the linear methods. However, a recent review of the EC8-3 by Araújo and Castro [4] summarised some inconsistencies and limitations in the European code, for example, the different analysis methods provided in EC8-3 may cause significant inconsistencies in demand estimations and it seems that the predefined capacity criteria for different limit states in terms of member plastic rotations are a direct reproduction of the former version of American code ASCE41-06, which were based on tests of typical American cross section profiles rather than the European profiles [4]. Another important issue is that the current EC8-3 only defines the behaviour requirements of non-structural members in a qualitative manner, through the definition of each limit states. Besides, since the EC8-3 requires safety check of every individual member, the assessment process can be extremely time-consuming and the onset of failure of a limit state is simply decided by the first member that exceeds corresponding criteria, which tends to neglect the redundancy of a structure. Consequently, further revision of EC8-3 is necessary for the next generation of Eurocode 8 regarding both the analysis methods and compliance criteria.

As an important part of the assessment of existing steel frames, selection of the most appropriate numerical model is strongly dependent on the specific target that is set to achieve. A comprehensive model that contains more detailing than a bare frame may lead to higher reliability of structural performance estimation, but this is not always true because of the complex nature of the interactions among structural and non-structural components, such as the masonry infill walls, beam-to-column connections and composite slab. It is now widely accepted that the contribution of infill walls to the lateral stiffness and strength of steel frame is significant and should be taken into consideration in assessing existing steel frames [1, 5]. Several previous studies have tried to develop simple but reliable models of masonry infill walls and incorporated them into bare frame models. A macro-model of masonry infill wall was proposed which uses a single equivalent strut in each diagonal direction with appropriate strut mechanical properties to capture the strut action caused by infill walls to the confining frames [5, 6, 7, 8, 9]. This macro-model has an advantage in terms of its combined efficiency and accuracy in the assessment of global response, despite some compromise has to be made to the local behaviour of infill walls. A valid constitution law also plays an essential role in the equivalent strut model due to the non-homogenous nature of the material [5].

The main aim of this study is to present the assessment of a case steel moment resisting frame (MRF) based on the procedure in EC8-3. Nonlinear static and dynamic analysis was performed to estimate the demand and capacity for each limit states. The steel frame was designed to sustain gravity loading only following the design code EC3. A 3D model was established in the Open System for Earthquake Engineering Simulation (OpenSees) analysis

software [10]. Special attention was paid to the contribution of masonry infills to the overall performance of the frame. In addition, multiple earthquakes were applied to the frame model in the nonlinear dynamic analyses so that potential cumulative damage on the structure was investigated as well. Capacity was assessed based on the criteria proposed in EC8-3 in terms of member plastic rotation. Criteria based on inter-storey drift ratio (IDR), which accounts for the stability of structures, were also used to assess the reliability of plastic rotation criteria.

2 ASSESSMENT FRAMEWORK IN EC8-3

This paper is aimed to present the assessment procedure of a steel frame based on the non-linear analyses in EC8-3, therefore, a brief description of the framework is presented. The focus of this study is nonlinear analysis; hence the procedure of linear analysis is not included here.

Three limit states are defined in EC8-3, namely the Damage Limitation (DL) limit state, the Significant Damage (SD) limit state and the Near Collapse (NC) limit state, compared to two in EC8-1 for general rules [11], which are the DL and ultimate limit state. By definition, as concluded in Table 1, the return periods for the DL, SD and NC limit state are 225, 475 and 2475 years respectively, corresponding to probabilities of exceedance of 20%, 10% and 2% in 50 years. It is interesting to notice that the ultimate limit state in EC8-1 is equivalent to the SD limit state in EC8-3 in terms of their return periods, while NC limit state is actually closer to the real collapse of structures, hence associated with a much longer return period. The explanation given is that NC limit state makes full use of the deformation capacity of structural elements, while SD limit state (ultimate limit state) leaves some residual lateral drift and stiffness and loading carrying capacity of vertical elements [2]. It is also worth noting that the DL limit state in EC8-1 has a shorter return period than that in EC8-3, so the former is more conservative than the latter. The above comparisons indicate that the three limit states for existing buildings are defined to prevent collapse of buildings rather than upgrading them to satisfy the design requirements for new buildings [4].

	EC8-3			EC8-1	
	DL	SD	NC	DL	Ultimate
Hazard level	225 years	475 years	2475 years	95 years	475 years
	or				
	20% in 50 years	10% in 50 years	2% in 50 years	10% in 10 years	10% in 50 years

Table 1: Performance requirements for different limit states in EC8-1 and EC8-3.

The EC8-3 also provides some guidance on the data collecting of existing buildings, where information of geometry, detailing and materials should be gathered. Three knowledge levels are summarised to deal with the uncertainties during the process of surveying, from limited to full knowledge level. A confidence factor is assigned to each knowledge level, which is used in the assessment of capacity as a partial safety factor. For the purpose of this study, full knowledge is assumed, thus a confidence factor of 1.0 is taken and no reduction is required in the safety verification.

Safety check in terms of demand and capacity is the last stage in the assessment framework of EC8-3. In the context of nonlinear analysis, demand can be taken as the results of analysis directly, but capacity differs between ductile and brittle structural elements. For ductile elements, their deformation capacity will be compared with the deformation demand, while for brittle elements, internal force capacity shall be compared with the corresponding force demand. In the case of steel frames, which is the case of this study, EC8-3 requires safety check

to be done considering the plastic rotation of columns and beams, where the capacity for each limit state is dependent on the yield rotation of each element, as summarised in Table 2. The table applies to Class 1 and 2 cross-sections only and the dimensionless axial force ν should not exceed 0.3. EC8-3 does not give any limits on other cross-sections or with higher value of ν. Recall that the criteria in Table 2 is in fact the same as the one used to be adopted in the American code ASCE41 for dimensionless axial force ν less than 0.2. For the determination of demand, i.e. the target displacement, in nonlinear static analysis, N2 method [12] is recommended by EC8-3.

Class of cross-section	DL	SD	NC
1	$1.0\theta_y$	$6.0\theta_y$	$8.0\theta_y$
2	$0.25\theta_y$	$2.0\theta_y$	$3.0\theta_y$

Table 2: Plastic rotation capacity proposed in EC8-3 with dimensionless axial force $\nu \leq 0.3$.

For non-structural elements, requirements are described in the definition of three limit states qualitatively. For DL limit state, infill walls may experience some cracking, but damage shall be repaired at a low cost. For SD limit state, although infill walls are damaged, but out-of-plane failure shall not happen. Finally, the NC limit state allows infill walls to be significantly damaged or even collapse. Quantitative specifications are not included in the current version of EC8-3.

3 CASE STUDY AND NUMERICAL MODELLING

The building considered in this study is a two-storey steel MRF, which has a rectangular layout in plan. The frame is 13.5 metres long, consisting of three bays, 8.5 meters in width and 6.6 metres in height with a storey height of 3.3 metres. Figure 1 shows the plan and side view of the frame. Composite floor slab and masonry infill walls are omitted for clarity. The steel frame was designed to resist gravity load only and does not have sufficient lateral stiffness and strength to survive a strong earthquake. The steel grade for all beams and columns is S355. The primary and perimeter beams are designed to be IPE270, all other beams are IPE200 and columns are HE240A. Moreover, beam-to-column connections are full penetration weld connection and the infill walls consist of two layers of 80-mm thick perforated bricks with a compressive strength of 9.7 N/mm^2 bound together through M5 mortar. Regarding the loading conditions, the self-weight of slab was taken as 240 kg/m^2, the density of bricks is 855 kg/m^3 and a live load of 2 kN/m^2 is also accounted for in the design.

	Cracking	Ultimate	Residual
Axial force (kN)	183	239	24
Strain	0.00009	0.00034	0.01063

Table 3: Modelling parameters of the trilinear curve for masonry infill walls.

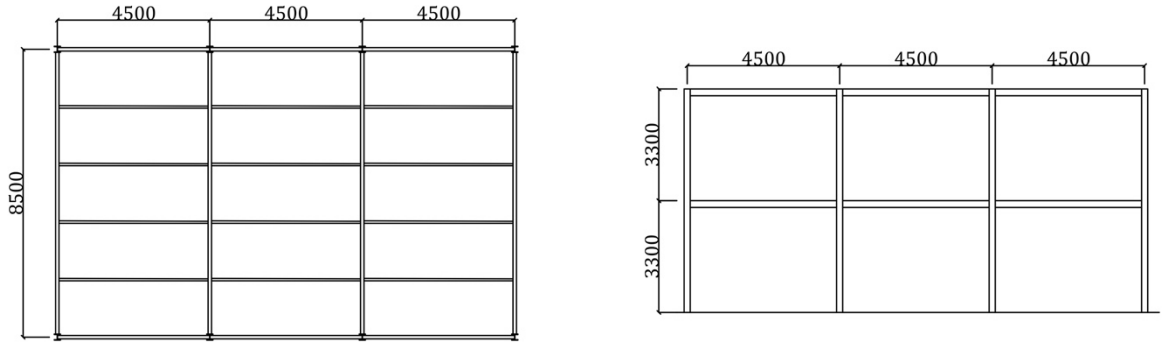

Figure 1: Plan layout and side view of the steel MRF.

Two 3D models of this steel MRF were established in OpenSees [10], namely a bare frame and an infilled frame. Columns were modelled using force-based beam-column elements with fibre section and 10 integration points along the length using Gauss-Lobatto integration method. Besides, the Steel01 material, which is a bilinear elastoplastic material model, was considered for structural steel with a hardening ratio of 0.02. Plastic hinges in beams were assumed to form at the ends of members, through lumped plasticity zero-length elements. The zero-length elements possess a trilinear moment-rotation relationship based on the Ibarra-Krawinkler-Deterioration (IKD) model [13, 14] to represent the rotational behaviour of beams. The parameters if the IKD model were calibrated based on finite element analyses carried out in ABAQUS 6.14. Rigid diaphragm action was achieved using rigid diagonal struts. Regarding the infills, the equivalent strut model [5] was chosen due to its simplicity and accuracy for evaluating global response. The constitution law was based on the Fardis-Panagiotakos model, which is a trilinear curve accounting for the cracking and ultimate strength of masonry infills, as well as degrading after the ultimate strength is reached [6]. The model applies to compression only and zero tension is considered. Since the modelling of infill walls is a key point in this study, the modelling parameters are summarised in Table 3. The analyses were performed in the longitudinal direction of the frame, as shown in Figure 1, where the weak axis of columns was involved and the contribution of infills were more significant.

4 ASSESSMENT RESULTS

4.1 Modal analysis

A modal analysis was performed at the beginning to capture the basic modal properties of the frame and the results are summarised in Table 4. The information obtained here will be helpful in the following assessment of the steel frame.

		1st mode	2nd mode
Period (sec)		0.74	0.25
Modal mass (%)		92%	8%
Mode shape	1st floor	0.42	1.00
	2nd floor	1.00	-0.54

Table 4: Modal property of the bare frame in the longitudinal direction.

It is anticipated from Table 4 that the seismic behaviour of the frame will be dominated by the fundamental mode, with a modal mass that accounts for 92% of the total mass. The modal

analysis was performed on the bare frame only. The presence of infills increases the initial lateral stiffness by a considerable amount, hence the initial fundamental period of the infilled frame is much lower than that of the bare frame, which is around 0.05 sec. However, since the masonry infills crack and fail quickly during the analysis, a quick drop was observed in the lateral stiffness of the infilled frame, hence the fundamental period was very unstable. It was also expected that the infilled frame would eventually have similar fundamental period to the bare frame after the loss of all infill walls.

4.2 Nonlinear static analysis

A total of four pushover analyses were carried out in this study. EC8-3 requires at least two lateral load patterns should be used in pushover analysis, namely a uniform pattern and a modal pattern. The uniform pattern (denoted as U) consists of lateral loads proportional to the lumped mass of each node, while the modal pattern (denoted as M) includes lateral loads proportional to both the mass and first mode shape of each node. Both of the two load patterns were applied to the bare and infilled frame. The performance points (demand) were determined based on the N2 method [12] suggested in EC8-1. The response spectrum adopts the Type 1 elastic response spectrum in EC8-1 for ground type B, and the reference peak ground acceleration was taken as 0.1975, 0.25 and 0.4275g for DL, SD and NC limit state, respectively. The choice of these parameters was based on the seismicity in Central Italy, where severe earthquake events have occurred in the past few years, causing collapse of numerous steel MRFs. Figure 2 shows the response spectrum in acceleration-displacement (AD) form for each limit state, as well as the capacity curves for the original frames and the equivalent SDOF systems. Since the uniform and modal lateral load patterns provided very similar capacity curves, only the seismic demands obtained from the modal pattern are presented in this paper. The global and inter-storey drift ratios at each performance point are also presented in Table 5.

It is clearly shown in Figure 2 that the presence of infill walls significantly increased the initial stiffness and maximum base shear of the frame. Besides, based on a damage assessment, it is found that columns in both models yield prior to the beams, which remain in elastic range up to NC limit state. This weak column-strong beam (WCSB) scenario is undesirable in modern seismic design code, which tends to concentrate plastic deformation within certain floors and increase seismic demands [15, 16]. It is also observed that for the bare frame, no plastic hinges were formed in columns at the DL and SD limit state. However, at NC limit state, plastic hinges were found in all ground floor columns of the bare frame, indicating that the frame was about to lose its load carrying capacity in the vertical direction. On the other hand, for the infilled frame, plastic hinges began to form at the point of maximum base shear, right after the exhaustion of ground floor infill walls. The turning point at 1.15% global drift marks the formation of plastic hinges in all ground floor columns. Apparently, the columns in the infilled frame failed quickly than those in the bare frame. This is possibly due to the strut action of the infill walls which caused higher local force on columns. In addition, as a result of the WCSB characteristic, all infills on the ground floor collapsed at the point of maximum base shear while those on the first floor barely cracked. Therefore, the presence of infills had great effects on the seismic behaviour of steel MRFs, emphasising the necessity of including infill walls in the seismic assessment.

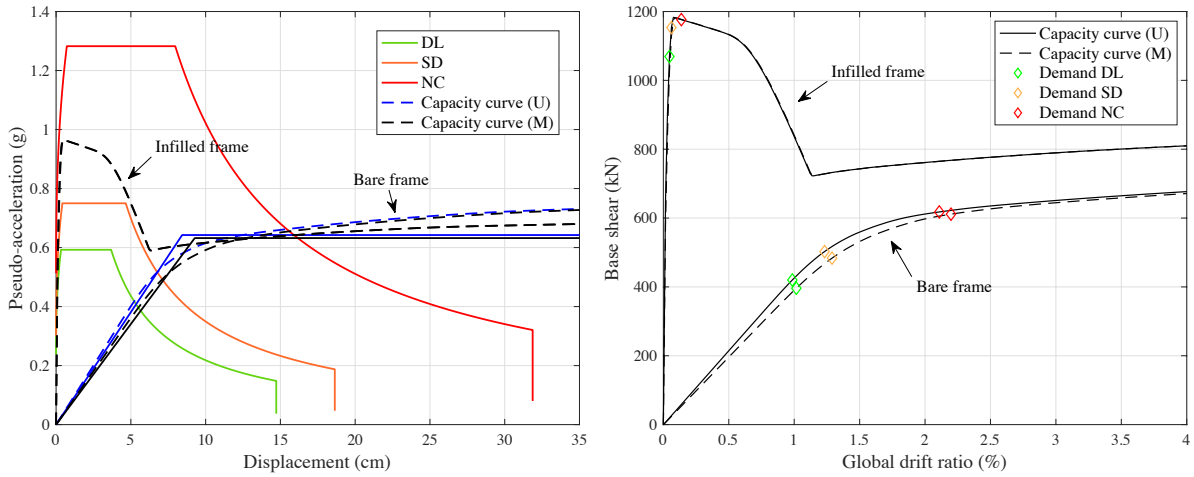

Figure 2: Response spectrum in AD form and capacity curves of the original frames (right) and the equivalent SDOF systems (left).

		Bare			Infilled		
		DL	SD	NC	DL	SD	NC
Global	Uniform	0.99	1.23	2.11	0.04	0.06	0.14
	Modal	1.02	1.29	2.20			
Ground floor	Uniform	1.13	1.45	2.88	0.08	0.09	0.26
	Modal	1.09	1.40	2.78			
1st floor	Uniform	0.81	0.98	1.27	0.02	0.02	0.01
	Modal	0.94	1.18	1.62			

Table 5: Global and inter-storey drift ratios (%) obtained from nonlinear static analyses.

An important step of the N2 method in EC8 is that an idealised bilinear curve should be derived to represent the behaviour of the equivalent SDOF system, as presented in Figure 2. However, a bilinear idealisation seems not appropriate in the case of infilled frames based on the shape of its capacity curve. As a result, the initial stiffness was adopted to continue the N2 method. Apparently, from Figure 2 and Table 5, the seismic demands on the infilled frame is much lower than those on the bare frame, because the presence of infill walls resulted in a sharp increase in the lateral stiffness and strength. However, the N2 may yield non-conservative estimation at the short-period range due to the high sensitivity of inelastic displacement to the change of structures [12]. In this study, the infill walls cracked and failed shortly after the start of pushover analysis, caused the global lateral stiffness to quickly decrease and eventually to be the same as that of the bare frame. Therefore, further research should be carried out to find out a more accurate rule for structures in the short-period range, where the effects due to changes of structural parameters are accounted for.

4.3 Nonlinear dynamic analysis

The time-history analysis utilised the records for the earthquake sequence initiated in Amatrice, a town in Central Italy, on 24th of August 2016. The Amatrice earthquake sequence includes one mainshock and four aftershocks whose peak ground accelerations are larger than 1.0g. The basic information of those strong ground motions is provided in Table 6, and the accelerogram and pseudo-acceleration spectrum for 5% damping are shown in Figure 3. EC8-3 requires at least 7 earthquake records to be involved in the time-history analysis, however,

the focus in this analysis is to investigate the potential effects of earthquake sequence and the presence of infill walls. Therefore, only one earthquake sequence is considered in this study.

As shown in the spectrum in Figure 3, the spectral acceleration of the unscaled record of mainshock at the fundamental period is 0.365g, which is less than the spectral acceleration at fundamental period corresponding to the DL limit state. This indicates that the frame may still be within the elastic range under the unscaled records. In order to observe some damage on the frame, the entire earthquake sequence was scaled by a factor of 1.37 and 2.36 such that the spectral acceleration of the new earthquake records at fundamental period equal to the one corresponding to the SD and NC limit state, thus the two scaled earthquakes are denoted as SD and NC, respectively. The spectral acceleration at fundamental period was used as the scaling parameter because as mentioned in the modal analysis, the seismic response of the steel frame in this study is dominated by the first mode, which takes up more than 90% of total mass. The mainshock record was applied to the frame alone at first and then with its aftershocks to represent single and multiple earthquakes.

Event	Date	M_w	M_L	R_{epi} (km)	PGA (g)	PGV (cm/s)	PGD (cm)
M/S	24-Aug-2016	6.0	6.0	8.5	0.87	43.5	8.5
A/S1	24-Aug-2016	4.3	4.5	3.6	0.19	6.8	0.5
A/S2	24-Aug-2016	5.3	5.4	20.9	0.11	5.1	0.9
A/S3	25-Aug-2016	4.4	4.3	3.6	0.23	9.6	0.6
A/S4	26-Aug-2016	4.8	4.7	3.1	0.34	11.0	0.6

		Bare		Infilled	
		SD	NC	SD	NC
Global	single	1.26	2.18	0.26	1.34
	multiple	1.26	2.18	0.26	1.34
Ground floor	single	1.46	2.73	0.50	2.67
	multiple	1.46	2.73	0.50	2.67
1st floor	single	1.37	1.87	0.03	0.04
	multiple	1.37	1.87	0.03	0.04
Residual drift	single	0.05	0.44	0.02	0.60
	multiple	0.05	0.44	0.02	0.60

Table 7: Peak global and inter-storey drift ratio and residual drift ratio (%) obtained from nonlinear dynamic analyses.

The failure mechanisms in time-history analysis under single or multiple earthquakes are similar to those in the pushover analysis. The occurrence of column plastic hinges and infill failure is limited to the ground floor, while beams are too strong to enter plastic range. Besides, the presence of infill walls led to higher local force at beam-to-column connections and accelerated the yield of columns.

The peak global, inter-storey and residual drift ratios of the bare and infilled frame obtained under single and multiple earthquakes are presented in Table 7. It is observed that there is no difference between the peak and residual drift ratios under single and multiple earthquakes. This is primarily due to the WCSB characteristic of the frame which led to the failure of columns but kept beams safe. Also, as a matter of numerical modelling, deterioration in unloading and reloading was not considered in the columns, and the aftershocks were not strong enough to activate columns into plastic range again. This is a major limitation of this study and further study addressing this issue should be conducted in the future. It is also noticed in Table 7 that the ground floor drift ratio of the infilled frame was nearly twice the global drift ratio, indicating that the global drift was in fact equal to the ground floor drift. This behaviour is significantly different from that of the bare frame, possibly due to the quick failure of ground floor infill walls and columns, causing the lateral stiffness of ground floor to be much lower than the first floor. When comparing with the results from nonlinear static analyses, good consistency was found for the bare frame. However, for the infilled frame, nonlinear static analysis gives extremely underestimated prediction of seismic demands, although it captured the same behaviour of lateral drift as nonlinear dynamic analysis did.

4.4 Safety verifications

At the safety verification stage, the seismic demands obtained from the nonlinear analyses are compared with the capacity determined based on the compliance criteria in EC8-3, which are based on the rotation of beams and columns. EC8-3 also requires that no yielding or buckling shall occur in columns for DL and SD limit state. To calculate the yield rotation of columns, the following equation is adopted:

$$\theta_y = \frac{M_{pl,Rd} L_s}{3EI}\left(1 - \frac{N_{Ed}}{N_{pl,Rd}}\right) \quad (1)$$

This equation is not proposed in the EC8-3 and is slightly different from the one proposed in the American code which uses half the length of element in the equation rather than the actual shear span L_s. Apart from the criteria proposed in EC8-3, previous studies also suggested the

check of IDR to ensure the stability of structures [2, 17, 18]. The recommended criteria of IDR in [18] for SD and NC limit state is given in Table 9. The value for DL limit state was derived from the serviceability requirement in EC8-1. Recall that the DL limit state in EC8-1 is more conservative than the DL limit state defined in EC8-3, the value of 1% may also be slightly conservative.

The capacity curves from pushover analyses incorporated capacity points are presented in Figure 4. In Figure 4, R represents the capacity of element rotation while D represents the capacity of IDR. It is obvious that for both frames, the rotation criteria only give more conservative predictions at the DL limit state. This indicates that the performance level at SD and NC limit state are not guaranteed by only using the rotation criteria. Also, in the case of bare frame, the locations of capacity points well match the definition of each limit state in EC8-3. However, for the infilled frame, the capacity points tend to correspond to a worse situation than that defined in EC8-3. For the safety verification, the bare frame failed the DL limit state but fulfilled the requirement of SD and NC limit state.

	DL	SD	NC
IDR (%)	1.0	2.5	4.0

Table 8: Criteria in terms of IDR for each limit state.

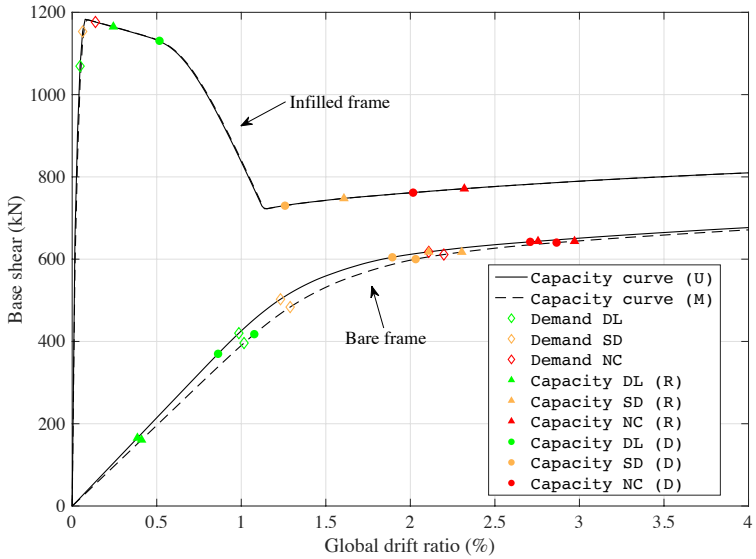

Figure 4: Capacity curves with demand and capacity points for safety verification.

The verification based on the results from nonlinear dynamic analyses was carried out by firstly checking each individual beam and column and then the IDR in Table 7. It is found that the bare and infilled frame survived the SD limit state under the SD earthquake, and survived the NC limit state only under the NC earthquake. Therefore, good consistency has been observed in the final verification results between the nonlinear static and dynamic analysis.

5 CONCLUSIONS

This paper presents a brief assessment of a steel MRF based on the framework in EC8-3 using nonlinear static and dynamic analysis. The potential effects of the presence of masonry infill walls and the use of multiple earthquakes instead of a single earthquake are investigated.

A modal analysis was performed at first, indicating that the seismic behaviour of the steel frame is dominated by its first mode, with a natural period of 0.74 sec. Nonlinear static and dynamic analyses were also performed and the following findings are concluded:

1. The presence of infill walls increases the initial lateral stiffness and strength significantly. An approximate 100% increase is found in the maximum base shear due to the incorporation of infill walls. The strut action induced by the infill walls causes the columns to fail earlier, which also affects the failure mechanism of the frame.
2. The sharp increase in the initial lateral stiffness puts the infilled frame in the short-period range, where the accuracy of N2 method is not guaranteed and non-conservative estimation may be provided. Big differences were found between the global and inter-storey drift ratios for the infilled frame from pushover and time-history analyses, while good consistency was observed in the performance points obtained for bare frame.
3. The use of multiple earthquakes does not influence the assessment results in this case study. This is because of the WCSB nature of the frame structure, whose failure mechanism is controlled by columns, as well as the modelling of structural steel for columns, which does not consider any deterioration in unloading and reloading stiffness.
4. The use of criteria based on beam and column rotation proposed by EC8-3 is not enough in this study, which does not address the issue due to stability. A criterion based on IDR gives more conservative capacity points than the rotation criteria for this case frame under SD and NC limit state.

Further research should be carried out to address the applicability of N2 method in the short-period range, which accounts for the presence of essential non-structural elements like the infill walls. This limitation of the N2 method also restrict the applicability of the bilinear idealisation proposed in EC8-1, which is no longer suitable for the case of an infilled frame. Further research using refined models which take degrading and deterioration of columns into consideration should also be conducted to assess the cumulative damage in columns under multiple earthquakes.

ACKNOWLEDGEMENT

The financial support from Seismic Engineering Research Infrastructure for HITFRAMES (SERA) Project, funded within the H2020-INFRAIA-2016-2017 Framework Programme of the European Commission under grant agreement No.730900 is greatly appreciated. NUMERICAL EVALUATION OF THE BEHAVIOUR FACTOR OF LIGHTWEIGHT STEEL LATERAL FORCE RESISTING SYSTEMS ACCORDING TO FEMA P695

Sarmad Shakeel, Luigi Fiorino, and Raffaele Landolfo

Department of Structures for Engineering and Architecture, University of Naples "Federico II", Italy
e-mail: sarmad.shakeel@unina.it

Abstract

Seismic design regulations rely on certain factors to reduce the earthquake actions due to inherent ductility and overstrength of the lateral force resisting systems. The behaviour factors given in Eurocodes are one such example, which when applied during the design process will ensure the life safety performance level of a building. Light-Weight Steel (LWS) structures fabricated with Cold Formed Steel (CFS) profiles are increasingly widespread in earthquake prone regions, however the current in practice edition of Eurocodes fails to acknowledge their seismic performance by not providing behaviour factors for them. The study presented herein addresses this issue by evaluating behaviour factor for the two commonly used LWS systems: CFS strap braced walls and CFS shear walls with gypsum board sheathing through FEMA P695 methodology. For each type of system, a set of archetypes, which represent a range of design parameters and building configurations are designed following the capacity design approach and their response is idealized by nonlinear numerical models. The performance of archetype models is evaluated systematically through the static pushover and the incremental dynamic analysis under a suite of forty-four normalized and scaled earthquake records, representing the probable seismic hazard to the buildings. Finally, by calculating the collapse probability while also considering the uncertainties from various sources, the suitability of a trial value of the behaviour factor used in the design phase of archetypes is evaluated. Based on the results, it is concluded that a behaviour factor of 2.5 and 2.0 for CFS strap braced walls and CFS shear walls with gypsum board sheathing is appropriate.

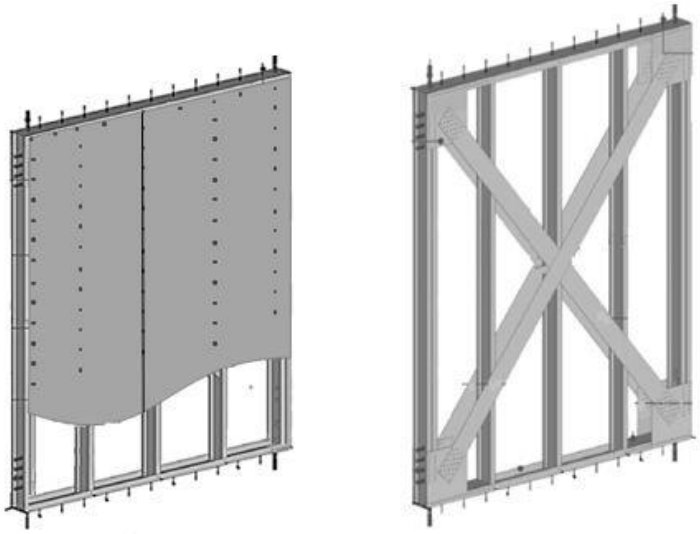
Keywords: Cold-formed steel, Shear walls, Gypsum board sheathing, Strap braced walls, Behaviour factor, FEMA P695

1 INTRODUCTION

Improved structural efficiency and superior environmental performance of Light-Weight Steel (LWS) constructions made with a Cold Formed Steel (CFS) frame and sheathing panels have made them stand out as a preferable alternative in contrast to traditional masonry or concrete constructions for low rise building applications. To resist the earthquake horizontal loads, two main energy dissipative solutions are used in LWS constructions: strap-braced and sheathed-braced. Lateral resistance can be provided by thin steel straps acting as braces in an X configuration or sheathing-braced solutions with steel sheets, wood or gypsum-based panels can provide the lateral bracing effect to withstand the horizontal loads.

Currently, only North American standard for seismic design of CFS structures AISI S400 [1] provides design guidelines for various typologies of Lateral Force Resisting Systems (LFRS) used in CFS constructions. In contrast with AISI S400, the main European earthquake standard EN 1998-1 [2] lacks guidelines for any type of LFRS used in LWS constructions. In order to bridge this gap, a series of numerical and experimental investigations were carried out at University of Naples Federico II, Italy, in recent years to better understand the seismic response of these constructions and to propose design guidelines within the European design framework. These studies are part of a wider effort [3–5] carried out at University of Naples Federico II to better understand the seismic performance of steel structures.

Behaviour factors are employed in EN 1998-1 for buildings equipped with LFRS to reduce the effect, of seismic actions due to building's inherent structural ductility and overstrength. The behaviour factor for any structural system can be evaluated preliminary through either a test-based or a numerical approach. In a test-based approach, usually monotonic and cyclic tests [6] of the prototypes representative of LFRS are used to evaluate the seismic response, while a numerical approach make uses of several building archetypes to evaluate the collapse probability of the LFRS system and to make a judgement on reasonable value of the behaviour factor. A more elaborate methodology is outlined by FEMA document P695 [7], which uses nonlinear numerical analysis techniques, and explicitly considers uncertainties in ground motions, modelling, design, and experimental data to achieve an acceptably low probability of collapse of the LFRS for a particular value of behaviour factor. The work presented in this paper uses this methodology to evaluate behaviour factor for CFS gypsum-sheathed shear walls and strap-braced walls (Fig. 1).



a) b)

Figure 1. a) CFS gypsum-sheathed shear wall b) CFS strap-braced wall.

The methodology outlined by FEMA P695 [7] considers an archetypes design space to characterize the system behaviour , which is designed using a trial value of behaviour factor and whose seismic response is idealized by nonlinear numerical models. A value of 2.5 and 2.0 is used as a trial value for CFS strap-braced walls and CFS gypsum-sheathed shear walls, respectively. The seismic performance of the archetypes is evaluated systematically through static pushover and incremental dynamic analysis techniques, by calculating the collapse probability, while also considering the uncertainties from various sources. On the basis of collapse probability, the suitability of trial value of behaviour factor used in the design phase of archetypes is evaluated. The organization of this paper also follows the arrangement of the different steps in defined by the FEMA methodology.

2 ARCHETYPE SELECTION AND DESIGN

A set of 14 archetypes (Table 1) are designed separately for each LFRS under investigation. The archetypes differed with each other in terms of occupancies, building heights (H) and seismic hazards. The complete design space is considered as one performance group due to the fact that the changes in structural configuration and gravity loads among different archetypes will not alter the behaviour of the LFRS significantly. Three anonymous geographical sites with low, medium and high seismic intensity levels representative of the type of seismic hazard exposed to European continent are assumed as location of the archetypes. The Low, Medium and High seismic hazard are assigned with reference peak ground acceleration ($a_{g,R)}$ values of 0.1g, 0.2g and 0.3g, respectively, in case of gypsum-sheathed shear walls and with the values of 0.15g, 0.25g and 0.35g, respectively in case of strap-braced walls. The reason for the choice of a comparatively lower hazard for gypsum-sheathed shear walls is due to their limited strength, with which it was not possible to design a reasonable number of archetypes at the same hazard level as that for strap-braced walls. All of the archetypes are assumed to be built on Soil class C and belong to an Importance class II according to EN 1998-1 [2].

Table 1. Archetype design space

Two type of occupancies are considered for the archetypes: residential and office. The major differences among the two occupancies is different intensity of the live loads they cause. In particular, EN 1990 [8] defines a live load of 2.0 kN/m^2 and 3.0 kN/m^2 for residential and office type of occupancies, respectively. The two occupancies also differ with each other in terms of accessibility to roof. In case of residential occupancy, the roof is considered accessible with an expected live load equal to the floors i.e. 2.0 kN/m^2, while the roof of the office archetype is considered inaccessible, except for normal maintenance and repair, which resulted in 0.4 kN/m^2 expected live load. Two different types of floor are used: a lightweight steel floor sheathed with panels (light solution) and a composite steel concrete deck (ordinary solution). The use of light floors is limited to archetypes with shear walls braced archetypes which resulted in an excessive design base shear, if an ordinary floor is used. In case of archetypes with strap-braced walls, only ordinary floors are used. The resulting dead loads on floors due to light or ordinary floor, ceilings and vertical partitions are 1.30 or 1.80, 0.10 and 0.80 kN/m^2, respectively, while the roof dead loads due to light or ordinary roof and ceilings are 1.40 or 2.30 and 0.10 kN/m^2, respectively. In addition to dead loads, a snow load of 1.00 kN/m^2 and a wind load of 0.35 kN/m^2 is assumed to be acting on the roof of archetypes. The height of the archetypes reflected the current trend of LWS construction application in seismic areas, which is only limited to low rise buildings. For residential building 3.0 to 12.0 m high archetypes are selected, while for office archetype maximum height of archetype is limited to 6.0 m. Total height of each storey for both type of occupancies is 3.0 m including a floor depth of 0.3 m.

The archetypes are structurally designed according to the relevant parts of Eurocodes. The design of archetypes against the gravity load is carried out using EN 1993-1-3 [9], which provides supplementary rules for CFS members and sheeting. The lateral loads acting on the archetypes included a wind load of 0.70 KN/m^2 and earthquake loads as explained earlier. Lateral force method in EN 1998-1 [2] is used to compute the design base shear, because all of the archetypes meet the criteria of regularity in structural plan and elevation. The seismic design base shear is distributed over height of structure corresponding to seismic mass of each floor or the first modal shape. Both types of lateral force distribution are used in pushover analysis of archetypes as explained in upcoming Sections in order to obtain the worst-case scenario response. A 2.40 m wide shear wall configuration, which is already tested by authors [6] and has shown acceptable performance under both cyclic [6] and shake table testing [10], is selected as the only configuration used here for archetypes with gypsum-sheathed shear walls as the LFRS. On the other hand, three wall configurations with Low, Medium and High shear force capacities were used for archetypes with strap-braced walls as LFRS. The low and medium capacity walls were tested experimentally in past [11], while high capacity wall was designed based on formulations given in [12].

3 NUMERICAL MODELLING

Numerical modelling of the archetypes is needed for their seismic performance evaluation. It is expected from the building using CFS gypsum-sheathed shear walls as LFRS, that it would mainly develop the nonlinear mechanism only at the sheathing connections, while rest of the element would remain elastic. For strap-braced wall, the main nonlinear mechanism only happens in steel straps due to their plastic yielding. Thus, the simulation of response of the walls is the single most important factor in the modelling of complete building response. OpenSees software [13] is used for developing the numerical models. A two-stage modelling approach is adopted. At first, numerical model for single wall is developed and calibrated based on the experimental results and then in the later stage, the model of the single wall is incorporated in

a complete building model representing the global response of the archetype. The choice of the type of model for single wall and different modelling options available in literature are explained in detail by authors in [14] for CFS gypsum-sheathed shear walls and in [12] for CFS strap-braced walls. A simplified model (Fig. 2), which relies on a pair of nonlinear diagonal truss elements is used to simulate the response of a wall. Pinching4 material available in OpenSees is used to represent the nonlinearity in truss elements, which have a unit area and are the representative of the behaviour of the walls as a whole. Rest of the wall elements, including chord studs and hold-down devices are also modelled as elastic elements, which are necessary for the transfer of forces to the rest of building.

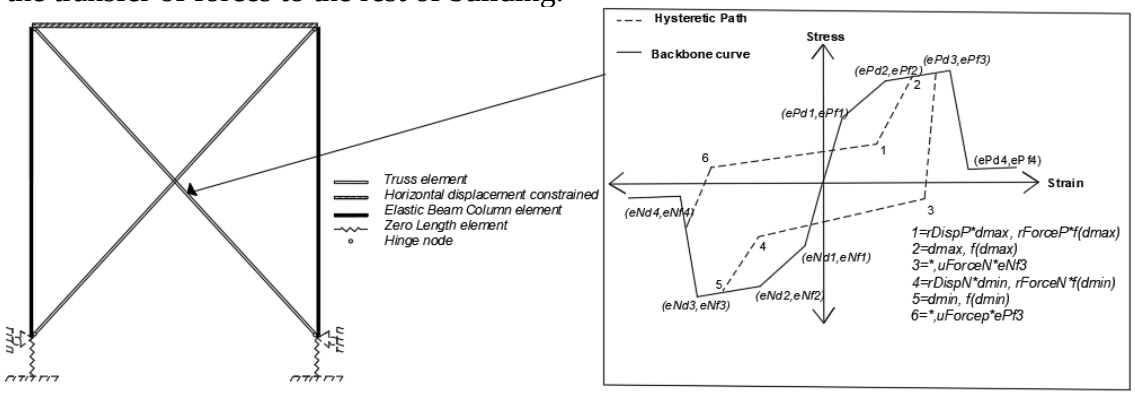

Figure 2. Simplified model for the walls

A three-dimensional model representing the most important structural elements that would have significant implications on the global seismic response of the building is created for each archetype. The skeleton of a typical CFS building is made by joining the wall elements, such as studs and wall tracks, to the floor elements, such as floor tracks and joists. The gravity studs are modelled using truss elements. Not all of the gravity load bearing studs are modelled, because the presence of gravity load bearing studs does not affect much the seismic performance of the archetypes since they cannot resist any bending moments. Moreover, adding all the studs in model would make the model unnecessarily complex. Floor elements (joist, tracks and composite floor) are modelled as the rigid elastic beam column elements. To capture the lateral displacement arising from P-delta effect, a rigid frame made of axially rigid elastic beam column elements having a co-rotational coordinate transformation is connected to the building in the direction of seismic action. Moment releases are created at the ends of columns of P-delta frame and are linked to the main building frame using the rigid truss elements. Moment releases at the ends of columns are intended to avoid any transfer of moments from P-delta fame to main frame and hence only transmitting the axial force, which induce an equivalent lateral displacement in the main frame. In the actual building, the studs are truss elements, and with the truss elements, it's not possible to simulate the p-delta effect. This is the main reason of using a separate frame. Gravity load is applied to the P-delta columns at floor levels. More information on modelling of CFS archetypes is give in [15]. For dynamic analysis, a 2% damping ratio is used based on the Rayleigh damping model. This 2% value reflected the measured damping values during the shaking table experiments [10] on a two storey CFS building.

4 SEISMIC ANALYSIS AND RESULTS

4.1 Non-linear static analysis

FEMA P695 [7] methodology uses non-linear static analysis to estimate archetype overstrength by calculating the ratio of maximum base shear resistance (V_{max}) of archetype obtained

through non-linear static analysis to the design base shear. After achieving the maximum base shear resistance, all archetype models have the concentration of damage at a ground storey in case of archetypes with shear walls, while in case of archetypes with strap-braced walls, the story with the damage concertation varied from case to case, depending on the distribution of shear resistance over the height of archetype. Moreover, this particular difference is due to the difference in design of both systems. In case of shear walls, all stories had a same design shear resistance, since there was only one configuration of gypsum-sheathed shear wall used in all archetypes on all floors. While in case of archetypes with strap-braced walls, the design shear resistance descended with ascending heights, since there were three different types of wall configurations used in archetypes design (see Section 2). The response in two planar directions do not differ much in terms of V_{max} in most cases, while the ultimate roof displacement (δ_u) presented slight differences. Ultimate roof displacement (δ_u) is taken as the roof displacement at the point of 20% strength loss ($0.8V_{max}$) in pushover analysis.

Additionally, the pushover analysis is also used to compute the period-based ductility according to formulations in FEMA, which is used to evaluate the effect of spectral shape of different earthquake records, used for dynamic analysis, on the archetype performance. Subsequently, the final value of over-strength and period-based ductility for each archetype is computed based on its average response in both planar directions and under both types of load distribution patterns based on FEMA P695 recommendations. These load patterns corresponded to the first modal shape, which has linearly increasing displacement over the height of an archetype or to the distribution of seismic mass of each floor over the height of an archetype.

4.2 Non-linear Incremental Dynamic Analysis (IDA)

The collapse performance of archetypes in terms of the Collapse Margin Ratio (CMR) can be assessed through Incremental Dynamic Analysis (IDA), which uses a set of ground motions scaled with increasing scaling factors to reach a magnitude that will cause the collapse. CMR is the ratio between median collapse intensity (S_{CT}) and maximum considered earthquake intensity (S_{MT}). The 4% inter storey drift ratio is used as a threshold value causing the collapse at global level for archetypes with CFS gypsum-sheathed shear walls. The 4% value is selected based on a similar study on shear walls sheathed with fibre cement board panels [16], which exhibit comparable behaviour as walls with gypsum board panels and are classified under the same category in AISI S400 [1]. Contrarily, a 5% inter storey drift value is chosen for archetypes with strap-braced archetypes as failure criterion. However, this value was chosen based on experiment results [11], in which strap-braced walls were able to sustain load carrying capacity until at least 5% drift in all specimens.

Far-field record set provided by FEMA P695 is used to conduct IDA in both planar directions with a 20% increment in intensity starting from a 20% (Scaling factor SF = 0.2) to 600% (SF = 6.0). Before applying the records to archetypes, they were normalized to remove the unwarranted variability between records due to inherent differences in event magnitude, distance to source, source type and site conditions, without eliminating overall record-to-record variability based on Peak Ground Velocity (PGV) and were matched to the archetype design response spectrum through the scaling of median response spectrum of all records within the range of fundamental vibration periods of archetypes. The SF=1.0 is representative of design level earthquake, while SF=1.5 corresponds to MCE (Maximum Considered Earthquake). Figure 3 shows the IDA curves for a three-storey residential (R3M) archetype for both types of LFRS under investigation.

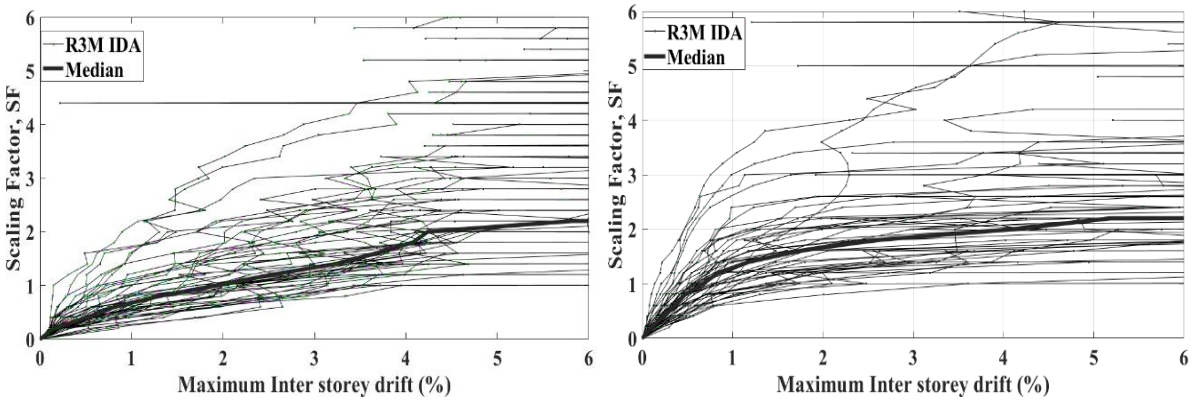

Figure 3. IDA curves: a) CFS Strap-braced walls, b) CFS gypsum-sheathed shear walls

5 SEISMIC PERFORMANCE EVALUATION

The acceptably low, yet reasonable, probability of collapse of structural systems is established by checking the suitability of the trial value of behaviour factor used in design as per performance evaluation criteria of FEMA P695. The CMR's obtained from the IDA analysis are adjusted to take into the spectral shapes of different records used for the analysis to obtain the adjusted CMR (ACMR), which is the product of CMR and a Spectral Shape Factor (SSF). Two performance criteria are defined by the methodology [7]: the average value of adjusted collapse margin ratio, $ACMR_{avg}$, for each performance group should be greater than $ACMR_{10\%}$, and the individual values of adjusted collapse margin ratio, $ACMR_i$, for each archetype within a performance group should be greater than $ACMR_{20\%}$. The values of $ACMR_{10\%}$ and $ACMR_{20\%}$ are the function of uncertainties, which are summed up as the total collapse uncertainty β_{TOT}, that takes into account the different sources of uncertainty which could contribute to the variability in collapse capacity. In particular, the main sources of uncertainty include: record to record uncertainty (β_{RTR}), design requirements uncertainty (β_{DR}), test data uncertainty (β_{TD}); and modelling uncertainty (β_{MDL}).

β_{RTR} represents the variability in response of the archetypes model under different ground motion records. FEMA P695 recommends to use β_{RTR} equal to 0.40 for archetypes having period-based ductility greater than 3, which is the case for all archetypes in this study. The other three uncertainty parameters β_{DR}, β_{TD} and β_{MDL}, are the qualitative measures. FEMA P695 provides the following qualitative scale to quantify them: (a) Superior: β=0.10, (b) Good: β=0.20, (c) Fair: β=0.35, and (d) Poor: β=0.50. A quality rating of 'Good' (β =0.20) is adopted for all of them in both cases except a 'superior' rating is given to test data available for gypsum-sheathed shear walls. In addition to quasi cyclic test data on the shear wall [6], there was also significant evidence on the seismic performance of gypsum-sheathed shear walls from shaking table tests [10]. Finally, the total collapse uncertainty β_{TOT} is computed to be 0.49 and 0.53 for gypsum-sheathed shear walls and strap-braced walls, respectively. Based on the value of β_{TOT}, $ACMR_{10\%}$ and $ACMR_{20\%}$ are obtained from Table 7-3 of FEMA P695. All of the archetypes in both cases passed the criterion, as it can be seen in Tables 2 and 3, and hence this concludes that the value of the behaviour factor equal to 2.5 and 2.0 used in design phase for strap-braced walls and gypsum-sheathed shear walls, respectively is appropriate.

Archetype ID	S_{CT}	S_{MT}	SSF	CMR	ACMR	$ACMR_{20\%}$	Pass/Fail	$ACMR_{avg}$	$ACMR_{10\%}$	Pass/Fail

Table 3. Performance evaluation of archetypes with CFS gypsum-sheathed shear walls

6 CONCLUSIONS

Behaviour factor for CFS gypsum-sheathed shear walls and CFS strap-braced walls, which are not yet standardized as seismic force resisting system in EN 1998-1, is evaluated here through FEMA P695 [7] methodology. A total of fourteen residential and office archetypes representing heights up to 12 m are designed following capacity design approach to withstand the low, medium and high seismic load. Numerical models of archetypes with an ability to simulate nonlinear hysteretic response of walls are developed in OpenSees software and analysed under the action of 44 records in FEMA P695 far-field record set. The analysis of models followed an incremental dynamic analysis approach until the collapse happens. Finally, by gauging the collapse performance of models against the FEMA P695 acceptance criteria for adjusted collapse margin ratios, it is concluded that a behaviour factor value of 2.0 and 2.5 is

appropriate for buildings using CFS gypsum-sheathed shear walls and CFS strap-braced walls as main seismic force resisting system, respectively.

Abstract. *Network arch bridges are arch bridges where hangers intersect each other at least twice. The concept has been developed firstly by Prof. Per Tveit during his Ph.D. Several network arch bridges have been built around the world due to the advantage this type of bridge presents. However, Network arch bridges as to conventional arch bridges are sensitive to lateral displacement under vertical loads. In this study, lateral structural response of network arch bridges against traffic loads has been analyzed through extensive non-linear analyses. The structural response of the arch showed a relationship between the lateral displacement and applied stress. In addition, it is observed that lateral arch's bracing changes the development of plastic hinges in the arch.*

1 INTRODUCTION

In bridges' industry, tied-arch bridges represent types of bridges where hangers are used to transfer vertical loads from deck to arches. In this condition, the arches are substantially subjected to compression axial force instead of in the deck or tie beam there is a tensile axial force and reduced bending moment due to hangers. Network arch bridges are widely spread around the world due to several advantages from the aesthetical aspect to the cost-performance ratio. The bridge has been developed by Per Tveit with the aim to develop innovative tied-arch bridges [1]. According to Per Tveit [2], network arch bridges are defined as tied arch bridges where inclined hangers intersect each other at least twice. These bridges are often mistaken to Nielsen bridges, which provide also inclined hangers but only once [3]. Fig.1 provides the common cable distribution in arch bridges from the vertical arrangement to network arrangement.

Due to excessive axial force developed in the arches, they are sensitive to undergo instability phenomenon, either in plane or out-of-plane or both. For this reason, it is usually necessary to provide an optimum cable arrangement, which gives a minimum stress distribution into structural elements. Several authors [4 - 6] focused their researches to deliver an optimal cable distribution within the arch.

In regards to the arch's instability phenomenon, three different behaviors are often observed (fig.2). Amongst them, out-of-plane buckling has captured great attention recently. Sakimoto et al. [7] conducted experimental tests on arches with square hollow sections to study the out-of-plane buckling of the arch. New column curves for the out-of-plane verification have been derived as the outcome. La poutré et al. **Error! Reference source not found.** investigated the elasto-plastic out of plane buckling response of roller bent circular steel arches under a vertical force located at the crown. Several tests were performed and the presence of plastic zones in the arch rib featured the arches failure. Spoorenberg et al. **Error! Reference source not found.** performed sensitivity numerical analyses to evaluate the influence of initial imperfections on the out-of-plane buckling response of steel arches. The authors proposed a design rule to check the response of freestanding circular roller bent steel arches under symmetric loads. When dealing with the analysis of lateral displacement of the arch, it is important to consider the existing imperfections of the element developed during the manufacturing process of the structural steel. Lonetti et al. [10], through non-linear analyses, showed the influence of considering geometrical imperfections in the analysis while the influence of geometrical out-of-plane imperfections on the lateral buckling behavior using a highly detailed finite element model has been investigated by Backer et al. [11].

In this study, the global lateral behavior of network arch bridges under traffic loads has been studied throughout extensive nonlinear finite element analyses. Initial geometric imperfections equivalent to the first buckling mode of the free arch have been assigned in arch elements. Finally, the influence of the lateral bracing typologies and its position to the lateral displacement have been developed.

2 DESCRIPTION OF THE BRIDGE

The bridge considered in this study is a 100 m span simply supported steel bridge. The height of the arch has been chosen to have a desired span/height ratio equal to 0.20. The bridge consists of two arch layouts with network arrangement of hanger. The two arches are welded directly to two lateral girder beams inter-connected throughout 10 m equally spaced transversal beams, which represents the width of the bridge. Each arch plane has 26 inclined cables to distribute the loads throughout structural elements. The structural response of an arch plane can be compared to an IPE section element where both arch and girder play the same role than the upper and lower flange and hangers are considered as the web. The deck will be composed of 8 m width traffic lane with two footways of 1 m width each. IPE lateral beams are used to connect altogether the two arches. To study the influence of lateral bracing, hollow circular elements have been used to connect the existing transversal arch beam. A global view of the arch bridge is presented in Fig.3 while the information regarding the dimension of the structural elements considered is presented in both Table 1.

3 DESCRIPTION OF THE FINITE ELEMENT MODEL

FEM analysis has been performed in this study considering 1D element for all structural elements unless cable and deck. The latter has been modelled as 2D shell elements with eight nodes quad8 and six degrees of freedom. Hanger's arrangement follows the radial distribution along the arches. Imperfections equal to first buckling mode of the arch has been applied to the arch before the buckling analysis of the whole model. To perform the GMNIA, a perfect

elasto-plastic steel material behavior has been considered. S420 and S355 steel classes were considered in the analysis while cables were modelled as tension only material to avoid any risk of buckling of slender cable section. An overview of the 3D FEM model is presented in Fig.4.

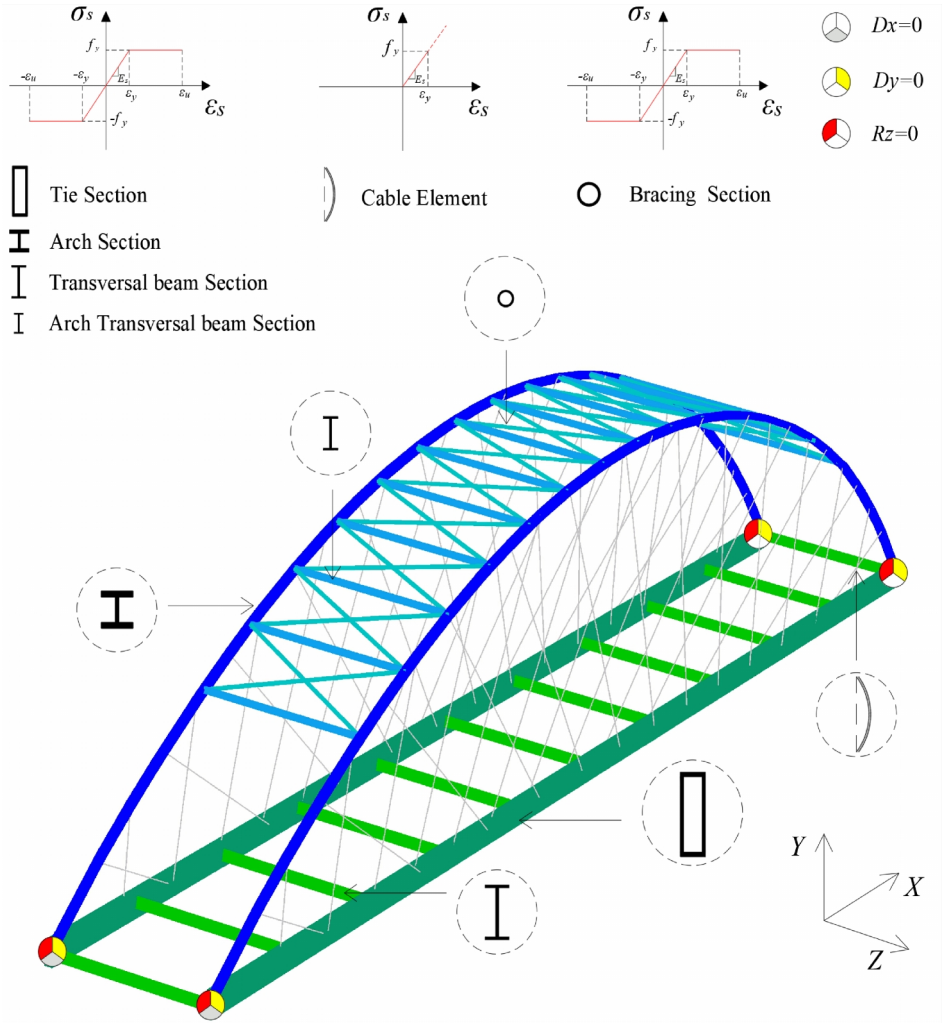

Fig. 4. 3D FEM model of a network arch bridge

4 LATERAL DISPLACEMENT OF NETWORK ARCH BRIDGES

In order to investigate the lateral sensitivity of the arches in network arch bridges, a geometrically and materially nonlinear analysis with imperfections (GMNIA) have been considered. Since the effect of traffic loads was primary investigated, analysis of the model with only permanent loads is run firstly. Then, progressively increasing the live loads to better figure out the influence of traffic loads in the out-of-plane structural response. The FEM analysis has been done following each step of the algorithm shown in Fig.5.

The results obtained from different braced length showed almost the same behaviour. The first hinge is formed when the vertical force in the arch is more or less 4000 kN for unbraced arches following successively the formation of second and third hinges. It is worth noting that the successive hinges in the arches are formed shortly after the first hinge. Fig. shows the stress level inducing the formation of the first three hinges. The benefit of wind bracing in the increase of lateral stiffness is evident as soon as both cases are drawn in the same graph. As

soon as the length of the braced zone of the arch increases, the critical load increases faster than the lateral displacement. For unbraced arches, the behaviour observed is the same for different cases studied while the situation is quite different for braced arches. In fact, for arches braced up to 80 and 90 %, softening behaviour is observed after the critical load is reached (Fig.). When the free end portal increase for arches with syst.1, a slight softening is observed after the critical buckling load of the arch.

Other results from FEM analysis showed that in general, the lateral sensitivity of both braced and unbraced arch bridges subjected to vertical loads is characterized by 3 states: one linear and two non-linear. From a stress point of view, the load increases linearly with the lateral displacement until the material reaches the yielding stress at point 2. Thus, the first hinge is formed with the partial plasticization of the section and will end the linear phase as shown in Fig. . The location of the first hinge may vary depending on the length of the arch where lateral bracing has been applied. It is worth noting that the first hinge is prone to be formed near the support due to the reaction of the abutment.

5 CONCLUSION

The global out-of-plane behavior of network arch bridge has been studied in this paper through intensive nonlinear analysis. The results from finite element models show a gradual yielding of arch either from the support toward the arch midspan or from the arch midspan toward the support. The yielding process is fast for the early case and the hinges are formed rapidly until the braced region of the arch while in the latter case, the development of yielding is prevented by the bracing system. On the other hand, for arches without lateral bracing, multi-shape modes are observed. The arches move to the second buckling mode at the end of the first nonlinear phase. During this phase, an increase of vertical loads is still visible. On the other hand, another behavior is observed for braced arches, which display a slight softening at the end of the first nonlinear phase.

Abstract. *The extended finite element method (XFEM) enriches the polynomial basis functions of standard finite elements with specialized non-smooth functions. The resulting approximation space can be used to solve problems with moving discontinuities, such as cracks, while avoiding the computational cost of remeshing. As the crack propagates, many artificial degrees of freedom are introduced near the crack tip, which can inflate the size of resulting linear system to be solved. In addition, the stiffness matrix of the cracked body may become ill-conditioned, causing slow convergence of iterative solvers. To overcome this, domain decomposition methods for solving the resulting linear systems of crack propagation problems is combined with XFEM to improve its performance. A suitable decomposition is proposed to avoid inter-subdomain boundaries near crack tip area. It is shown that choosing the proper FETI method, offers significant speedup compared to a direct solver that uses the common finite element solution techniques by means of Cholesky/LDL factorization, even if the execution is performed on a single-core systems.*

1 INTRODUCTION

The extended finite element method (XFEM) enriches the polynomial basis functions of standard finite elements with specialized non-smooth functions [1]. The resulting approximation space can be used to solve problems with moving discontinuities, such as cracks, while avoiding the computational cost of remeshing. Although the local enrichment strategy of XFEM is computationally efficient, it can rapidly increase the size of the resulting linear system in large scale problems. In addition, the stiffness matrix may become ill-conditioned, causing slow convergence of iterative solvers.

In this paper, the application of domain decomposition methods for solving the resulting linear systems is proposed. Among such methods we will focus to the family of finite element tearing and interconnecting (FETI) methods which were originally developed for the standard finite element method. In a FETI method, the finite element model is decomposed into several subdomains and the continuity at the boundary freedom degrees is enforced by applying Lagrange multipliers. These are the unknowns of an equivalent dual linear system, which can be solved by processing each subdomain independently. To speed up the solution process of each subdomain the standard preconditioners (e.g. preconditioned conjugate gradient method - PCG) are used. When FETI methods are combined with XFEM, the identification of rigid body motions of floating subdomains must be purely identified. Round-off errors in the computation of the rigid body motions can increase the PCG iterations that are required to solve the interface problem. Thus, a FETI method and can be combined with an effective mesh partitioning algorithm to ensure a decomposition into balanced subdomains that does not slow down the convergence.

A benchmark structure under fatigue crack growth is analyzed to demonstrate the capabilities of the proposed algorithm. A suitable decomposition is proposed to avoid inter-subdomain boundaries near crack tip area. It is shown that choosing the proper FETI method, offers significant speedup compared to a direct solver that uses the common finite element solution techniques by means of Cholesky/LDL factorization, even if the execution is performed on a single-core systems.

The paper is organized as follows: a brief description of modeling crack propagation with XFEM is given first, with special emphasis to fatigue crack growth. Subsequently, the FETI methods are discussed and their basic concepts are presented. Finally numerical tests are provided for illustrating the capabilities of the proposed methodology.

2 MODELING CRACK PROPAGATION USING XFEM

This paper focuses on the 2D mixed-mode linear elastic fracture mechanics (LEFM) formulation, where the size of cracked plastic zone is sufficiently small and it is embedded within an elastic zone around the crack tip. The inelastic behavior at the crack tip can cause a fatigue crack growth, meaning that the crack will grow under conditions of cyclic applied loading. The basic assumptions of LEFM in order to quantify crack growth around the crack tip in the presence of constant amplitude cyclic stress intensity, are given in the next sections.

2.1 XFEM basic ingredients

According to XFEM, special functions are added to the finite element approximation based on the partition of unity (PU) [2] and additional degrees of freedom are introduced to selected nodes of the finite element mesh near to discontinuities providing a higher level of accuracy. The quasi-static crack propagation simulations can be carried out without the need of remesh-

ing, modeling the domain with standard finite elements without explicitly meshing the crack surfaces.

Two basic types of enrichment functions are used: (i) the Heaviside function (step function) and (ii) the asymptotic crack-tip enrichment functions derived from LEFM [3]. The displacement field for a single "nominal" element can be expressed as a superposition of the standard $\vec{u}^{\text{std}}$, the crack-split $\vec{u}^{\text{H}}$ and the crack-tip $\vec{u}^{\text{tip}}$ fields as:

$$\vec{u}(\vec{x}) = \vec{u}^{\text{std}} + \vec{u}^{\text{enr}} = \vec{u}^{\text{std}} + \vec{u}^{\text{H}} + \vec{u}^{\text{tip}} \tag{1}$$

or more explicitly:

$$\vec{u}(\vec{x}) = \underbrace{\sum_{j=1}^{n} N_j(\vec{x})\vec{u}_j}_{\vec{u}^{\text{std}}} + \underbrace{\sum_{h=1}^{n_h} N_h(\vec{x})H(\vec{x})\vec{a}_h + \sum_{k=1}^{n_t} N_k(\vec{x})\Big(\sum_{l=1}^{n_f} F_l(\vec{x})\vec{b}_k^l\Big)}_{\vec{u}^{\text{enr}}} \tag{2}$$

The first contributing part ($\vec{u}^{\text{std}}$) on the right-hand side of Eq. (2) corresponds to the classical finite element approximation of the displacement field, while the second part ($\vec{u}^{\text{enr}}$) refers to the enrichment approximation which takes into account the existence of discontinuities. This second contributing part utilizes additional degrees of freedom to facilitate modeling of the discontinuous field, without modeling it explicitly. n is the number of nodes in each finite element model with standard degrees of freedom $\vec{u}_j$ and shape functions $N_j(\vec{x})$, n_h is the number of nodes in the elements containing the crack face (but not the crack tip), $\vec{a}_h$ is the vector of additional degrees of freedom for modeling crack faces defined by the Heaviside function $H(\vec{x})$, n_t is the number of nodes associated with the crack tip in its influence domain and $\vec{b}_k^l$ is the vector of additional degrees of freedom for modeling crack tips.

Furthermore, $F_l(\vec{x})$ are the crack-tip enrichment functions, given by:

$$\{F_l(r,\theta)\}_{l=1}^4 = \left\{\sqrt{r}\sin(\frac{\theta}{2}); \sqrt{r}\cos(\frac{\theta}{2}); \sqrt{r}\sin(\frac{\theta}{2})\sin(\theta); \sqrt{r}\cos(\frac{\theta}{2})\sin(\theta)\right\} \tag{3}$$

The elements which are cut entirely by the crack, are enriched with the Heaviside (step) function H. The Heaviside function is a discontinuous function across the crack surface and is constant on each side of the crack. Splitting the domain by the crack causes a displacement jump and the Heaviside function provides the desired behavior to approximate the real displacement field.

2.2 Crack representation by level sets

In association to XFEM, the level set method (LSM) [4] is adopted to describe the geometry of the crack. The LSM was originally proposed for tracking moving interfaces, and became a key ingredient of XFEM for describing complicated geometrical interfaces by computing their motion on a fixed finite element mesh. Thus, level set functions offer an elegant way of modeling cracks which take the form of signed distance functions. In order to fully characterize a crack discontinuity, two level set functions are defined as signed distance functions: (i) a normal level set function ϕ and (ii) a tangent level set function ψ. To define the signed distance functions, the interface Γ can be regarded as the zero level contour of the level set function $\phi(\vec{x})$. The distance d from a point $\vec{x}$ to the interface Γ is defined as:

$$d = \|\vec{x} - \vec{x}_\Gamma\| \tag{4}$$

where $\vec{x}_\Gamma$ is the normal projection of $\vec{x}$ on Γ. Mathematically, the signed distance function $\phi(\vec{x})$ can be defined as,

$$\phi(\vec{x}) = \min \|\vec{x} - \vec{x}_\Gamma\| \, \text{sign}(\vec{n_1} \cdot (\vec{x} - \vec{x}_\Gamma)) \tag{5}$$

where $\vec{n_1}$ is the unit normal vector to the crack at point $\vec{x_\Gamma}$ (see Fig. 1).

For the case of an edge crack, to construct the two level set functions, the approach proposed by Stolarska et al. [5] is adopted. The crack tip segment is extended to "meet" the boundary of the domain and the normal level set function ϕ is then defined using Eq. (5), from the original crack segment Γ (at crack tip j) and the virtual segments (extensions) ($\phi = 0$ and $\psi = 0$) (see Fig. 1). Similar, the tangent level set function ψ as the signed distance to the plane including

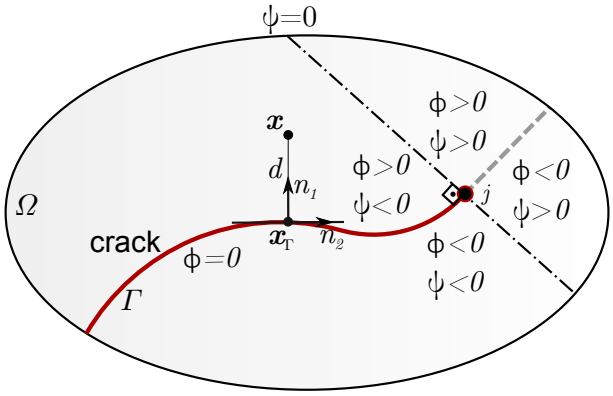

Figure 1: Signed distance definition, and corresponding level set functions ϕ and ψ in crack tip point $\vec{x}_\Gamma$.

the crack front and perpendicular to the crack surface, is defined as follows:

$$\psi(\vec{x}) = \min \|\vec{x} - \vec{x}_\Gamma\| \, \text{sign}(\vec{n_2} \cdot (\vec{x} - \vec{x}_\Gamma)) \tag{6}$$

where $\vec{n_2}$ is the unit vector tangent to the crack at its tip. The crack can now be represented by the two level set functions ϕ and ψ such that $\phi = 0$ for the crack surface Γ. Consequently, the crack tip j is identified on an intersection of normal and tangent zero level set functions, i.e. intersection of $\phi = 0$ and $\psi = 0$. In the remaining domain, ϕ has a positive value above the crack, while ψ has a positive value to the right of the unit normal vector $\vec{n_1}$ at the crack tip j. The crack tip level set ψ is generally assumed to be orthogonal to ϕ, i.e. $\phi\psi = 0$. It is also assumed that once a part of the crack has formed, that part will no longer change its shape or move.

2.3 Computation of the crack growth direction

The accuracy and reliability of the method primarily on the continuity and the determination of the crack path. Among the existing crack growth criteria, the maximum hoop stress criterion [7], is adopted. According to this criterion: (i) the crack initiation will occur when the maximum hoop stress reaches a critical value and (ii) the crack will grow along direction θ_{cr} in which circumferential stress $\sigma_{\theta\theta}$ is maximum.

The circumferential stress $\sigma_{\theta\theta}$ in a polar coordinate system (r, θ) (see Fig. 2) along the direction of the crack propagation is a principal stress. Hence, the critical crack propagation direction θ_{cr} is determined by setting the shear stress $\sigma_{r\theta}$ equal to zero, i.e.:

$$\sigma_{r\theta} = \frac{1}{2\sqrt{(2\pi r)}} cos\frac{\theta_{cr}}{2}\Big(K_I sin\theta_{cr} + K_{II}(3cos\theta_{cr} - 1)\Big) = 0 \tag{7}$$

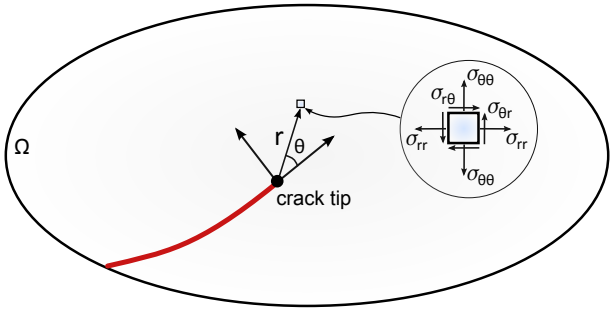

Figure 2: Polar coordinates in the crack tip coordinate system.

leading to the following expression of the crack growth direction θ_c, in terms of local crack tip coordinate system:

$$\theta_c = \theta_{cr} = 2arctan\frac{1}{4}\Big(\frac{K_I}{K_{II}} \pm \sqrt{\frac{K_I^2}{K_{II}} + 8}\Big) \tag{8}$$

2.4 Computation of fatigue cycles

Fatigue crack growth is quantified using Paris law [8], which is originally proposed for single mode deformation cases, and correlates crack propagation rate under fatigue loading with the stress intensity factors (SIFs). For the case of mixed-mode loading, a modified Paris law is defined using the effective stress intensity factor range $\Delta K_{\text{eff}} = K_{\max} - K_{\min}$. For a certain fatigue loading level, where the crack grows by length Δa in ΔN_c cycles, Paris law reads:

$$\frac{\Delta a}{\Delta N_c} \approx \frac{da}{dN_c} = C(\Delta K_{\text{eff}})^m \tag{9}$$

where C and m are empirical material constants. m is often called as the *Paris exponent* and is typically defined in the range of $3 \div 4$ for common steel and aluminium alloys. Eq. (9) represents a linear relationship between $log(\Delta K_{\text{eff}})$ and $log(\frac{da}{dN_c})$ which is used to describe fatigue crack propagation in Region II (Fig. 3). For calculating the effective mixed-mode stress

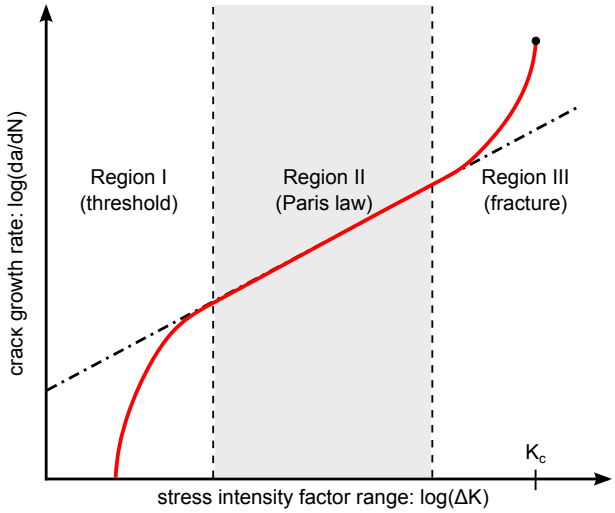

Figure 3: Logarithmic crack growth rate and effective region of Paris law.

intensity factor ΔK_{eff}, the energy release rate model is adopted, leading to:

$$\Delta K_{\text{eff}} = \sqrt{\Delta K_I^2 + \Delta K_{II}^2} \tag{10}$$

Subsequently, the number of the corresponding cycles for a crack growth Δa is computed according to [3]:

$$\Delta N_c = \frac{\Delta a}{C(\Delta K_{\text{eff}})^m} \tag{11}$$

Similar to strength of materials theory where the calculated stress is compared with an allowable stress defining the material strength, LEFM assumes that unstable fracture occurs when SIF K reaches a critical value K_c, called *fracture toughness*, which represents the capacity of a material to withstand a given stress field at the crack tip and to resist into the progressive tensile crack extension. In other words, K_c is a material constant and is used as a threshold value for SIFs.

3 FETI Methods

Domain decomposition methods (DDM) split the domain into smaller subdomains which can be processed independently. Among such methods, the finite element tearing and in interconnecting (FETI) DDMs exhibit the highest scalability, when executed in distributed computing environments. The first FETI method (FETI-1) was introduced by Farhat et al. [11], and is the first implementation of FETI methods which uses Lagrange multipliers to describe the forces between the subdomains. Later, dual-primal FETI (FETI-DP) was introduced by Farhat et al. [12], as a simpler and in many cases more efficient, alternative.

3.1 FETI-1

In FETI-1 method, the domain is divided into disconnected subdomains as in Fig. 4 and the continuity between them is retained by enforcing equal displacements for instances of the same boundary DOF (degree of freedom).

$$\left[\begin{array}{cc} 1 & -1 \end{array} \right] \left[\begin{array}{c} u_k^{(1)} \\ u_k^{(2)} \end{array} \right] = 0 \tag{12}$$

By gathering the 1, -1 and 0 coefficients in a signed boolean matrix $\boldsymbol{B}^s$ for all boundary DOFs of a subdomain:

$$\sum_{s=1}^{N_s} \boldsymbol{B}^s \boldsymbol{u}^s = \boldsymbol{0} \tag{13}$$

To solve the initial linear system in the presence of these constraints, we apply Lagrange multipliers at boundary DOFs. These are dual quantities and can be viewed as forces, while displacements are primal quantities. Using the superscript e to denote the aggregation of all subdomain matrices/vectors into an expanded matrix/vector, the resulting linear system is written as:

$$\left[\begin{array}{cc} \boldsymbol{K}^e & (\boldsymbol{B}^e)^T \\ \boldsymbol{B}^e & \boldsymbol{0} \end{array} \right] \left[\begin{array}{c} \boldsymbol{u}^e \\ \boldsymbol{\lambda} \end{array} \right] = \left[\begin{array}{c} \boldsymbol{f}^e \\ \boldsymbol{0} \end{array} \right] \tag{14}$$

A subdomain of FETI-1 can be floating, meaning there are not enough constrained DOFs and its stiffness matrix $\boldsymbol{K}^s$ is singular. To overcome this, we use a generalized inverse $(\boldsymbol{K}^s)^+$

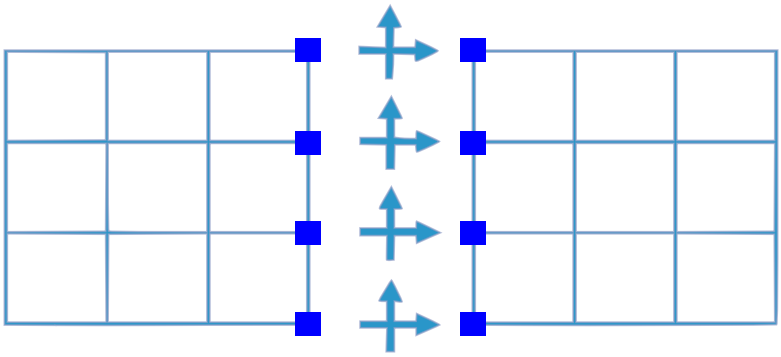

Figure 4: Langrange multipliers applied to boundary DOFs of subdomains.

and a normalized basis for its nullspace $\boldsymbol{R}^s$, which corresponds to the rigid body motions of the floating subdomain.

$$(\boldsymbol{K}^s)^+ = \begin{bmatrix} (\boldsymbol{K}^s_{11})^{-1} & \boldsymbol{0} \\ \boldsymbol{0} & \boldsymbol{0} \end{bmatrix} \tag{15}$$

$$\boldsymbol{R}^s = \begin{bmatrix} (\boldsymbol{K}^s_{11})^{-1}\boldsymbol{K}^s_{12} \\ \boldsymbol{I} \end{bmatrix} \tag{16}$$

where the subscripts 1/2 denote linearly independent/dependent rows and columns, respectively. If the subdomain has sufficient constraints then $\boldsymbol{R}^s = \emptyset$ and $(\boldsymbol{K}^s)^{-1}$. The interface problem of FETI-1 is as follows:

$$\begin{bmatrix} \boldsymbol{F}_I & -\boldsymbol{G}_I \\ -\boldsymbol{G}_I^T & 0 \end{bmatrix} \begin{bmatrix} \boldsymbol{\lambda} \\ \boldsymbol{a} \end{bmatrix} = \begin{bmatrix} \boldsymbol{d} \\ -\boldsymbol{e} \end{bmatrix} \tag{17}$$

where $\boldsymbol{a}$ expresses linear combinations of the normalized rigid body motions in $\boldsymbol{R}$, $\boldsymbol{F}_I$ is the flexibility matrix, $\boldsymbol{G}$ aggregates the rigid body motions, $\boldsymbol{d}$ are the displacements due to applied forces (boundary conditions and loading) and $\boldsymbol{e}$ is the work of rigid body motions due to these applied forces.

$$\boldsymbol{F}_I = \sum_{s=1}^{N_s} \boldsymbol{F}_I^s = \sum_{s=1}^{N_s} \boldsymbol{B}^s (\boldsymbol{K}^s)^+ (\boldsymbol{B}^s)^T \tag{18}$$

$$\boldsymbol{d} = \sum_{s=1}^{d_s} \boldsymbol{F}_I^s = \sum_{s=1}^{N_s} \boldsymbol{B}^s (\boldsymbol{K}^s)^+ \boldsymbol{f}^s \tag{19}$$

$$\boldsymbol{G}_I = \begin{bmatrix} \boldsymbol{B}^{(1)}\boldsymbol{R}^{(1)} & \boldsymbol{B}^{(2)}\boldsymbol{R}^{(2)} & \dots & \boldsymbol{B}^{(N_s)}\boldsymbol{R}^{(N_s)} \end{bmatrix} \tag{20}$$

The linear system of Eq. (17) is not symmetric positive definite. To solve it using the preconditioned conjugate gradient (PCG) method, we must project it into another space using a projection matrix $\boldsymbol{P}$ and then solve the following system:

$$\boldsymbol{P}^T \boldsymbol{F}_I \boldsymbol{P} \bar{\boldsymbol{\lambda}} = \boldsymbol{P}^T (\boldsymbol{d} - \boldsymbol{F}_I \boldsymbol{P} \boldsymbol{\lambda}_0) \tag{21}$$

where

$$\boldsymbol{P} = \boldsymbol{I} - \boldsymbol{G}_I (\boldsymbol{G}_I^T \boldsymbol{G}_I)^{-1} \boldsymbol{G}_I^T \tag{22}$$

$$\boldsymbol{\lambda}_0 = \boldsymbol{G}_I (\boldsymbol{G}_I^T \boldsymbol{G}_I)^{-1} \boldsymbol{e} \tag{23}$$

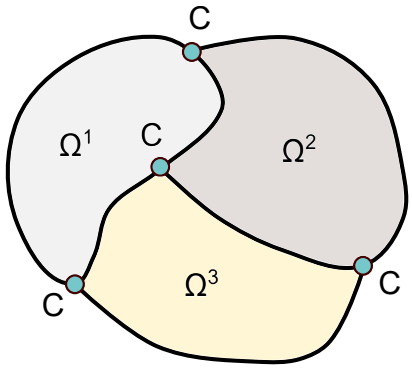

Figure 5: Definition of corner nodes (C).

$$\boldsymbol{\lambda} = \boldsymbol{\lambda}_0 + \boldsymbol{P}\bar{\boldsymbol{\lambda}} \tag{24}$$

$$\boldsymbol{a} = (\boldsymbol{G}_I^T \boldsymbol{G}_I)^{-1} \boldsymbol{G}_I^T (\boldsymbol{F}_I \boldsymbol{\lambda} - \boldsymbol{d}) \tag{25}$$

The coarse problem of FETI-1 is expressed in the linear system $\boldsymbol{G}_I^T \boldsymbol{G}_I x = y$ of Eq. (22) and it helps speed up convergence by globally distributing the error at each PCG iteration. Finally we calculate the displacements depending on if the subdomain is floating or not:

$$\boldsymbol{u}^s = (\boldsymbol{K}^s)^+ (\boldsymbol{f}^s - (\boldsymbol{B}^s)^T \boldsymbol{\lambda}) + \boldsymbol{R}^s \boldsymbol{a}^s \implies \boldsymbol{u}^s = (\boldsymbol{K}^s)^{-1} (\boldsymbol{f}^s - (\boldsymbol{B}^s)^T \boldsymbol{\lambda}) \tag{26}$$

3.2 FETI-DP

The FETI-DP method is based on a dual-primary formulation of the problem to be solved. The main difference between the FETI-DP method and the FETI-1 method is that in FETI-DP, in every iteration of the PCG method, the compatibility of displacements is imposed to a small subset of primal *corner* DOFs, while the compatibility of displacements to the remaining boundary DOFs is only achieved after convergence.

We define *corner* nodes and corner or primal DOFs (Fig. 5). All other DOFs are called *remainder* and are further separated into boundary-remainder and boundary-internal. We then perform static condensation of the remainder DOFs in each subdomain and assemble the resulting matrices/vectors into global ones:

$$\boldsymbol{K}_{cc}^* = \sum_{s=1}^{N_s} (\boldsymbol{L}_c^s)^T \left(\boldsymbol{K}_{cc}^s - (\boldsymbol{K}_{rc}^s)^T (\boldsymbol{K}_{rr}^s)^{-1} \boldsymbol{K}_{rc}^s \right) \boldsymbol{L}_c^s \tag{27}$$

$$\boldsymbol{f}_c^* = \sum_{s=1}^{N_s} (\boldsymbol{L}_c^s)^T \left(\boldsymbol{f}_c^s - (\boldsymbol{K}_{rc}^s)^T (\boldsymbol{K}_{rr}^s)^{-1} \boldsymbol{f}_r^s \right) \tag{28}$$

where the subscripts r and c denote the rows/columns corresponding to remainder and corner DOFs respectively. $\boldsymbol{L}_c$ are unsigned boolean matrices (entries are 0 or 1) mapping global corner displacements to subdomain corner displacements. With an appropriate selection of corner nodes, the matrices $\boldsymbol{K}_{rr}$ is invertible, thus there are no floating subdomains. For the signed boolean matrices $\boldsymbol{B}_r$, we will use the columns of $\boldsymbol{B}$ that correspond to remainder DOFs.

The interface problem of FETI-DP can be written as follows:

$$\left(\boldsymbol{F}_{Irr} + \boldsymbol{F}_{Irc}(\boldsymbol{K}_{cc})^{-1}(\boldsymbol{F}_{Irr})^{T}\right)\boldsymbol{\lambda} = \boldsymbol{d}_r - \boldsymbol{F}_{Irc}(\boldsymbol{K}_{cc})^{-1}\boldsymbol{f}_c^* \tag{29}$$

where $\boldsymbol{d}_r$ are the displacements due to boundary conditions and loading and $\boldsymbol{F}_{Irr}$ is the flexibility matrix. The linear system of Eq. (29) can be solved using the PCG method.

$$\boldsymbol{d}_r = \sum_{s=1}^{N_s} \boldsymbol{B}_r^s(\boldsymbol{K}_{rr}^s)^{-1}\boldsymbol{f}_r^s \tag{30}$$

$$\boldsymbol{F}_{Irr} = \sum_{s=1}^{N_s} \boldsymbol{B}_r^s(\boldsymbol{K}_{rr}^s)^{-1}(\boldsymbol{B}_r^s)^{T} \tag{31}$$

$$\boldsymbol{F}_{Irc} = \sum_{s=1}^{N_s} \boldsymbol{B}_r^s(\boldsymbol{K}_{rc}^s)^{-1}\boldsymbol{K}_{rc}^s\boldsymbol{L}_c^s \tag{32}$$

The coarse problem of FETI-DP is expressed in the linear system $\boldsymbol{K}_{cc} * x = y$ of Eq. (29) and it helps speed up convergence by globally distributing the error at each PCG iteration. After solving the interface problem the displacements can be calculated using:

$$\boldsymbol{u}_c = \left(\boldsymbol{K}_{cc}^*\right)^{-1}\left(\boldsymbol{f}_c^* + (\boldsymbol{F}_{Irc})^{T}\boldsymbol{\lambda}\right) \tag{33}$$

$$\boldsymbol{u}_r^s = (\boldsymbol{K}_{rr}^s)^{-1}\left(\boldsymbol{f}_r^s - \left(\boldsymbol{B}_r^s\right)^{T}\boldsymbol{\lambda} - \boldsymbol{K}_{rc}^s\boldsymbol{L}_c^s\boldsymbol{u}_c\right) \tag{34}$$

3.3 Preconditioning

Both FETI-1 and FETI-DP can use the same preconditioners to speed up the convergence of PCG when solving the interface problem. The idea is to approximate the inverse of the flexibility matrix, which is defined for the boundary DOFs. The most common preconditioners used are Dirichlet and lumped ones.

Dirichlet preconditioner

A Dirichlet preconditioner is defined as follows:

$$\boldsymbol{F}_I^{-1} = \sum_{s=1}^{N_s} \boldsymbol{B}_{pb}^s\boldsymbol{S}^s(\boldsymbol{B}_{pb}^s)^{T} \tag{35}$$

where $\boldsymbol{S}^s$ is the Schur complement of internal dofs (internal-remainder in FETI-DP)

$$\boldsymbol{S}^s = \boldsymbol{K}_{bb}^s - (\boldsymbol{K}_{ib}^s)^{T}(\boldsymbol{K}_{ii}^s)^{-1}\boldsymbol{K}_{ib}^s \tag{36}$$

$\boldsymbol{B}_{pb}$ are sparse matrices that perform mapping (like $\boldsymbol{B}$) and scaling, e.g. for a homogeneous stiffness distribution among subdomains:

$$\boldsymbol{B}_{pb}^s = \boldsymbol{B}_b^s(\boldsymbol{M}_b^s)^{-1} \tag{37}$$

where $\boldsymbol{B}_b$ are the columns of $\boldsymbol{B}$ corresponding to boundary DOFs (boundary remainder in FETI-DP) and $\boldsymbol{M}_b$ is a diagonal matrix whose diagonal entries are the multiplicity of the corresponding DOFs, i.e. how many subdomains have instances of the DOFs.

Lumped preconditioner

A lumped preconditioner is defined as follows:

$$\boldsymbol{F}_I^{-1} = \sum_{s=1}^{N_s} \boldsymbol{B}_{pb}^s \boldsymbol{K}_{bb}^s (\boldsymbol{B}_{pb}^s)^T \tag{38}$$

In general, a lumped preconditioner is faster to compute and implement, but does not speed up the convergence of PCG as much as Dirichlet.

Diagonal Dirichlet preconditioner

A Diagonal Dirichlet preconditioner is defined as follows:

$$\boldsymbol{F}_I^{-1} = \sum_{s=1}^{N_s} \boldsymbol{B}_{pb}^s \hat{\boldsymbol{S}}^s (\boldsymbol{B}_{pb}^s)^T \tag{39}$$

where $\hat{\boldsymbol{S}}^s$ is an approximation of the Schur complement of internal dofs (internal-remainder in FETI-DP).

$$\hat{\boldsymbol{S}}^s = \boldsymbol{K}_{bb}^s - (\boldsymbol{K}_{ib}^s)^T (\boldsymbol{D}_{ii}^s)^{-1} \boldsymbol{K}_{ib}^s \tag{40}$$

where $\boldsymbol{D}_{ii}^s$ is the diagonal of $\boldsymbol{K}_{ii}^s$. In general, the computational cost of computing and implementing a diagonal Dirichlet preconditioner, as well as the resulting reduction of PCG iterations falls between that of Dirichlet and lumped preconditioner.

4 Combining XFEM with FETI

Using FETI methods to solve the linear systems resulting from XFEM during crack propagation can speed up the process. FETI methods are inherently parallel and can be executed on distributed computing environments concurrently. Compared to other domain decomposition methods, FETI methods scale extremely well with the number of processors in a network environment.

Even on a single-core system, FETI methods can result in a speedup over direct solvers. Due to domain decomposition, the stiffness matrix of each subdomain will have lower bandwidth than the stiffness matrix of the global domain. Non zero entries of the stiffness matrix correspond to DOFs of the same element. These DOFs are numbered closer to each other in a subdomain that has fewer DOFs than the whole model. In contrast, direct solvers rely on factorizing the stiffness matrix and their main bottleneck is its bandwidth. The more subdomains a domain decomposition solvers uses, the smaller the bandwidth of the resulting stiffness matrices.

To use FETI-1 for XFEM one needs to correctly identify the rigid body motions of the floating subdomains defined in Eq. (16). Round-off errors in the computation of the rigid body motions can increase PCG iterations required to solve the interface problem. FETI-DP on the other hand requires an appropriate selection of corner nodes to avoid singular matrices. Both methods can use the standard preconditioners described in Section 3.3. They should also be combined with an effective mesh partitioning algorithm to ensure a decomposition into balanced subdomains that does not slow down convergence.

5 NUMERICAL EXAMPLE

The test case deals with a fatigue crack growth in a double cantilever beam (DCB) [10]. The geometry of the DCB are $h = 3.94$ in and $L = 3h = 11.82$ in, as shown in Fig. 6. The thickness of the beam is equal to 1 in. The first crack segment is horizontal at half the beam's height and has length $a = 3.95$ in. An extra crack segment is added with length $da = 0.5$ in with an inclination angle $d\theta = 5.71^o$, to avoid pure Mode I propagation. The right side of the DCB is fixed, while a cyclic load $P = 197$ lbs is applied on the top left and bottom left corners. The material properties are $E = 3 \cdot 10^7$ psi and $v = 0.3$, while plane stress conditions are considered.

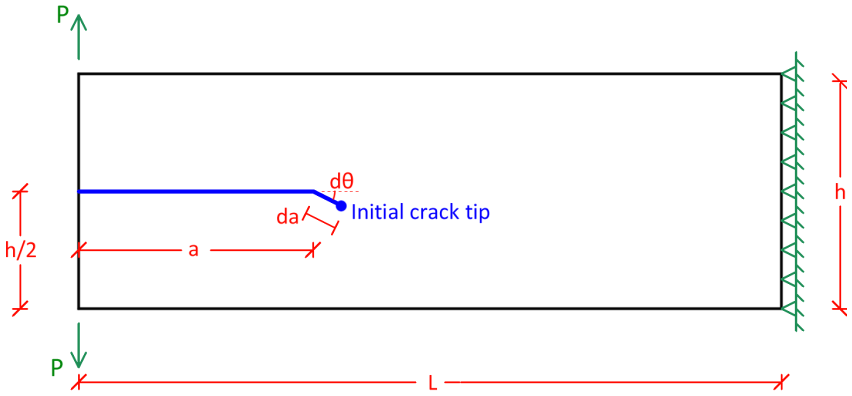

Figure 6: Geometry characteristics of the double cantilever beam.

The beam is discretized with standard QUAD4 finite elements, forming a uniform mesh. XFEM analysis is performed at 7 propagation steps, with topological tip enrichment. All analyses were conducted on a single-core system (Intel Core i7-6700 @3.40GHz CPU / 8 GB RAM) using three different types of solvers: i) a direct solver (with LDL factorization), ii) a FETI-1 solver and iii) a FETI-DP solver. In all analyses approximate minimum degree (AMD) reordering was used to reduce the bandwidth of the resulting stiffness matrices. Fig. 7 shows the crack path at the last step of the XFEM analysis.

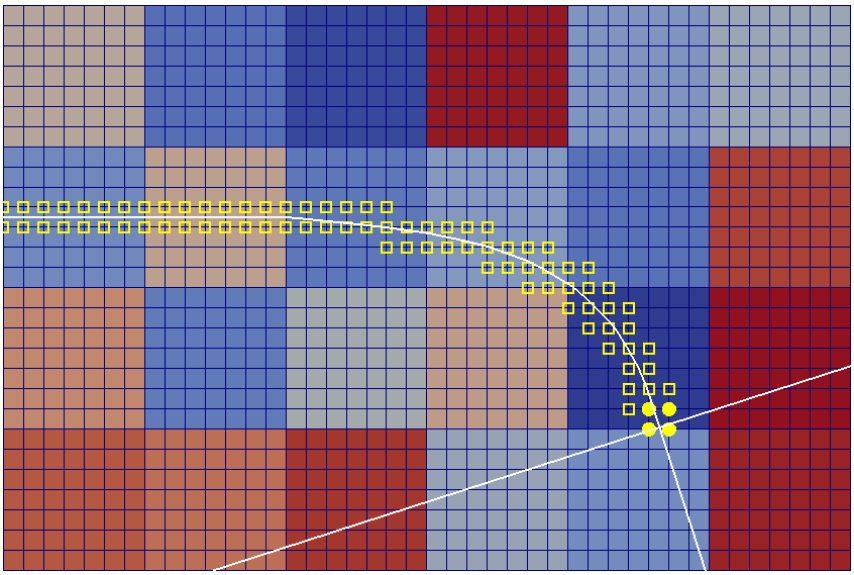

Figure 7: Crack propagation in a double cantilever beam.

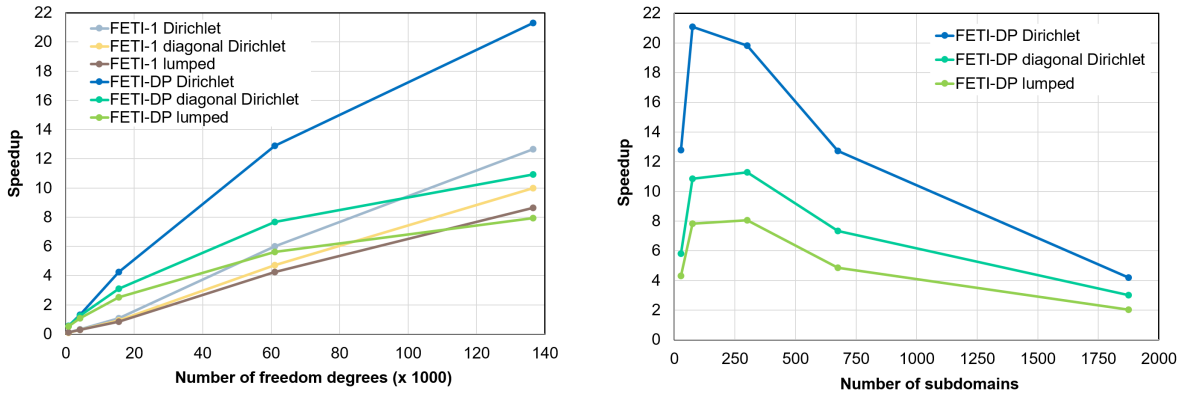
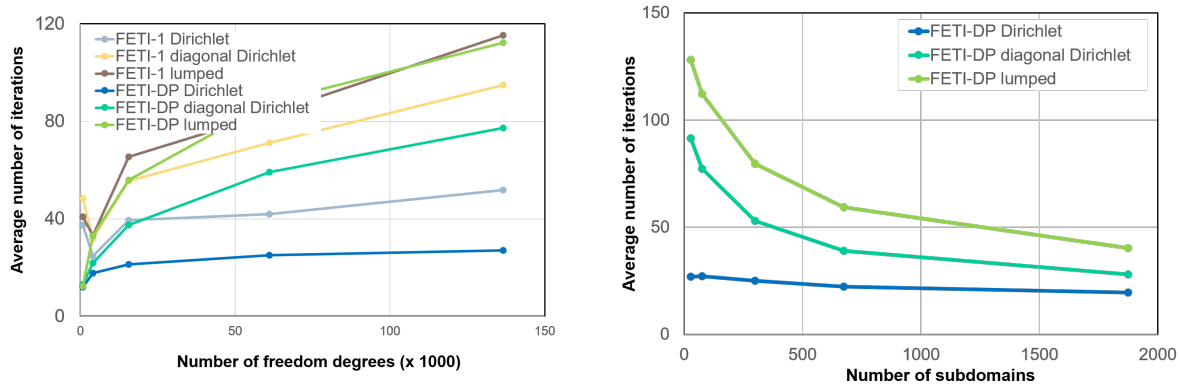
The speedup of FETI-1 and FETI-DP solver over the direct solver is depicted in Fig. 8 versus the number of DOFs and the number of subdomains. It is shown that FETI-DP exhibits excellent performance compared to other two solvers. More specific, it offers significant speedup (up to 22X) compared to the direct solver for all meshes examined. Furthmore, the Dirichlet preconditioner outperforms lumped and diagonal Dirichlet (up to a factor of 10X). The average number of PCG iterations is depicted in Fig. 9 versus the number of DOFs and the number of subdomains. The number of required PCG iterations remained low throughout the crack propagation analysis and was not affected by the ill-conditioned due to the enriched DOFs, while the optimal number of subdomains depends on the mesh size. On the other hand, FETI-1 required more PCG iterations to converge, as more enriched DOFs are added to the system. Although FETI-1 is inferior to FETI-DP, it still results in a speedup of the solution phase compared to the direct solver (up to 12X). Again Dirichlet precondition outperforms the other two in terms of average number of iterations required for the convergence.



(a) (b)

Figure 8: Speedup over direct solver versus number of (a) dofs and (b) subdomains.



(a) (b)

Figure 9: Average number of PCG iterations vs number of (a) dofs and (b) subdomains.

6 CONCLUSIONS

- FETI-1 and FETI-DP can be used for the solution of the linear systems resulting from 2D crack propagation in the XFEM framework.
- They offer significant speedup compared to a direct solver that uses Cholesky/LDL factorization and reordering, even when run on a single-core system.
- Potentially they can be run on distributed computing environments to further reduce the computational time.
- FETI-DP is simpler to use than FETI-1 and more efficient, since the number of PCG iterations is marginally increased by the ill-conditioning caused by enriched dofs.
- For both methods, Dirichlet preconditioner performs the best, while lumped preconditioner performs the worst.

Keywords: Stochastic Dynamics, Non-Gaussian random excitation, Transient moment analysis, Moment Equation, Equivalent non-Gaussian excitation method, Kurtosis.

Abstract. *The transient response analysis of a linear system subjected to non-Gaussian random excitation is carried out by using the equivalent non-Gaussian excitation method. The non-Gaussian excitation is prescribed by both the probability density function and the power spectrum. Since the excitation is expressed by the Itô stochastic differential equation, moment equations for the response can be derived from the governing equations for the excitation and the system. However, the moment equations are generally not closed owing to the nonlinearity of the diffusion coefficient in the governing equation for the excitation. Thus, using the equivalent non-Gaussian excitation method, the diffusion coefficient is replaced approximately by the equivalent diffusion coefficient, which is expressed by a quadratic polynomial. After the replacement of the diffusion coefficient, we could derive a closed set of the moment equations and obtain the time evolution of the response moments by solving these equations. In numerical examples, the analytical method is applied to a linear system under non-Gaussian excitation with the widely different probability distributions and bandwidth. It is shown that the analytical results of the transient response kurtosis agree very well with the corresponding Monte Carlo simulation results in all cases considered in the examples.*

1 INTRODUCTION

Stochastic analysis of the response of machines and structures subjected to random excitation have been performed widely for many decades. In many cases, the random excitation has been assumed to be a Gaussian process. This assumption is due to the fact that many random processes in engineering problems have the probability density functions similar to the Gaussian distribution. However, some random excitations (e.g. road roughness[1], shallow water waves[2] and wind pressure acting on low-rise buildings[3]) possess highly non-Gaussianity. The response of systems under non-Gaussian excitation is generally also non-Gaussian even if the system is linear, and the response characteristics are quite different with those in the case of Gaussian excitation. Therefore, response analysis in consideration of the non-Gaussian nature of random excitation is important to evaluate system response and reliability correctly.

In recent years, the equivalent non-Gaussian excitation method was presented to obtain the statistical moments of the response of non-Gaussian randomly excited systems[4]. It was demonstrated that this method leads to the accurate results of the variance, skewness and kurtosis of the stationary response for the random excitation with a wide range of the non-Gaussian probability distributions and the bandwidth of the power spectrum. On the other hand, the effectiveness of the method in transient analysis has not been verified yet.

In this study, we carry out the transient response analysis of a linear system subjected to non-Gaussian random excitation by the equivalent non-Gaussian excitation method. The non-Gaussian excitation is prescribed by both the probability density function and the power spectrum. Since the excitation is expressed by the Ito stochastic differential equation, moment equations for the response can be derived from the governing equations for the excitation and the system. However, the moment equations are not closed in most cases due to the nonlinearity of the diffusion coefficient in the governing equation for the excitation. Accordingly, using the equivalent non-Gaussian excitation method, the diffusion coefficient is replaced by the equivalent diffusion coefficient approximately. The square of the equivalent diffusion coefficient is expressed by a quadratic polynomial. The coefficients of the polynomial are determined according to the criterion of the least mean square error between the original diffusion coefficient and the equivalent counterpart. After the replacement of the diffusion coefficient, we can derive a closed set of the moment equations and obtain the time evolution of the response moments by solving these equations.

In numerical examples, the above-mentioned method is applied to a linear system under non-Gaussian excitation with the widely different probability distributions and bandwidth. It is shown that the analytical results of the transient response moments up to the fourth order agree very well with the corresponding Monte Carlo simulation results in all cases considered in the examples.

2 DESCRIPTION OF SYSTEM AND NON-GAUSSIAN RANDOM EXCITATION

2.1 System

Consider a single-degree-of-freedom linear system described by

$$\ddot{X} + 2\zeta\dot{X} + X = U(t) \tag{1}$$

where ζ is the damping ratio, t is the non-dimensional time parameter and dot sign denotes the derivative with respect to time t. $U(t)$ is a zero-mean stationary non-Gaussian random excitation.

2.2 Non-Gaussian random excitation

The non-Gaussian random excitation $U(t)$ considered in this study is prescribed by both the marginal probability density function $p_U(u)$ and the power spectral density $S_U(\omega)$. As the excitation probability density $p_U(u)$, various shapes of non-Gaussian distributions are taken into account.

The power spectrum $S_U(\omega)$ is expressed by

$$S_U(\omega) = \frac{\alpha \mathrm{E}[U^2]}{\pi(\omega^2 + \alpha^2)} \tag{2}$$

where α is the bandwidth parameter and $\mathrm{E}[U^2]$ is the mean square value of the excitation. $S_U(\omega)$ is shown in Fig. 1. This spectral density has a peak at zero frequency. The excitation is wide-band when α is large, on the other hand, the low-frequency component of the excitation is dominant when α is small.

The excitation $U(t)$ with the specified probability density $p_U(u)$ and the power spectrum $S_U(\omega)$ given by Eq. (2) can be described by the following one-dimensional Itô stochastic differential equation[5]

$$dU = -\alpha U dt + D(U) dB(t) \tag{3}$$

where α is the bandwidth parameter in Eq. (2), $B(t)$ is a Wiener process and the diffusion coefficient $D(u)$ is expressed by

$$D^2(u) = -\frac{2\alpha}{p_U(u)} \int_{-\infty}^{u} s p_U(s) ds \tag{4}$$

It is found that the non-Gaussian distribution $p_U(u)$ is reflected in $D(u)$. On the other hand, the information on the power spectrum $S_U(\omega)$ is included in the drift coefficient in Eq. (3) (see Ref.[5]).

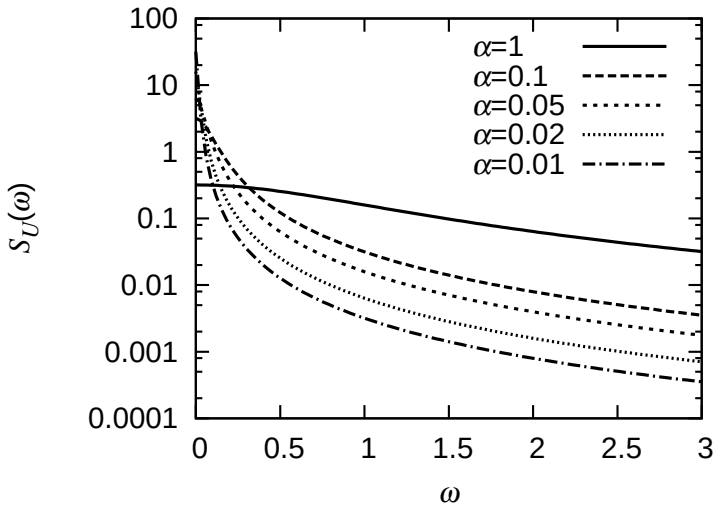

Figure 1: Power spectrum of excitation ($\mathrm{E}[U^2] = 1$).

3 EQUIVALENT NON-GAUSSIAN EXCITATION METHOD

3.1 Moment equations

The augmented system consisted of the equation of motion of the system (1) and the governing equation for the excitation (3) is described by a set of Itô stochastic differential equations as follows:

$$dX = \dot{X}dt \tag{5}$$

$$d\dot{X} = (-2\zeta\dot{X} - X + U)dt \tag{6}$$

$$dU = -\alpha U dt + D(U)dB(t) \tag{7}$$

Then, applying the Itô's formula[6] to Eqs. (5)-(7), the $(i+j+k)$th-order moment equations for the system response can be derived.

$$\begin{aligned}\frac{d}{dt}\mathrm{E}[X^i\dot{X}^jU^k] =& i\mathrm{E}[X^{i-1}\dot{X}^{j+1}U^k] - j\mathrm{E}[X^{i+1}\dot{X}^{j-1}U^k] - (2j\zeta + k\alpha)\,\mathrm{E}[X^i\dot{X}^jU^k] \\ &+ j\mathrm{E}[X^i\dot{X}^{j-1}U^{k+1}] + \frac{1}{2}k(k-1)\mathrm{E}[X^i\dot{X}^jU^{k-2}D^2(U)]\end{aligned} \tag{8}$$

However, $\mathrm{E}[X^i\dot{X}^jU^{k-2}D^2(U)]$ on the right-hand side of Eq. (8) is complicated form in most cases because of the nonlinearity of the diffusion coefficient $D^2(u)$ given by Eq.(4). Therefore, the moment equations (8) are generally not closed. In this paper, the equivalent non-Gaussian excitation method[4] is applied to obtain a closed set of the moment equations approximately.

3.2 Equivalent non-Gaussian excitation method

In the equivalent non-Gaussian excitation method, the diffusion coefficient $D(U)$ in Eq. (7) is replaced approximately with the equivalent diffusion coefficient $D_{eq}(U)$. The square of $D_{eq}(U)$ is expressed by a quadratic polynomial.

$$D_{eq}^2(U) = A_{eq}U^2 + B_{eq}U + C_{eq} \tag{9}$$

where the coefficients A_{eq}, B_{eq} and C_{eq} of the polynomial are adjusted according to the criterion of minimization of the mean square error $\mathrm{E}[e^2]$ between the square of the original diffusion coefficient $D^2(U)$ and the square of the equivalent one $D_{eq}^2(U)$.

$$\mathrm{E}[e^2] = \mathrm{E}[(D^2(U) - D_{eq}^2(U))^2] = \mathrm{E}[(D^2(U) - A_{eq}U^2 - B_{eq}U - C_{eq})^2] \tag{10}$$

Minimization of $\mathrm{E}[e^2]$ is realized when the following three conditions hold:

$$\frac{\partial \mathrm{E}[e^2]}{\partial A_{eq}} = 0, \quad \frac{\partial \mathrm{E}[e^2]}{\partial B_{eq}} = 0, \quad \frac{\partial \mathrm{E}[e^2]}{\partial C_{eq}} = 0 \tag{11}$$

Solving Eq. (11) with respect to A_{eq}, B_{eq} and C_{eq} leads to

$$\begin{aligned}A_{eq} =& \frac{(\mathrm{E}[U^2] - \mathrm{E}[U]^2)(\mathrm{E}[U^2D^2(U)] - \mathrm{E}[U^2]\mathrm{E}[D^2(U)])}{(\mathrm{E}[U^4] - \mathrm{E}[U^2]^2)(\mathrm{E}[U^2] - \mathrm{E}[U]^2) - (\mathrm{E}[U^3] - \mathrm{E}[U]\mathrm{E}[U^2])^2} \\ &- \frac{(\mathrm{E}[U^3] - \mathrm{E}[U]\mathrm{E}[U^2])(\mathrm{E}[U^2D^2(U)] - \mathrm{E}[U^2]\mathrm{E}[D^2(U)])}{(\mathrm{E}[U^4] - \mathrm{E}[U^2]^2)(\mathrm{E}[U^2] - \mathrm{E}[U]^2) - (\mathrm{E}[U^3] - \mathrm{E}[U]\mathrm{E}[U^2])^2}\end{aligned} \tag{12}$$

$$
\begin{aligned}
B_{eq} =& \frac{(\mathrm{E}[U^4] - \mathrm{E}[U^2]^2)(\mathrm{E}[UD^2(U)] - \mathrm{E}[U]\mathrm{E}[D^2(U)])}{(\mathrm{E}[U^4] - \mathrm{E}[U^2]^2)(\mathrm{E}[U^2] - \mathrm{E}[U]^2) - (\mathrm{E}[U^3] - \mathrm{E}[U]\mathrm{E}[U^2])^2} \\
&- \frac{(\mathrm{E}[U^3] - \mathrm{E}[U]\mathrm{E}[U^2])(\mathrm{E}[U^2D^2(U)] - \mathrm{E}[U^2]\mathrm{E}[D^2(U)])}{(\mathrm{E}[U^4] - \mathrm{E}[U^2]^2)(\mathrm{E}[U^2] - \mathrm{E}[U]^2) - (\mathrm{E}[U^3] - \mathrm{E}[U]\mathrm{E}[U^2])^2}
\end{aligned} \tag{13}
$$

$$
C_{eq} = \mathrm{E}[D^2(U)] - A_{eq}\mathrm{E}[U^2] - B_{eq}\mathrm{E}[U] \tag{14}
$$

Next, we derive the 2nd, 3rd and 4th order moment equations for the stationary excitation $U(t)$ by letting $(i, j, k) = (0, 0, 2), (0, 0, 3), (0, 0, 4)$ in Eq. (8) as follows:

$$
-2\alpha\mathrm{E}[U^2] + \mathrm{E}[D^2(U)] = 0 \tag{15}
$$

$$
-3\alpha\mathrm{E}[U^3] + 3\mathrm{E}[uD^2(U)] = 0 \tag{16}
$$

$$
-4\alpha\mathrm{E}[U^4] + 6\mathrm{E}[u^2D^2(U)] = 0 \tag{17}
$$

From Eqs. (12)-(17), it can be seen that the coefficients A_{eq}, B_{eq} and C_{eq} are evaluated by the moments up to the 4th order of $U(t)$. The moments $\mathrm{E}[U^n]$ $(n = 1, 2, 3, 4)$ can be calculated analytically or numerically from the non-Gaussian distribution $p_U(u)$, which is given beforehand to prescribe the excitation $U(t)$. Therefore, A_{eq}, B_{eq} and C_{eq} can be calculated, and the equivalent diffusion coefficient $D_{eq}(U)$ can be obtained by substituting the three coefficients into Eq. (9).

By replacing $D(U)$ in Eq.(7) with $D_{eq}(U)$ determined through the above procedure, the stochastic differential equation governing the equivalent non-Gaussian excitation can be obtained as

$$
dU = -\alpha U dt + \sqrt{A_{eq}U^2 + B_{eq}U + C_{eq}}dB(t) \tag{18}
$$

Finally, the $(i + j + k)$th-order moment equations are derived from Eqs. (5), (6) and (18).

$$
\begin{aligned}
\frac{d}{dt}\mathrm{E}[X^i\dot{X}^jU^k] =& i\mathrm{E}[X^{i-1}\dot{X}^{j+1}U^k] - j\mathrm{E}[X^{i+1}\dot{X}^{j-1}U^k] \\
&+ \left(-2j\zeta - k\alpha + \frac{1}{2}k(k-1)A_{eq}\right)\mathrm{E}[X^i\dot{X}^jU^k] \\
&+ j\mathrm{E}[X^i\dot{X}^{j-1}U^{k+1}] + \frac{1}{2}k(k-1)B_{eq}\mathrm{E}[X^i\dot{X}^jU^{k-1}] \\
&+ \frac{1}{2}k(k-1)C_{eq}\mathrm{E}[X^i\dot{X}^jU^{k-2}]
\end{aligned} \tag{19}
$$

In Eq.(19), the moments of order higher than $(i + j + k)$ do not appear. Therefore, Eq. (19) is closed form and can be solved analytically to obtain the time evolution of the response moments.

The solution of the 2nd-order response moment to Eq.(19) coincides perfectly with the exact solution. This is due to the following two facts:

- The power spectrum of the excitation given by Eq.(2) remains unchanged after replacing the diffusion coefficient $D(U)$ by $D_{eq}(U)$[4].
- The 2nd-order response moment of a linear system is determined from the excitation power spectrum $S_U(\omega)$ and the frequency response function $H(\omega)$ of the system as follows[7]:

$$\begin{aligned}\sigma_X^2(t) = \int_{-\infty}^{\infty} & S_U(\omega)|H(\omega)|^2 \\ & \times \{1 + \exp(-2\zeta t)\left[1 + \frac{2\zeta}{\sqrt{1-\zeta^2}}\sin\sqrt{1-\zeta^2}t\cos\sqrt{1-\zeta^2}t\right. \\ & - \exp(\zeta t)\left(2\cos\sqrt{1-\zeta^2}t + \frac{2\zeta}{\sqrt{1-\zeta^2}}\sin\sqrt{1-\zeta^2}t\right)\cos\omega t \\ & - \exp(\zeta t)\left(\frac{2}{\sqrt{1-\zeta^2}}\right)\sin\sqrt{1-\zeta^2}t\sin\omega t \\ & \left.\left. + \frac{2\zeta^2 - 1 + \omega^2}{1-\zeta^2}\sin^2\omega t\right]\right\} d\omega \end{aligned} \tag{20}$$

Furthermore, in the previous study[4], it was shown that since the coefficients A_{eq}, B_{eq} and C_{eq} are determined by the moments $\mathrm{E}[U^n]$ $(n = 1, 2, 3, 4)$, the equivalent non-Gaussian excitation governed by Eq. (18) retains the moments up to the 4th order which are the same as those of the original excitation, and this feature enables us to obtain the accurate results of the stationary response moments up to the 4th order.

In the next section, the validity of the equivalent non-Gaussian excitation method in transient response moment analysis will be examined.

4 NUMERICAL EXAMPLE

The equivalent non-Gaussian excitation method described in the previous section will now be applied to a linear system subjected to non-Gaussian excitation with the generalized Gaussian distribution.

4.1 Excitation probability distribution and diffusion coefficient

In this example, the generalized Gaussian distribution[8] is used for the non-Gaussian distribution of the excitation. The distribution with zero mean is defined as

$$p_U(u) = \frac{\kappa}{2a\Gamma(1/\kappa)}\exp\left(-\frac{|u|^\kappa}{a^\kappa}\right) \tag{21}$$

where $\Gamma(\cdot)$ is the gamma function and $\kappa(>0)$ represents the shape parameter. By varying κ, it is possible to characterize a large class of distributions with the widely different kurtosis. The Laplace, Gaussian and uniform distributions are special cases of the generalized Gaussian distribution with $\kappa = 1$, $\kappa = 2$ and $\kappa \to \infty$, respectively. a is the scale parameter. The variance σ^2 of the distribution is expressed by

$$\sigma^2 = a^2\Gamma\left(\frac{3}{\kappa}\right)\Gamma\left(\frac{1}{\kappa}\right)^{-1} \tag{22}$$

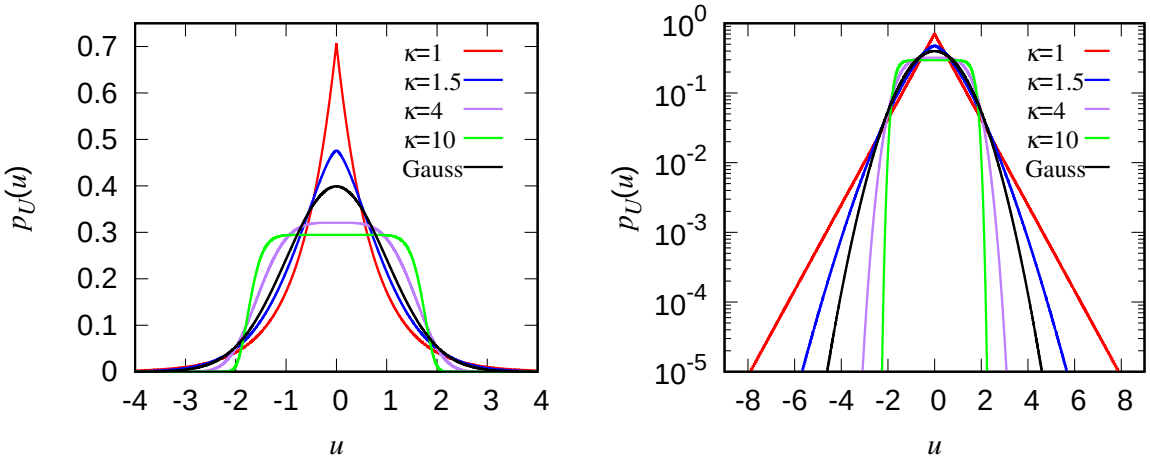

Figure 2: Generalized Gaussian distribution with zero mean and unit variance. Left : linear scale, Right : logarithmic scale.

In this study, a is adjusted so that σ^2 is equal to 1, irrespective of the shape parameter κ. The kurtosis γ_{4U} is given by

$$\gamma_{4U} = \Gamma\left(\frac{5}{\kappa}\right)\Gamma\left(\frac{1}{\kappa}\right)\Gamma\left(\frac{3}{\kappa}\right)^{-2} - 3 \tag{23}$$

In Fig. 2, the generalized Gaussian distributions for four types of κ are shown. In the case of $\kappa < 2$, the distribution has the heavier tail and larger kurtosis than those of a Gaussian distribution ($\kappa = 2$). On the other hand, the distribution for $\kappa > 2$ becomes the light-tailed distribution with smaller kurtosis compared to Gaussian distribution.

By Eq. (4), the diffusion coefficient $D(u)$ corresponding to the the generalized Gaussian distribution is derived as

$$D^2(u) = \frac{2\alpha a^2}{\kappa}\Gamma\left(\frac{2}{\kappa}, \frac{|u|^\kappa}{a^\kappa}\right)\exp\left(\frac{|u|^\kappa}{a^\kappa}\right) \tag{24}$$

where $\Gamma(\cdot,\cdot)$ is the upper incomplete gamma function.

4.2 Application of equivalent non-Gaussian excitation method

Since the diffusion coefficient $D(u)$ given by Eq. (24) is the complicated expression, the moment equations (8) are not closed. Therefore, the equivalent non-Gaussian excitation method is applied. $D(U)$ is replaced approximately with the equivalent diffusion coefficient $D_{eq}(U)$ expressed by Eq. (9). The moments up to the 4th order of the generalized Gaussian distribution are given as follows:

$$\begin{aligned} &\mathrm{E}[U^n] = a^n\Gamma\left(\frac{n+1}{\kappa}\right)\Gamma\left(\frac{1}{\kappa}\right)^{-1}, \quad n = 2, 4 \\ &\mathrm{E}[U] = \mathrm{E}[U^3] = 0 \end{aligned} \tag{25}$$

Using Eqs.(12)-(17) and (25), A_{eq}, B_{eq} and C_{eq} can be calculated. The coefficient B_{eq} is equal to 0 since the 1st and 3rd order moments of the excitation are zero. Then, substituting A_{eq}, B_{eq} and C_{eq} into Eq. (18) gives the stochastic differential equation for the equivalent non-Gaussian excitation. Finally, using this equation and Eqs. (5) and (6), the moment equations can be derived (Eq. (19)).

In this example, all the odd-order response moments are zero since the system is linear and the excitation distribution is symmetric. Thus, the second and fourth order moment equations are solved. These moment equations are written in appendix.

4.3 Parameters for numerical Example

- Damping ratio $\zeta = 0.05$
- Bandwidth parameter of excitation
  $\alpha = 0.01 \quad (\alpha/\zeta = 0.2)$
  $\alpha = 0.05 \quad (\alpha/\zeta = 1)$
  $\alpha = 1 \qquad (\alpha/\zeta = 20)$
- Shape parameter of generalized Gaussian distribution
  $\kappa = 1 \qquad$ (kurtosis $\gamma_{4U} = 3$)
  $\kappa = 1.5 \quad$ (kurtosis $\gamma_{4U} = 0.761954$)
  $\kappa = 4 \qquad$ (kurtosis $\gamma_{4U} = -0.811560$)
  $\kappa = 10 \quad$ (kurtosis $\gamma_{4U} = -1.11584$)

Three types of the excitation bandwidth parameter α are considered: $\alpha = 0.01$ (smaller than the damping ratio ζ which corresponds to the bandwidth of the frequency response function of a linear system), $\alpha = 0.05$ (the same as ζ) and $\alpha = 1$ (larger than ζ). The shape parameter κ of the generalized Gaussian distribution is also changed such that the shapes of the probability densities are quite different from each other. The distributions with $\kappa = 1$ and 1.5 have the larger kurtosis than that of a Gaussian distribution (kurtosis $= 0$), whereas the distributions with $\kappa = 4$ and 10 have the small kurtosis compared to a Gaussian distribution. The four types of the distributions are shown in Fig. 2.

Assume that the initial conditions of the system are $X(0) = 0$, $\dot{X}(0) = 0$ and the excitation is added to the system at $t = 0$.

4.4 Results

As mentioned above, all the odd-order response moments are zero since the system is linear and the excitation distribution is symmetric and zero-mean. Furthermore, when the equivalent non-Gaussian excitation method is used, the exact solution of the 2nd-order response moment can be obtained. Thus, the results of the response kurtosis, which is calculated from the 2nd and 4th order moments, is compared with the Monte Carlo simulation result.

The results of the transient displacement kurtosis are shown in Figs. 3-6. In these figures, the solid line and $\odot$ denote the analytical results and the corresponding Monte Carlo simulation results, respectively. The analytical results are in good agreement with the simulation results in all cases considered here. These results illustrate that the effectiveness of the equivalent non-Gaussian excitation method for transient response moment analysis of the system under non-Gaussian excitation with the widely different probability densities and a wide range of the bandwidth.

From Figs. 3-6, the following characteristics of the displacement response kurtosis could be found.

- Immediately after the excitation is applied to the system ($t \simeq 0$), the response kurtosis becomes almost the same as the excitation kurtosis, irrespective of the excitation bandwidth α.

- When the excitation bandwidth is narrower than the bandwidth of the system ($\alpha = 0.01$), the response kurtosis approaches zero (i.e., Gaussian) at period 2π and becomes a value close to the excitation kurtosis in steady state.
- In the case of the excitation bandwidth similar to the system bandwidth ($\alpha = 0.05$), the response kurtosis approaches zero at period 2π as in the case of $\alpha = 0.01$, on the other hand, the kurtosis of the stationary response is closer to 0 than that for $\alpha = 0.01$.
- When the excitation bandwidth is wider than that of the system ($\alpha = 1$), the response kurtosis changes almost monotonically and becomes a value close to zero in steady state.

These response characteristics will be investigated and discussed in detail in future work.

5 CONCLUSIONS

The transient response moment analysis has been performed for a linear system subjected to non-Gaussian random excitation using the equivalent non-Gaussian excitation method. The non-Gaussian random excitation is prescribed by both the probability density function and the power spectrum, and is described by an Itô stochastic differential equation. Since moment equations, which is derived from the governing equations for the excitation and the system, are generally not closed due to the nonlinearity of the diffusion coefficient in the stochastic differential equation for the excitation. Thus, by applying the equivalent non-Gaussian excitation method, the diffusion coefficient is replaced by the equivalent one approximately. The square of the equivalent diffusion coefficient is expressed by a quadratic polynomial. The coefficients of the polynomial are determined by minimizing the mean square error between the original diffusion coefficient and the equivalent counterpart. After the replacement of the diffusion coefficient, we can derive a closed set of the moment equations and obtain the transient response moments by solving these equations. The solution of the 2nd-order response moment coincides precisely with the exact solution because the replacement of the diffusion coefficient does not change the power spectrum of the excitation.

In numerical examples, the equivalent non-Gaussian excitation method has been applied to a linear system under non-Gaussian excitation with the generalized Gaussian distribution. It has been shown that the analytical results of the kurtosis of the transient response is in good agreement with the corresponding Monte Carlo simulation results in all cases considered in the examples. This is because the equivalent non-Gaussian excitation obtained by replacing the diffusion coefficient retains the moments up to the 4th order which are the same as those of the original excitation.

In this study, only the case of non-Gaussian excitation with a symmetric probability distribution has been considered. In our future work., application of the equivalent non-Gaussian excitation method to the case of random excitation with an asymmetric probability distribution will be performed to examine the validity of the method for various shapes of non-Gaussian distributions of the excitation.

Appendix

The 2nd and 4th order moment equations to be solved are shown below. These equations can be derived from Eq. (19).

2nd-order moment equations

$$\frac{d\mathrm{E}[X^2]}{dt} = 2\mathrm{E}[X\dot{X}] \tag{26}$$

$$\frac{d\mathrm{E}[X\dot{X}]}{dt} = -\mathrm{E}[X^2] + \mathrm{E}[\dot{X}^2] - 2\zeta\mathrm{E}[X\dot{X}] + \mathrm{E}[XU] \tag{27}$$

$$\frac{d\mathrm{E}[XU]}{dt} = -\alpha\mathrm{E}[XU] + \mathrm{E}[\dot{X}U] \tag{28}$$

$$\frac{d\mathrm{E}[\dot{X}^2]}{dt} = -2\mathrm{E}[X\dot{X}] - 4\zeta\mathrm{E}[\dot{X}^2] + 2\mathrm{E}[\dot{X}U] \tag{29}$$

$$\frac{d\mathrm{E}[\dot{X}U]}{dt} - \mathrm{E}[XU] - (2\zeta + \alpha)\mathrm{E}[\dot{X}U] + 2\mathrm{E}[U^2] \tag{30}$$

$$\frac{d\mathrm{E}[U^2]}{dt} = (-2\alpha + A_{eq})\mathrm{E}[U^2] + C_{eq} \tag{31}$$

4th-order moment equations

$$\frac{d\mathrm{E}[X^4]}{dt} = 4\mathrm{E}[X^3\dot{X}] \tag{32}$$

$$\frac{d\mathrm{E}[X^3\dot{X}]}{dt} = -\mathrm{E}[X^4] - 2\zeta\mathrm{E}[X^3\dot{X}] + 3\mathrm{E}[X^2\dot{X}^2] + \mathrm{E}[X^3U] \tag{33}$$

$$\frac{d\mathrm{E}[X^2\dot{X}^2]}{dt} = -2\mathrm{E}[X^3\dot{X}] - 4\zeta\mathrm{E}[X^2\dot{X}^2] + 2\mathrm{E}[X\dot{X}^3] + \mathrm{E}[X^2\dot{X}U] \tag{34}$$

$$\frac{d\mathrm{E}[X\dot{X}^3]}{dt} = -3\mathrm{E}[X^2\dot{X}^2] - 6\zeta\mathrm{E}[X\dot{X}^3] + 3\mathrm{E}[X\dot{X}^2U] + \mathrm{E}[\dot{X}^4] \tag{35}$$

$$\frac{d\mathrm{E}[X^3U]}{dt} = -\alpha\mathrm{E}[X^3U] + 3\mathrm{E}[X^2\dot{X}U] \tag{36}$$

$$\frac{d\mathrm{E}[X^2U^2]}{dt} = (-2\alpha + A_{eq})\mathrm{E}[X^2U^2] + 2\mathrm{E}[X\dot{X}U^2] + C_{eq}\mathrm{E}[X^2] \tag{37}$$

$$\frac{d\mathrm{E}[XU^3]}{dt} = (-3\alpha + 3A_{eq})\mathrm{E}[XU^3] + \mathrm{E}[\dot{X}U^3] + 3C_{eq}\mathrm{E}[XU] \tag{38}$$

$$\frac{d\mathrm{E}[X^2\dot{X}U]}{dt} = -\mathrm{E}[X^3U] - (2\zeta + \alpha)\mathrm{E}[X^2\dot{X}U] + \mathrm{E}[X^2U^2] + 2\mathrm{E}[X\dot{X}^2U] \tag{39}$$

$$\frac{d\mathrm{E}[X\dot{X}^2U]}{dt} = -2\mathrm{E}[X^2\dot{X}U] - (4\zeta+\alpha)\mathrm{E}[X\dot{X}^2U] + 2\mathrm{E}[X\dot{X}U^2] + \mathrm{E}[\dot{X}^3U] \tag{40}$$

$$\begin{aligned}\frac{d\mathrm{E}[X\dot{X}U^2]}{dt} =& -\mathrm{E}[X^2U^2] - (2\zeta+2\alpha-A_{eq})\mathrm{E}[X\dot{X}U^2] + \mathrm{E}[XU^3] \\ &+ \mathrm{E}[\dot{X}^2U^2] + C_{eq}\mathrm{E}[X\dot{X}]\end{aligned} \tag{41}$$

$$\frac{d\mathrm{E}[\dot{X}]}{dt} = -4\mathrm{E}[X\dot{X}^3] - 8\zeta\mathrm{E}[\dot{X}^4] + 4\mathrm{E}[\dot{X}^3U] \tag{42}$$

$$\frac{d\mathrm{E}[\dot{X}^3U]}{dt} = -3\mathrm{E}[X\dot{X}^2U] - (6\zeta+\alpha)\mathrm{E}[\dot{X}^3U] + 3\mathrm{E}[\dot{X}^2U^2] \tag{43}$$

$$\frac{d\mathrm{E}[\dot{X}^2U^2]}{dt} = -2\mathrm{E}[X\dot{X}U^2] - (4\zeta+2\alpha-A_{eq})\mathrm{E}[\dot{X}^2U^2] + 2\mathrm{E}[\dot{X}U^3] + C_{eq}\mathrm{E}[\dot{X}^2] \tag{44}$$

$$\frac{d\mathrm{E}[\dot{X}U^3]}{dt} = -\mathrm{E}[XU^3] - (2\zeta+3\alpha-3A_{eq})\mathrm{E}[\dot{X}U^3] + \mathrm{E}[U^4] + 3C_{eq}\mathrm{E}[\dot{X}U] \tag{45}$$

$$\frac{d\mathrm{E}[U^4]}{dt} = (-4\alpha+6A_{eq})\mathrm{E}[U^4] + 6C_{eq}\mathrm{E}[U^2] \tag{46}$$

Abstract

Floating bridges serve as attractive solutions where classical bridge concepts are not possible. However, compared to more commonly encountered bridge concepts such as cable-supported bridges, their dynamic behavior remains less investigated. Here, an end-supported pontoon bridge, currently under development by the Norwegian Public Roads Administration (NPRA) for the Bjørnafjord crossing in Norway, is considered as a case study to investigate its dynamic behavior under combined wind and wave loading. The stochastic dynamic behavior of the bridge are evaluated using state-of-the-art time domain analysis techniques. The frequency-dependent motion induced forces are modeled using state-space formulations, which are then embedded into the general-purpose finite element software ABAQUS, where the global dynamic analysis is carried out. Results of global response measures at the bridge girder are presented and the results are carefully discussed.

Keywords: floating bridge, buffeting, first-order waves, stochastic dynamics, radiation forces, self-excited forces, state-space model

1 INTRODUCTION

Although they are still relatively rare, floating bridges offer viable and economically efficient alternatives to the more classical long-span bridges. Span lengths so far has not been crossed with cable-supported bridges can possibly be crossed with floating bridges, without needing massive increase in the cost due to impractically large section dimensions. Such a solution for crossing the 5 km wide, Bjørnafjord in Norway is currently under evaluation of the Norwegian Public Roads Administration (Statens Vegvesen) as part of the Ferry Free E39 Coastal Highway Project [1]. In contrast to the cable-supported bridges, however, the dynamic behavior of such structures under environmental actions is far less investigated. The harsh nature of the Norwegian fjords together with its complex and mountainous topography in addition to the uniquely large scale of the structure makes such an evaluation increasingly challenging for the designing engineers. Significant efforts in understanding the underlying complex dynamics of the system are therefore necessary.

Dynamic analysis of floating bridges under random environmental loads require a stochastic dynamics approach, where the hydrodynamic effects at the pontoon locations and the aerodynamic interaction of the bridge girder with the wind should be modeled. Such an analysis can be carried out both in the frequency domain using spectral analysis [2,3] and in the time domain using Monte Carlo simulations [4,5]. Although significantly less time-efficient, time domain methods allow incorporation of the nonlinearities in the system. In a time domain approach, structural and geometric nonlinearities and nonlinear wind and wave forces can be included in the dynamic analysis, the effects of which might be important in case of such a slender structure. However, the frequency-dependent motion-induced forces, namely the aerodynamic self-excited forces and the hydrodynamic radiation forces that arise from the fluid-structure interaction, are more difficult to model in a time domain approach. For computational efficiency, radiation forces are conveniently modeled by state-space models [6,7] in analysis of large offshore structures and recently same approach was adopted for floating bridges [5]. Similar approaches can also be encountered in modeling of the self-excited forces in aerodynamic analysis of bridge decks [5,8,9].

Numerical simulations of the dynamic behavior of a super-long curved floating pontoon bridge under combined wind and wave actions are carried out in this study. The analysis is carried out in time domain, where the motion-induced forces are modeled using state-space models. The analysis results are presented in terms of standard deviations of the girder displacement and section forces.

Figure 1: Floating bridge crossing the Bjørnafjord

2 THE FLOATING BRIDGE CONCEPT

The floating bridge concept studied here is currently under concept development phase and considered a viable option for crossing the Bjørnafjord in Norway, which is a 5 km wide fjord in Hordaland, Norway. The fjord is exposed to strong winds and waves from the Norwegian Sea and the depth of the seabed does not allow for abutments, which would support a classical bridge. Therefore, a floating bridge with that is supported by pontoons is considered for the crossing (Figure 1). The proposed bridge consists of mainly three parts: a cable-stayed bridge that would allow the passage of ships underneath it, a high-bridge part that provides the transition between the cable-stayed bridge and the pontoon bridge, and the low bridge that sits on floating pontoons (Figure 2). On top of each pontoon, columns support the bridge girder, which has a streamlined girder of 31 meters wide and 3.5 meters deep. The bridge is also curved, providing an arching effect against the harsh environmental loading from the open-sea exposure.

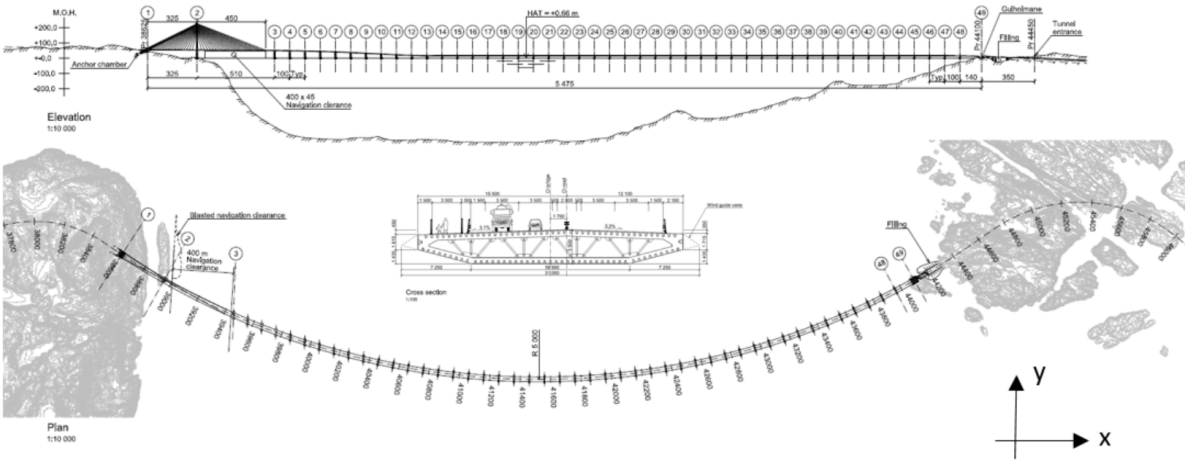

Figure 2: Technical Drawings (courtesy of Norwegian Public Roads Administration)

3 MODELING FRAMEWORK

In the framework of finite element discretization, the equation of motion of the structure under wind and wave loading, including the fluid-structure interaction terms, can be written as [5,7]

$$\mathbf{M}_s\ddot{\mathbf{u}}(t)+\mathbf{C}_s\dot{\mathbf{u}}(t)+(\mathbf{K}_s+\mathbf{K}_h)\mathbf{u}(t)=\mathbf{F}_{wind}+\mathbf{F}_{buff}(t)+\mathbf{F}_{se}(t)+\mathbf{F}_{wave}(t)-\mathbf{F}_{rad}(t) \quad (1)$$

where $\mathbf{M}_s$, $\mathbf{K}_s$, $\mathbf{C}_s$ are the structural mass, stiffness and damping matrices, $\mathbf{K}_h$ is the hydrostatic restoring stiffness matrix and $\mathbf{u}(t)$ is the vector of displacements. $\mathbf{F}_{wind}$ is the static wind load vector, $\mathbf{F}_{buff}(t)$ is the buffeting load vector and $\mathbf{F}_{wave}(t)$ is the first order wave load vector. $\mathbf{F}_{se}(t)$ and $\mathbf{F}_{rad}(t)$ denote the aerodynamic self-excited forces and the hydrodynamic radiation forces, respectively. The structural matrices are easily obtained using a finite element model of the structure (Figure 3), where the frequency-independent hydrostatic stiffness matrix can be obtained based on the buoyancy.

3.1 Motion-induced forces

The frequency-dependent motion-induced forces, $\mathbf{F}_{se}(t)$ and $\mathbf{F}_{rad}(t)$ will be modeled by state-space models for computational efficiency. The state-space model adopted for both terms can be written as

$$\begin{aligned}\dot{\mathbf{X}}(t) &= \mathbf{D}\mathbf{X}(t) + \mathbf{E}\mathbf{u}(t) \\ \mathbf{z}(t) &= \mathbf{Q}\mathbf{X}(t)\end{aligned} \tag{2}$$

where **X**(t) is the so-called state vector and **D, E, Q** are matrices of the model, $\mathbf{z}(t)$ denotes the frequency dependent part of the force vector. The system of equations given in the model gives a linear, continuous and time invariant system that describes the relationship between the motion of the structure and the motion-induced forces. The composition of the **D, E, Q** matrices depend on the functional form assumed to represent the forces. The detailed formulation of the models can be found in [5,10].

3.2 Buffeting and first-order wave forces

The buffeting forces due to wind turbulence and the wave forces are stochastic dynamic forces acting on the structure at pontoon locations and along the girder. They can be modeled as time-dependent nodal forces in the finite element framework described. However, the stochastic processes are generally defined in the form of spectral density matrices and Monte Carlo simulations are needed to obtain representative time-series of the processes.

Neglecting the aerodynamic admittance terms, the buffeting load vector for a girder node can be written assuming three degrees-of-freedom associated with the drag, lift and pitch motions of the girder as

$$F_{buff}(x,t) = \frac{\rho U B}{2}\begin{bmatrix} 2(D/B) & (D/B)C_D' - C_L' \\ 2C_L & C_L' + (D/B)C_D' \\ 2BC_M & BC_M' \end{bmatrix}\begin{bmatrix} u(x,t) \\ w(x,t) \end{bmatrix} \tag{3}$$

where ρ is the air density, U is the mean wind velocity and B is the width of the bridge deck. C_D, C_L and C_M are the aerodynamic static coefficients of the bridge deck. Lastly, $u(x,t)$ and $w(x,t)$ are the time-series of the along-wind and vertical turbulences.

Similarly, the first-order wave forces exerted upon pontoons by the incident waves, this time acting on a node with six degrees of freedom, can be written as

$$\begin{aligned} F_{wave}(x,y,t) &= \sum_n \sum_m \left|\mathbf{T}(\omega_n,\theta_m)\right|\eta_{nm}\cos\left(k_n(x\cos(\theta_m) + y\cos(\theta_m) - \omega_n t + \varepsilon_{mn} - \phi_{mn}\right),\ n,m = \{1,2,...6\} \\ \eta_{nm} &= \sqrt{2S_\eta(\omega_n,\theta_n)\Delta\omega\Delta\theta},\ \phi_{mn} = \tan^{-1}\left(\frac{\mathrm{Im}\left(\mathbf{T}(\omega_n,\theta_m)\right)}{\mathrm{Re}\left(\mathbf{T}(\omega_n,\theta_m)\right)}\right) \end{aligned} \tag{4}$$

where ω, θ, η and k denote the frequency, direction, wave amplitude and wave number, respectively and $\mathbf{T}$ is the transfer function, which can be obtained via potential theory.

4 NUMERICAL SIMULATIONS

A detailed finite element model of the bridge, which was created in the general-purpose commercial finite element software ABAQUS [11] was supplied by the Norwegian Public Roads administration. The model (Figure 3) consists of beam elements representing the bridge girder and the columns and nodes at the water level at the pontoon locations. At the pontoon nodes, structural springs are used to model the hydrostatic stiffness of the pontoons. Prior to modal and dynamic analyses, the static loading on the structure, namely the prestressing of the cables, self-weight of the structure and the static wind loads are applied to get the correct stiffness. Eigenvalue analysis is carried out after the application of static loads. The first four mode shapes, along with the corresponding natural frequencies are shown in Figure 4. The first natural period of the structure is found to be around 116 seconds.

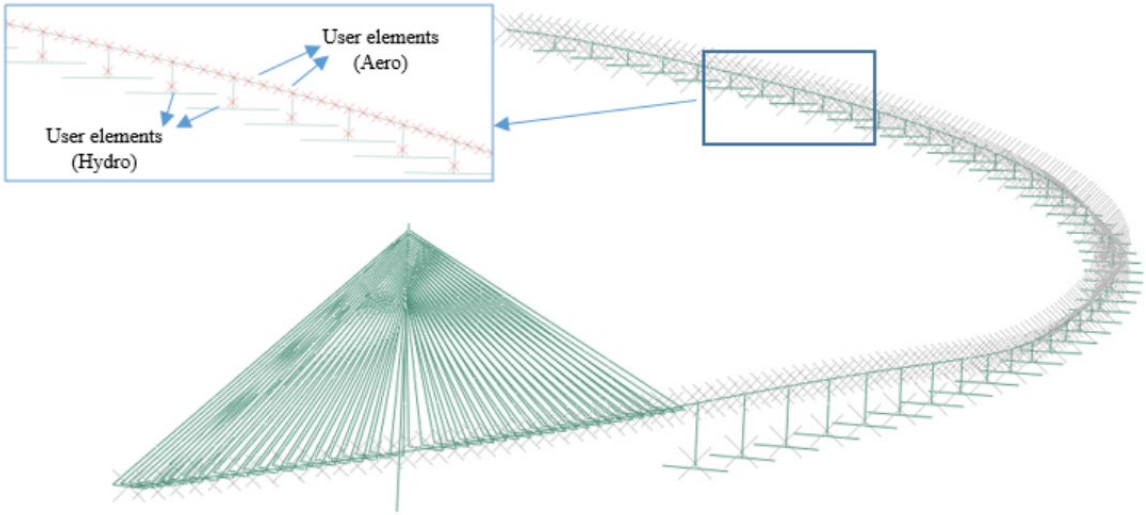

Figure 3: Finite element model of the bridge with aero and hydro user elements

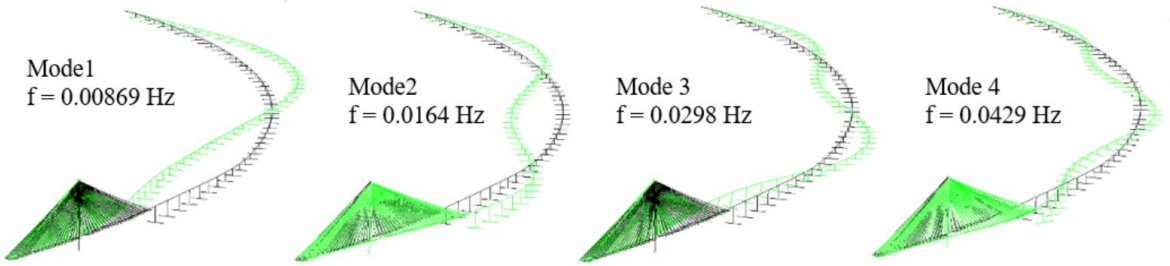

Figure 4: First four mode shapes and natural frequencies

4.1 Stochastic dynamic analysis

As discussed earlier, the definition of the stochastic environmental loads in the finite element model requires simulation of random time series from the processes defined by spectral characteristics. Time series of wind and wave forces are generated using an FFT-based simulation scheme [12]. The spectral densities of the processes are taken according to the design guidelines and the forms and parameters of the spectra are presented in Table 1. A Kaimal type of spectra along with Davenport coherence scheme is assumed for the wind turbulence,

where the Jonswap spectrum along with a cos-2s directional distribution is adopted for the wave spectrum.

Wind spectra	parameters					
$\frac{S_i f}{\sigma_i^2} = \frac{A_i f_z}{\left(1+1.5A_i f_z\right)^{5/3}},\ f_z = \frac{fz}{U},\ i = u, w$	U	30 m/s	C_{wy}	6.5	$C_D(C_D')$	0.53(0)

$D(\theta) = \cos^{2s}\left(\frac{\theta}{2}\right)$						

Table 1: Analysis input

The self-excited forces are modeled using the state-space model described in Eqn (2). The self-excited forces obtained by the quasi-steady theory are curve fitted by rational functions and the obtained coefficients are used to deduce the aerodynamic state-space model. Similarly, the hydrodynamic added mass and damping obtained from potential flow analyses in WADAM software using a panel model of the pontoon. The coefficients, which are obtained only at discrete frequencies, are then curve fitted using the method developed in [13]. The results of the curve fitting are then used to deduce the hydrodynamic state-space model.

The state-space models cannot be directly incorporated into the commercial finite element software. To overcome this obstacle, additional node elements at the existing nodes of the finite element model, defined by a user subroutine are introduced into the model, following the work of [5], where details of the implementation can be found.

5 ANALYSIS RESULTS

Dynamic analysis of the bridge is carried in time domain using the ABAQUS model, including the aerodynamic and hydrodynamic effects. 5 simulations of 1-hour duration each have been performed. The global responses along the length of the bridge girder, namely the strong and weak axis bending moments, the axial force and the displacements in three degrees-of-freedom (drag, lift and pitch) are extracted by post-processing the analysis results. The standard deviations of the global responses are then calculated using the hour-long signals at each node or integration point along the girder. The resulting standard deviations of the responses are plotted in Figure 5 for each simulation, where the average of five simulations is also shown.

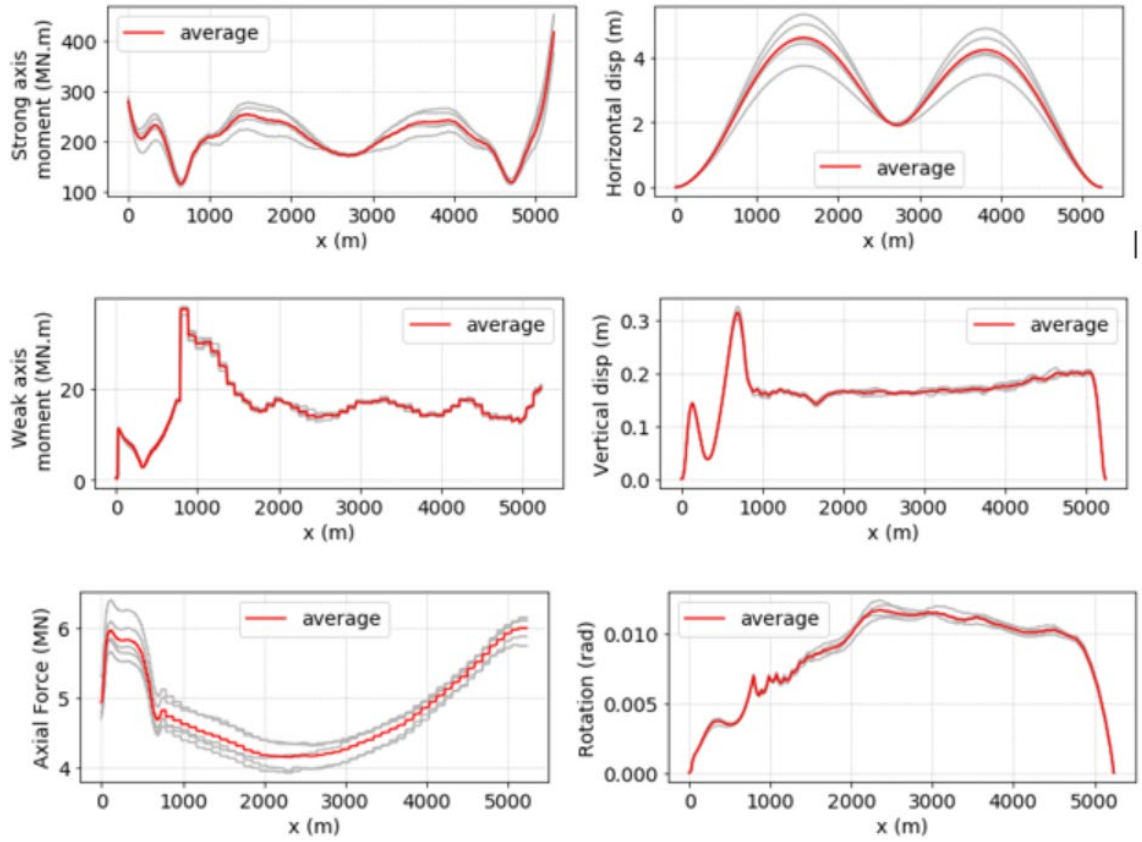

Figure 5: Standard deviations of the global responses of the bridge girder: the gray lines show different simulations, where the red lines are the averaged results

6 CONCLUSIONS

Dynamic behavior of a super-long curved pontoon bridge crossing the Bjørnafjord in Norway is investigated in this study under wind and wave loading. The analysis methodology is described and selected global responses under a certain environmental condition are presented.

Although the time-domain method discussed here has been used and verified against well-established frequency domain analyses before [5,10], comparisons are still necessary to ensure reliability of the approach. Such an analysis framework allows inclusion of also nonlinear phenomena with reasonable cost of computation, and opens possibilities for many investigations concerning the dynamic behavior of the structure. The contributions of wind and wave loadings and their interaction, different sources of damping, hydrodynamic interaction of the pontoons and global parametric stability of the entire bridge can be listed among others.

Abstract

In this paper, the evolutionary (time varying) power spectra of seismic accelerograms are estimated using the recently proposed method of separation. The procedure is based on a number of sample functions of the non-stationary random process characterizing the seismic event. These sample functions are artificial accelerograms as well as natural ground motion records. The key advantage of the method of separation is the minimization of spectral dispersion due to optimum time-frequency localization. However, it requires at least approximate spectral separability of the input samples to achieve satisfactory accuracy. The estimated evolutionary spectra are found to be in good agreement with those of the input samples in an average sense and can be used to generate artificial accelerograms compatible with specific ground motion records.

Keywords: Accelerogram, Random Process, Evolutionary Spectrum, Spectral Representation.

1 INTRODUCTION

Acceleration time histories are usually used to represent the seismic ground motion as they contain information regarding both the nature of seismic wave propagation and the soil properties. Ground motion time histories are used as input in the nonlinear dynamic analysis of engineering structures. Since there are still not enough records of strong earthquakes at a specific site, the generation of artificial accelerograms becomes necessary. The lack of regulatory provisions regarding the algorithms for the generation of acceleration time histories and the underlying assumptions has led to the development of a wide variety of methods based on non-stationary random process theory. The basic distinction made between these methods is about whether the produced accelerograms are design spectrum compatible [2, 3, 5, 6] or their evolutionary (time varying) power spectra match recorded data [4, 7, 8, 12].

This paper assesses the performance of the method of separation proposed by Schillinger and Papadopoulos in [9] for the estimation of evolutionary power spectra using a number of sample functions of the random process characterizing the seismic event. These sample functions are artificial accelerograms generated by the algorithm of Sabetta and Pugliese [8] as well as natural ground motion records. The key advantage of the method of separation is the minimization of spectral dispersion due to optimum time-frequency localization. However, it requires at least approximate spectral separability of the input samples to achieve reasonable accuracy.

The paper is organized as follows: An introduction to evolutionary power spectra along with a detailed description of the method of separation are provided in Section 2. Section 3 is devoted to the estimation of evolutionary power spectra based on a set of artificial accelerograms whereas the case of natural ground motion records used as input is examined in Section 4. The paper closes with a discussion and related conclusions in Sections 5 and 6.

2 EVOLUTIONARY POWER SPECTRA - THE METHOD OF SEPARATION

One of the most widely used techniques for the simulation of earthquakes as random processes is the spectral representation method [10]. This method is based on the power spectrum, which is related to the average energy of the random process and is obtained in seismic applications from measured ground accelerations. Despite its importance in the dynamic analysis of structures, there is little experience so far in accurately determining the evolutionary (time-varying) power spectrum of seismic motion. This is mainly achieved with the adoption of time-frequency analysis techniques in the framework of digital time signal processing.

The evolutionary power spectrum $S(\omega,t)$ is dependent on both frequency ω and time t and can be defined as the distribution of the mean square of the stochastic process $f(t)$ over the time-frequency domain:

$$E\left[\left|f(t)\right|^2\right] = 2\int_0^\infty S(\omega,t)d\omega \tag{1}$$

The power spectrum $S(\omega,t)$ satisfies spectral separability if it can be decomposed into a homogeneous spectrum part $S_h(\omega)$ and a modulating time envelope $g_h(t)$ as follows:

$$S(\omega,t) = S_h(\omega)g_h(t) \tag{2}$$

The corresponding stochastic process is called separable. The homogeneous spectrum part of the above equation expresses the distribution of energy over the frequency space ω and can be determined from a series of samples $f^{(i)}(t)$ of the random process by the so-called periodogram:

$$\tilde{S}_h(\omega) = E\left[\frac{1}{2\pi L}\left|\int_0^L f^{(i)}(t) w\left(t-\frac{L}{2}\right) e^{-I\omega t} dt\right|^2\right] \tag{3}$$

where L is the total sample length and window w is centered at $t=L/2$. However, the distribution over time cannot be appropriately matched by Eq. (3), since it finds an average over the entire duration of the signal. This is achieved with the use of the evolutionary power spectrum. By combining Eqs. (1) and (2), we get:

$$E\left[\left|f(t)\right|^2\right] = 2\int_0^\infty S_h(\omega) g_h(t) d\omega = g_h(t) 2\int_0^\infty S_h(\omega) d\omega \tag{4}$$

from which it follows that:

$$\tilde{g}_h(t) = \frac{E\left[\left|f^{(i)}(t)\right|^2\right]}{2\int_0^\infty \tilde{S}_h(\omega) d\omega} \tag{5}$$

By combining Eqs. (2) and (5), the estimation of the evolutionary power spectrum by the method of separation is finally obtained as [9]:

$$S(\omega,t) = E\left[\left|f^{(i)}(t)\right|^2\right] \frac{\tilde{S}_h(\omega)}{2\int_0^\infty \tilde{S}_h(\omega) d\omega} \tag{6}$$

Factor 1/2 in the right-hand side fraction is necessary, because Eq. (6) takes into account only one side of the symmetric two-sided power spectrum. Eq. (6) can be interpreted as the distribution of the mean square of the samples $f^{(i)}(t)$ over the frequency domain at each time instant t.

3 EVOLUTIONARY SPECTRA ESTIMATION BASED ON ARTIFICIAL ACCELEROGRAMS

In this section, the method of separation will be used to compute the evolutionary power spectrum of a specific earthquake (Lazio-Abruzzo, May 1984) based on 50 artificial accelerograms with the characteristics of this earthquake, derived from the Sabetta and Pugliese algorithm [8]. The method of separation is implemented in MATLAB software.

The algorithm of Sabetta and Pugliese incorporates the dependence of the motion on the magnitude, the distance from the source and the geological conditions, in order to generate realistic accelerograms. Based on these parameters, the evolutionary power spectrum or physical spectrum of the motion $S(\omega,t)$ is computed using a lognormal function [8]. The accelerograms are generated by spectral representation where the transient nature of the seismic process is incorporated in the coefficients of the series $C_n(t)$, which are determined by the physical spectrum:

$$a(t) = 2\sum_{n=1}^{N} C_n(t) \cos(\omega_n t + \phi_n), \quad C_n(t) = \sqrt{S(\omega_n,t)\Delta\omega} \tag{7}$$

Parameters of the Lazio-Abruzzo earthquake (as recorded in Garigliano station) related to the geophysical characteristics of the site under consideration were first introduced in the Sabetta and Pugliese algorithm to produce 50 compatible artificial accelerograms. The generated

accelerograms have the same peak ground acceleration, time duration and small differences in their form. The parameters used as input are the following:

- Moment magnitude: $M_w = 5.8$
- Epicentral distance: R = 52.6 km
- Local soil conditions: deep alluvial soil

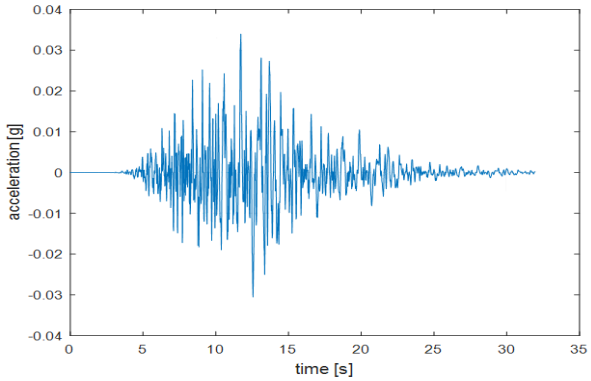

Figure 1: Typical accelerogram from Sabetta and Pugliese algorithm.

Fig. 1 shows a typical accelerogram out of the 50 produced for this paper. The estimation of the peak ground acceleration from the Sabetta and Pugliese algorithm for the parameters given above is 33.8 cm/s^2 and of the velocity is 2.5 cm/s. The duration of the time histories is approximately 32 s.

As demonstrated in [11], the algorithm achieves in most cases a very good match of the response spectrum of the input earthquake although it has not been developed with the aim of producing spectrum-compatible accelerograms. It is capable of delivering spectra that can satisfactorily be adapted to the Eurocode 8 design spectrum although the values of the maximum spectral accelerations of most spectra are smaller than the regulatory range for a particular combination of parameters. Finally, it has been shown that the computed spectra, although dispersed around the median, do not differ from this in their shape.

After generation of the artificial accelerograms with the Sabetta and Pugliese algorithm, their evolutionary power spectra have been computed using the method of separation discussed in the previous section. Figs. 2-4 show respectively the real spectrum of the Lazio-Abruzzo earthquake, the physical spectrum calculated by the Sabetta and Pugliese algorithm and the ensemble (mean) evolutionary power spectrum computed with the method of separation from 50 artificial accelerograms.

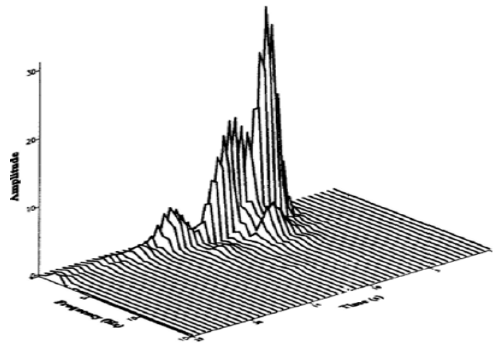

Figure 2: The real power spectrum of Lazio-Abruzzo earthquake [8].

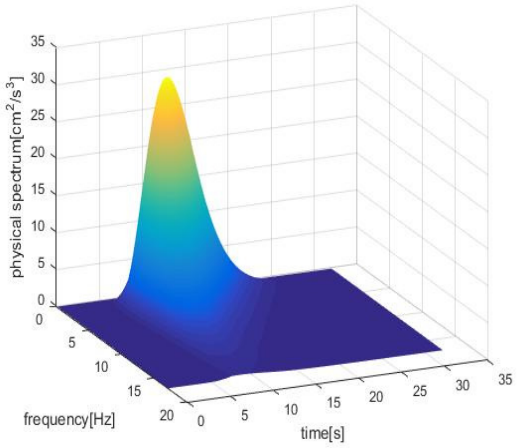

Figure 3: Lazio-Abruzzo earthquake: Physical spectrum calculated from Sabetta and Pugliese lognormal function.

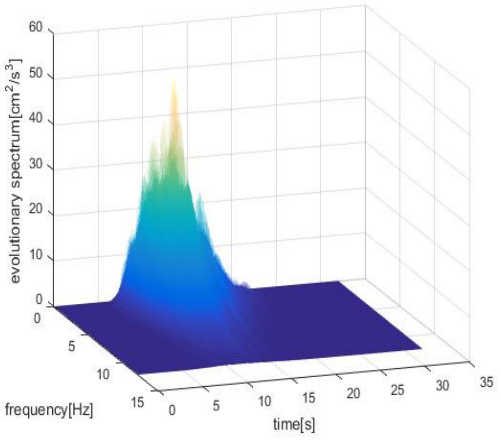

Figure 4: Evolutionary (mean) power spectrum computed using the method of separation from 50 artificial accelerograms.

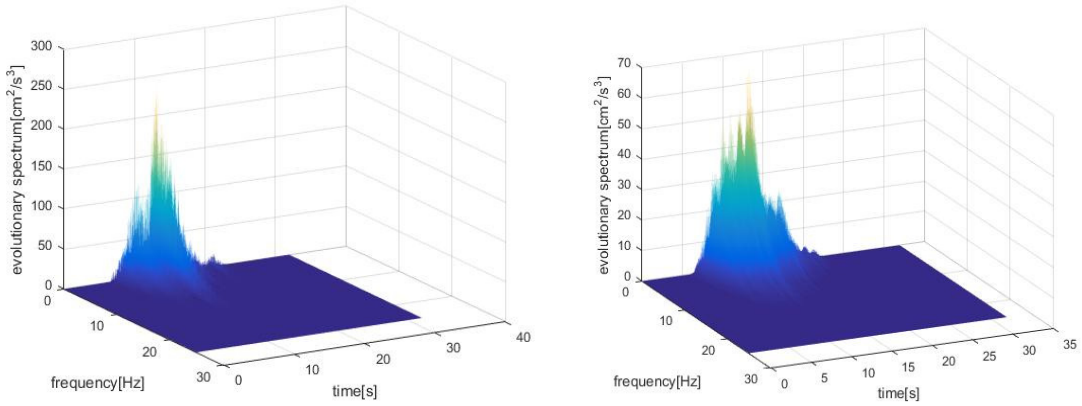
50 accelerograms have been used because it was observed that the more samples were introduced in the separation algorithm, the more homogenized, smooth and close to the values of the real and the physical spectrum was the respective diagram. This is illustrated in Figs. 4-5 which show the evolutionary power spectra of 50, 1 and 10 artificial accelerograms with the parameters given above.



(a) (b)

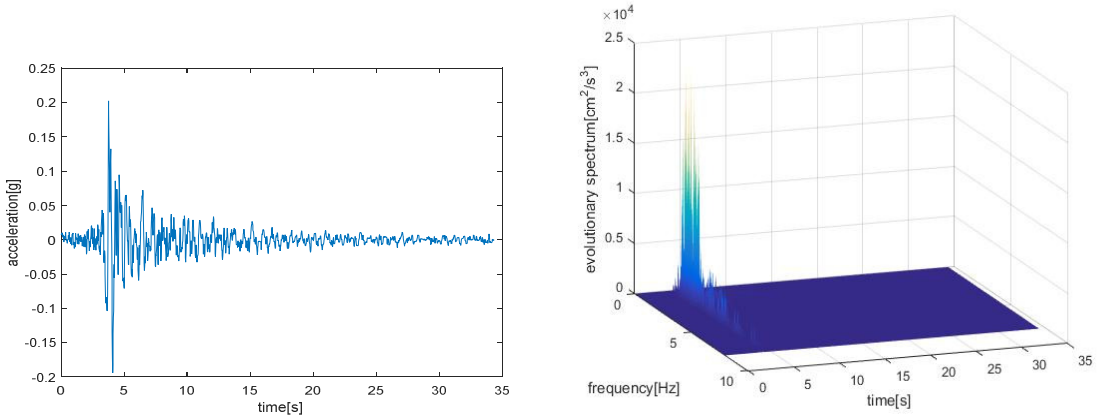
Figure 5: Evolutionary power spectrum of (a) one and (b) ten artificial accelerograms computed using the method of separation.

4 EVOLUTIONARY SPECTRA ESTIMATION BASED ON REAL ACCELEROGRAMS

After producing the evolutionary spectra of artificial accelerograms derived from the Sabetta and Pugliese algorithm, some examples of evolutionary spectra of recorded accelerograms are also provided. The accelerograms were selected with peak ground accelerations in the range 0.9-2.3 m/s^2 from the European Strong-Motion Database (ESD) [1].

A. Earthquake: Montenegro (aftershock), Station: Bar-Skupstina Opstine

- Moment magnitude: $M_w = 6.2$
- Epicentral distance: R = 33 km
- Peak ground acceleration: PGA = 0.2g
- Date: 24/05/1979

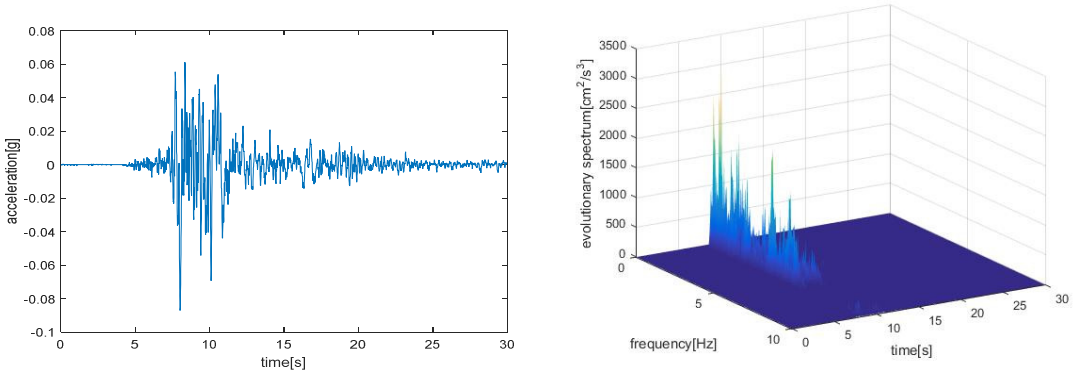


(a) (b)

Figure 6: (a) Accelerogram of earthquake A and (b) its evolutionary power spectrum computed using the method of separation.

B. Earthquake: Ano Liosia, Station: Athens 2 (Chalandri District)

- Moment magnitude: $M_w = 6$
- Epicentral distance: R = 20 km
- Peak ground acceleration: PGA = 0.09g
- Date: 07/09/1999

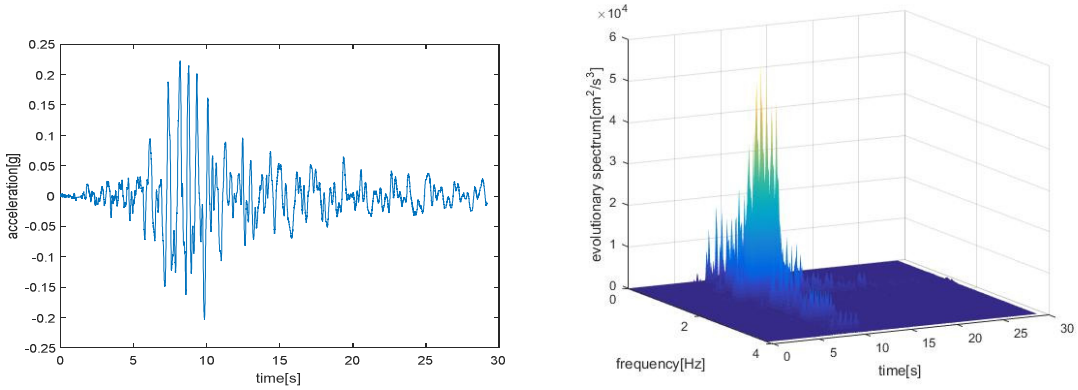


(a) (b)

Figure 7: (a) Accelerogram of earthquake B and (b) its evolutionary power spectrum computed using the method of separation.

C. Earthquake: Adana, Station: Ceyhan-Tarim Ilce Mudurlugu

- Moment magnitude: $M_w = 6.3$
- Epicentral distance: R = 30 km
- Peak ground acceleration: PGA = 0.23g
- Date: 27/06/1998



(a) (b)

Figure 8: (a) Accelerogram of earthquake C and (b) its evolutionary power spectrum computed using the method of separation.

5 DISCUSSION

Based on the above results, it can be noticed that the evolutionary power spectrum of the 50 artificial accelerograms (Fig. 4) approaches the physical spectrum of the Sabetta and Pug-

liese algorithm (Fig. 3) but is less smooth as it is not calculated by an analytical lognormal function. It is also similar to the real spectrum, which appears to exhibit a higher concentration of values at smaller frequencies (<5 Hz) than the other two. The evolutionary spectrum has larger values in this frequency range than the physical spectrum.

A general observation based on the power spectra of Figs. 4, 6b-8b is that the distribution of the seismic energy over time follows the corresponding accelerogram and is concentrated at time instants of high acceleration values. The evolutionary spectra present also a large fluctuation in the frequency domain.

6 SUMMARY AND CONCLUSIONS

- In this paper, the evolutionary power spectra of artificial and real accelerograms were computed using the method of separation. The Sabetta & Pugliese algorithm was used to produce artificial accelerograms. The analyses were performed in MATLAB using 50 artificial and three real accelerograms to implement the method of separation.
- The evolutionary power spectrum estimated using the method of separation was in general found to be similar to the physical spectrum of the Sabetta and Pugliese algorithm and to the real spectrum of the particular earthquake examined but it also presented some differences. This is mainly due to the small number of accelerograms that were used. As shown in [9], it took up to 10,000 samples of the stochastic process to obtain a smooth approximation of the spectrum.
- Another reason is that the physical spectrum used by the Sabetta and Pugliese algorithm to produce the accelerograms is not separable, which means that the method of separation requires at least approximate spectral separability of the input samples to achieve satisfactory accuracy.
- Further investigation is deemed necessary using a larger number of time histories as input and, perhaps, more reliable intensity measures, such as spectral acceleration, for the selection and/or generation of ground motions.
- The estimated evolutionary spectra can be used as input in the spectral representation method to produce artificial accelerograms compatible with given recordings.

AN EFFICIENT TRANSMISSION OPERATOR FOR COMPUTING WAVE PROPAGATION BY DOMAIN DECOMPOSITION

Denis Duhamel[1]

Keywords: Domain decomposition, wave, Helmholtz, finite element, transmission operator.

Abstract. *For large size problems, domain decompositions can be used to solve wave propagation problems such as the Helmholtz equation. Generally, this leads to an iterative process where data are exchanged at the boundary between subdomains. Depending on the quality of this exchange the number of iterations is more or less. Moreover, this number of iterations can depend on the frequency and on the number of domains. Here, we propose transmission operators approximating the Dirichlet to Neumann (DtN) operator which is known to be near optimal. We show this can be done using only the solution of problems involving sparse matrices and so keeping the computational time at an acceptable level. When this is combined with the double sweep preconditioner and that the computational domain is decomposed into a sequel of slices this results in an algorithm with a low number of iterations. Different examples are presented to support the precedent analysis.*

1 INTRODUCTION

Solving wave propagation problems described by the Helmholtz equation is important in many domains such as acoustics or elastic wave propagation. This can be difficult as the frequency increases because fine meshes have to be used in these cases. One possibility to increase the computing power is to use domain decompositions for which the domain is decomposed into subdomains on which the solutions can be computed more easily by solving small size problems. This generally involves an iterative scheme with a communication between the subdomains at each step, for instance by the transmission of data across the boundary of subdomains.

Many works have been done in the past on this subject where we find methods in which the subdomains overlap or not. In the field of non-overlapping methods we find the works on FETI methods as in [1] or for the application to the Helmholtz equation in [2] where interdomains fields continuity is obtained by Lagrange multipliers. These Lagrange multipliers are computed by solving a relatively small dual problem by a preconditioned conjugate gradient algorithm.

Another possibility is to use overlapping or non-overlapping Schwartz methods as in [3, 4, 5] where the solution is computed iteratively in each subdomain and transmission conditions are defined at the boundary of each domain from the solutions in the subdomains at the precedent step. The convergence rate mainly depends on this transmission operator at the boundary, the best one being the DtN map, see [6, 7], but it is too complicated to compute for being usable. Different methods have been proposed to approximate this complex non-local operator by a simpler one, often by local operators on the boundary, see for instance [8] and [9] for an uptodate view on the subject. A PML layer can also be used as in [10].

Here we propose a new transmission operator defined from the solution of a wave problem in domains around the computed subdomain as in the PML but with a simpler formulation which does not need modifications to the problem formulation or computations of new stiffness matrices. For being efficient, a preconditionner must be used with these methods such as the double sweep preconditionner found in [11, 12, 13].

In section 2, the method is described for the case of a problem posed on two half planes where analytical results can be found following the approach of [5] but with a new transmission operator, then this is applied to more general domains which can be decomposed into a sequel of slices. Finally, in section 3, numerical results are presented before a conclusion.

2 COMPUTATION BY DOMAIN DECOMPOSITION

The objective is to solve a wave propagation problem by domain decomposition. We consider here the case of the Helmholtz equation given by

$$\Delta p + k^2 p = 0 \tag{1}$$

with p the pressure, $k = \omega/c$ the wavenumber, c the sound velocity, $\omega = 2\pi f$ and f the frequency. This is defined on a domain Ω with a Neumann boundary condition as $\frac{\partial p}{\partial n} = q$ on the boundary Γ of Ω.

2.1 Case of two half-planes

Consider first the Helmholtz equation defined on a plane (x, y) which is divided into two half-plane subdomains by the line $x = 0$, see figure 1. Taking the Fourrier transform in the y variable with the wavenumber k_y, one obtains the following sequel of one-dimensional problems in the

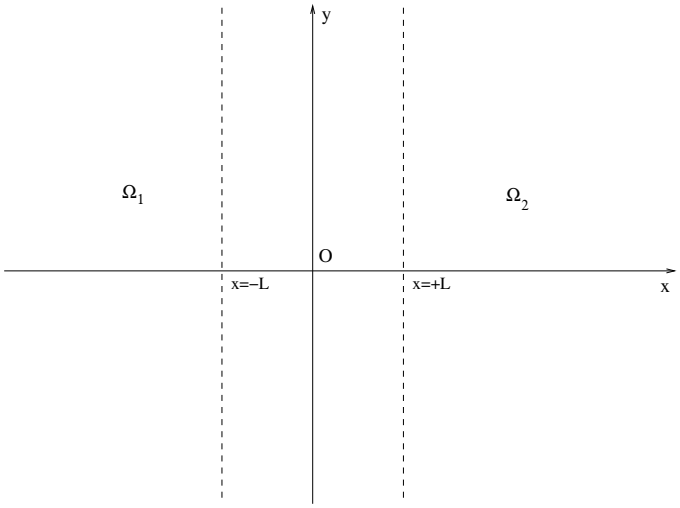

Figure 1: Two half-planes with additional slices of thickness L.

two sub-domains, which are respectively

$$\begin{aligned} \frac{\partial^2 p_1^{n+1}}{\partial x^2} + (k^2 - k_y^2) p_1^{(n+1)} &= 0 \quad for\ x < 0 \\ \frac{\partial p_1^{(n+1)}}{\partial x} + \sigma_1(k_y) p_1^{(n+1)} &= \frac{\partial p_2^{(n)}}{\partial x} + \sigma_1(k_y) p_2^{(n)} \quad at\ x = 0 \end{aligned} \tag{2}$$

$$\begin{aligned} \frac{\partial^2 p_2^{(n+1)}}{\partial x^2} + (k^2 - k_y^2) p_2^{(n+1)} &= 0 \quad for\ x > 0 \\ -\frac{\partial p_2^{(n+1)}}{\partial x} + \sigma_2(k_y) p_2^{(n+1)} &= -\frac{\partial p_1^{(n)}}{\partial x} + \sigma_2(k_y) p_1^{(n)} \quad at\ x = 0 \end{aligned} \tag{3}$$

with $\sigma_1(k_y)$ and $\sigma_2(k_y)$ two well chosen functions to assure the convergence of the iterative process. The solutions are respectively

$$\begin{aligned} p_1^{(n+1)}(x) &= e^{-\lambda(k_y)x} p_1^{(n+1)}(0) \quad for\ x < 0 \\ p_2^{(n+1)}(x) &= e^{\lambda(k_y)x} p_2^{(n+1)}(0) \quad for\ x > 0 \end{aligned} \tag{4}$$

with $\lambda(k_y) = i\sqrt{k^2 - k_y^2}$. From the transmission conditions (second lines of 2 and 3), one gets

$$\begin{aligned} p_1^{(n+1)}(0) &= \frac{\lambda(k_y) + \sigma_1(k_y)}{-\lambda(k_y) + \sigma_1(k_y)} p_2^{(n)}(0) \\ p_2^{(n+1)}(0) &= \frac{\lambda(k_y) + \sigma_2(k_y)}{-\lambda(k_y) + \sigma_2(k_y)} p_1^{(n)}(0) \end{aligned} \tag{5}$$

so that

$$p_1^{(2n)}(0) = \rho^n(k_y) p_1^{(0)}(0) \tag{6}$$

with

$$\rho(k_y) = \frac{\lambda(k_y) + \sigma_1(k_y)}{-\lambda(k_y) + \sigma_1(k_y)} . \frac{\lambda(k_y) + \sigma_2(k_y)}{-\lambda(k_y) + \sigma_2(k_y)} \tag{7}$$

Different possibilities for choosing the values of σ_1 and σ_2 are discussed in [5]. Here, we propose another way of building these functions. The value of $\sigma_1(k_y)$ is obtained from the solution of the problem in the slice $0 < x < L$ with absorbing boundary conditions at $x = L$, more precisely from the solution of the problem

$$\begin{aligned} \frac{\partial^2 p_1}{\partial x^2} + (k^2 - k_y^2) p_1 &= 0 \quad for\ 0 < x < L \\ p_1 &= p \quad for\ x = 0 \\ \frac{\partial p_1}{\partial x} - \gamma_1(k_y) p_1 &= 0 \quad for\ x = L \end{aligned} \tag{8}$$

and $\sigma_1(k_y)$ is defined such that $\frac{\partial p_1}{\partial x}(0) + \sigma_1(k_y) p = 0$. The solution of problem 8 is given by

$$p_1(x) = a e^{\lambda(k_y)x} + b e^{-\lambda(k_y)x} \tag{9}$$

with the coefficients a and b such that

$$\begin{aligned} a + b &= p \\ \lambda(k_y)(a e^{\lambda(k_y)L} - b e^{-\lambda(k_y)L}) - \gamma_1(k_y)(a e^{\lambda(k_y)L} + b e^{-\lambda(k_y)L}) &= 0 \end{aligned} \tag{10}$$

The second relation of 10 leads to $b = R_1 a$ with $R_1 = \frac{\lambda(k_y) - \gamma_1(k_y)}{\lambda(k_y) + \gamma_1(k_y)} e^{2\lambda(k_y)L}$, so that we get

$$\sigma_1(k_y) = -\lambda(k_y) \frac{1 - R_1}{1 + R_1} \tag{11}$$

Similarly one gets

$$\sigma_2(k_y) = -\lambda(k_y) \frac{1 - R_2}{1 + R_2} \tag{12}$$

In the case $k_y = 0$, taking $\gamma_1 = \gamma_2 = ik$, one gets $R_1 = R_2 = R$ and the classical values $\sigma_1 = \sigma_2 = -ik$. From (11) and (12) we obtain the value of $\rho(k_y)$ by relation 7 giving $\rho(k_y) = R^2$ in the case $\gamma_1 = \gamma_2 = ik$. The function $\rho(k_y)$ is plotted versus k_y/k for several values of kL in figure 2. For $kL = 0$, the evanescent waves are not attenuated and the process cannot converge. On the contrary, for $kL > 0$, the value of $\rho(k_y)$ is lower than one for the entire spectrum leading to the convergence of the iterative process and all the more so as the value of kL is high.

2.2 General method

We consider now a more general domain which is decomposed into vertical slices as shown in figure 3. In each vertical band i, one has to solve at step $n + 1$

$$\begin{aligned} \Delta p_i^{(n+1)} + k^2 p_i^{(n+1)} &= 0 \ in\ \Omega_i \\ \frac{\partial p_i^{(n+1)}}{\partial n_i} + S_{i,i-1} p_i^{(n+1)} &= g_{i,i-1}^{(n)} = -\frac{\partial p_{i-1}^{(n)}}{\partial n_{i-1}} + S_{i,i-1} p_{i-1}^{(n)} \ on\ \Gamma_{i-1,i} \\ \frac{\partial p_i^{(n+1)}}{\partial n_i} + S_{i,i+1} p_i^{(n+1)} &= g_{i,i+1}^{(n)} = -\frac{\partial p_{i+1}^{(n)}}{\partial n_{i+1}} + S_{i,i+1} p_{i+1}^{(n)} \ on\ \Gamma_{i,i+1} \end{aligned} \tag{13}$$

with the operators S as approximations of the DtN operators on the boundaries and the $g_{i,i+1}$ are updated by

$$\begin{aligned} g_{i,i+1}^{(n+1)} &= -\frac{\partial p_{i+1}^{(n+1)}}{\partial n_{i+1}} + S_{i,i+1} p_{i+1}^{(n+1)} \\ &= -g_{i+1,i}^{(n)} + (S_{i,i+1} + S_{i+1,i}) p_{i+1}^{(n+1)} \end{aligned} \tag{14}$$

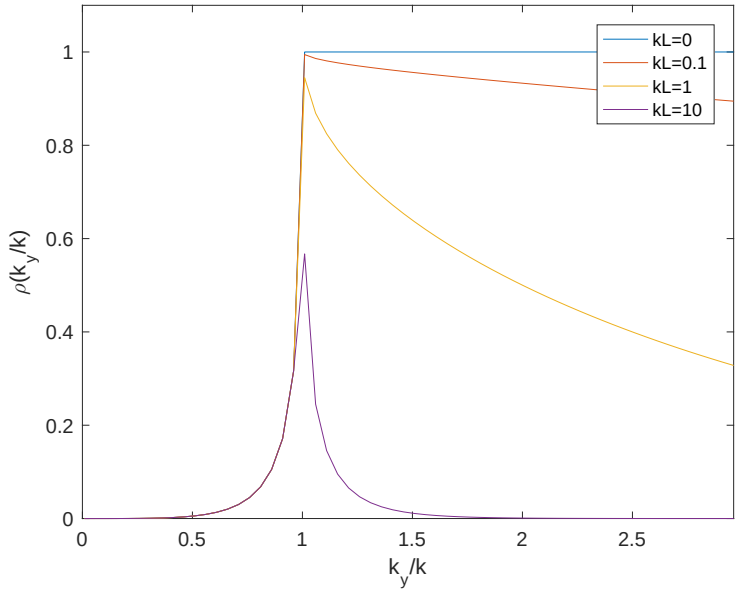

Figure 2: Values of ρ for different kL

with a similar formula for $g_{i,i-1}^{(n+1)}$.

The operator $S_{i,i+1}p_{i+1}^{(n+1)}$ is obtained by solving the Helmholtz equation in the domain Ω_{i+1} with an absorbing boundary condition on $\Gamma_{i+1,i+2}$, that is

$$\begin{aligned} \Delta u + k^2 u &= 0 \; in \; \Omega_{i+1} \\ \frac{\partial u}{\partial n_{i+1}} - iku + \frac{i}{4k}\frac{\partial^2 u}{\partial \tau^2} &= 0 \; on \; \Gamma_{i+1,i+2} \\ u &= p_{i+1}^{(n+1)} \; on \; \Gamma_{i,i+1} \end{aligned} \tag{15}$$

and $S_{i,i+1}p_{i+1}^{(n+1)} = \frac{\partial u}{\partial n_{i+1}}$ on $\Gamma_{i,i+1}$ giving an approximation of the DtN operator on that interface.

The operator $S_{i+1,i}p_{i+1}^{(n+1)}$ is obtained by solving the Helmholtz equation in the domain Ω_i with an absorbing boundary condition on $\Gamma_{i-1,i}$, that is

$$\begin{aligned} \Delta u + k^2 u &= 0 \; in \; \Omega_{i} \\ \frac{\partial u}{\partial n_{i}} - iku + \frac{i}{4k}\frac{\partial^2 u}{\partial \tau^2} &= 0 \; on \; \Gamma_{i-1,i} \\ u &= p_{i+1}^{(n+1)} \; on \; \Gamma_{i,i+1} \end{aligned} \tag{16}$$

with $\frac{\partial}{\partial \tau}$ the tangential derivative and $S_{i+1,i}p_{i+1}^{(n+1)} = \frac{\partial u}{\partial n_i}$ on $\Gamma_{i,i+1}$ giving an approximation of the DtN operator on that interface.

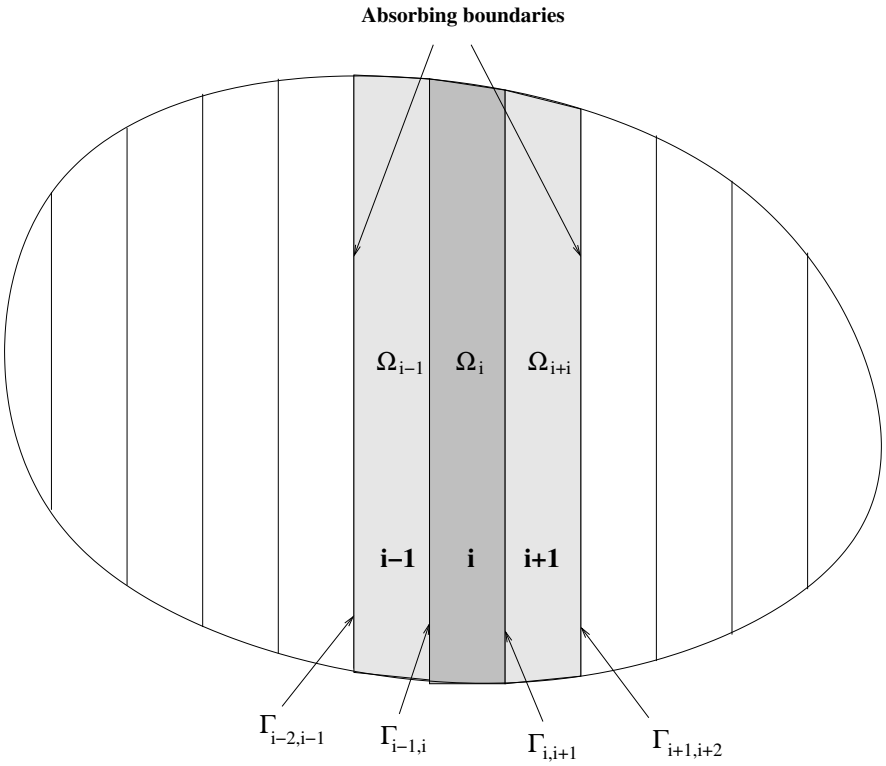

Figure 3: Domain and its decomposition into subdomains

Combining relations 13, 15 and 16, to update the solution in Ω_i, one has to solve

$$\begin{aligned}
\Delta p_i^{(n+1)} + k^2 p_i^{(n+1)} &= 0 \; in \; \Omega_i \\
\Delta u_{i-1}^{(n+1)} + k^2 u_{i-1}^{(n+1)} &= 0 \; in \; \Omega_{i-1} \\
\Delta u_{i+1}^{(n+1)} + k^2 u_{i+1}^{(n+1)} &= 0 \; in \; \Omega_{i+1} \\
\frac{\partial p_i^{(n+1)}}{\partial n_i} + \frac{\partial u_{i-1}^{(n+1)}}{\partial n_{i-1}} &= g_{i,i-1}^{(n)} \; on \; \Gamma_{i-1,i} \\
\frac{\partial p_i^{(n+1)}}{\partial n_i} + \frac{\partial u_{i+1}^{(n+1)}}{\partial n_{i+1}} &= g_{i,i+1}^{(n)} \; on \; \Gamma_{i,i+1} \\
\frac{\partial u_{i-1}^{(n+1)}}{\partial n_{i-1}} - iku_{i-1}^{(n+1)} + \frac{i}{4k}\frac{\partial^2 u_{i-1}^{(n+1)}}{\partial \tau^2} &= 0 \; on \; \Gamma_{i-2,i-1} \\
\frac{\partial u_{i+1}^{(n+1)}}{\partial n_{i+1}} - iku_{i+1}^{(n+1)} + \frac{i}{4k}\frac{\partial^2 u_{i+1}^{(n+1)}}{\partial \tau^2} &= 0 \; on \; \Gamma_{i+1,i+2}
\end{aligned} \tag{17}$$

The last equations of (15) and (16) provide the relations of continuity between the solutions in the adjacent domains. At the discrete level this problem is solved by assembling the dynamic stiffness matrices of the domains Ω_{i-1}, Ω_i and Ω_{i+1} and putting forces on the interfaces $\Gamma_{i-1,i}$ and $\Gamma_{i,i+1}$ defined respectively by the functions $g_{i,i-1}^{(n)}$ and $g_{i,i+1}^{(n)}$. For external boundaries, the boundary condition of the problem should be used, for instance $\frac{\partial p}{\partial n} = q_0$ for a Neumann boundary defined by a function q_0.

The problem is then solved by the GMRES algorithm associated to the double sweep preconditionner described in [11, 12, 13]. For the updating of $g_{i,i+1}$, one has to solve the problems

(15) and (16) and use their solutions in (14).

3 NUMERICAL EXAMPLES

3.1 Rectangle

We first consider the case of a rectangular domain of size $1m \times 1m$ with a boundary condition given by a plane wave e^{ikx} on the left and right boundaries as $\frac{\partial p}{\partial n} = ikn_x e^{ikx}$. The mesh is created with triangular elements of degree 2 (52633 nodes for 5 subdomains up to 80401 nodes for 100 subdomains). The mesh for 100 subdomains is shown on figure 4 where each domain is a fine vertical band. Computations are done for different frequencies and number of subdomains. Table 1 shows that in this case the number of iterations is very low and do not depend on the frequency or the number of subdomains. The solution for 100 subdomains and the frequency 2000Hz is shown on the right of figure 5.

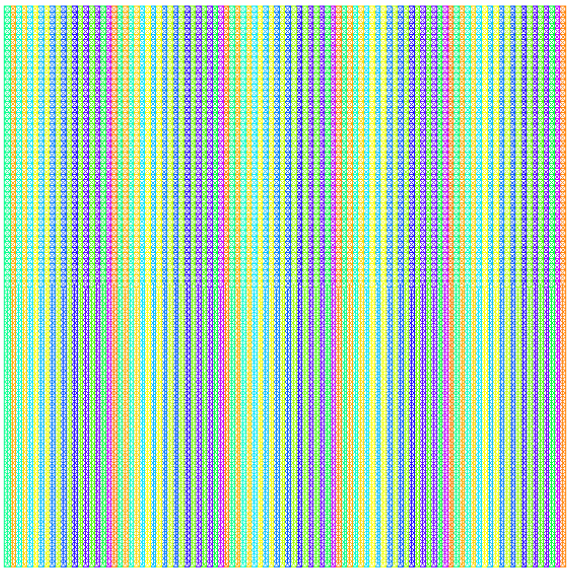

Figure 4: Rectangular domain with 100 subdomains

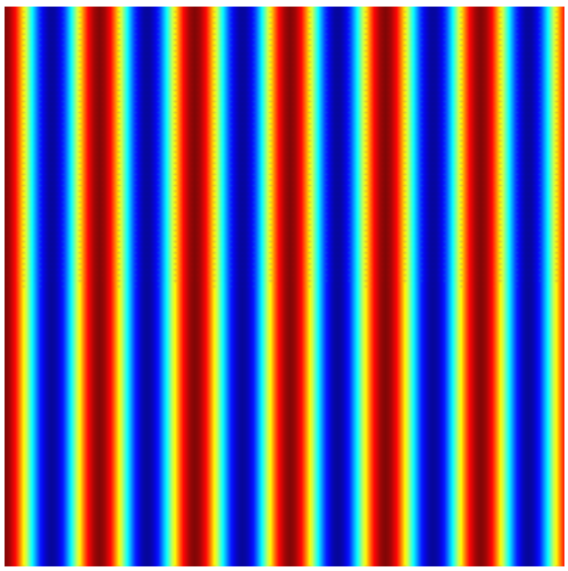

Figure 5: Solution at 2000Hz for 100 subdomains

Other computations are made with the boundary condition given by $cos(k_y y)e^{ik_x x}$ with $k_y = 4\pi/L_y$ and $k_x = \sqrt{k^2 - k_y^2}$. The number of iteration is given in table 2 while the solutions for 500 Hz and 2000 Hz are given in figures 6 and 7. In figure 6 the boundary condition leads to an evanescent wave while in figure 6 a propagating wave is clearly visible. This number of iterations is low except for 100 subdomains and low frequencies. This needs further studies to understand this phenomenon as usually the number of iteration is increasing with the frequency.

Frequency	Number of subdomains		
	5	25	100
500 Hz	4	4	4
1000 Hz	4	4	4
2000 Hz	4	4	4

Table 1: Number of iterations for different frequencies and number of subdomains.

Frequency	Number of subdomains		
	5	25	100
500 Hz	10	15	73
1000 Hz	13	15	41
2000 Hz	17	18	20

Table 2: Number of iterations for different frequencies and number of subdomains.

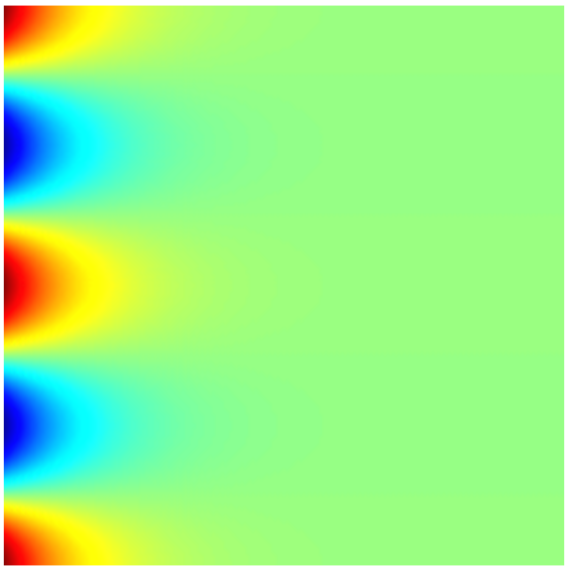

Figure 6: Solution at 500Hz for 100 subdomains

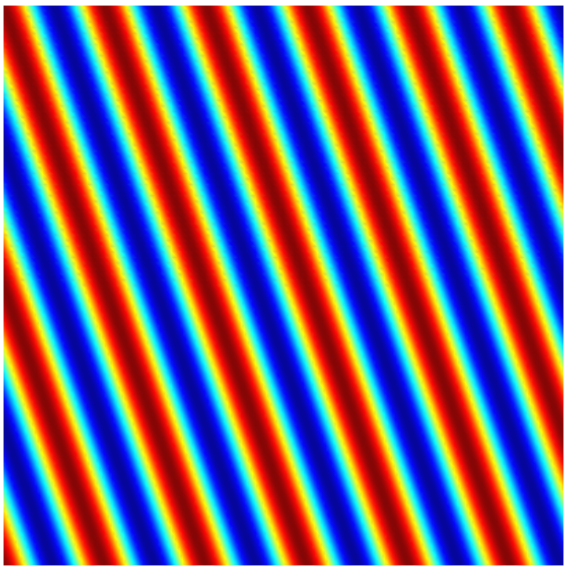

Figure 7: Solution at 2000Hz for 100 subdomains

3.2 Disk

The domain is now a disk of radius 1m whose mesh and decomposition into 100 subdomains is shown in figure 8. The solution for the plane wave excitation is shown in figure 9. In this case the number of iterations is shown in table 3. There is a slow increase in the number of iteration with the frequency and the number of subdomains.

Frequency	Number of subdomains		
	5	25	100
500 Hz	10	14	26
1000 Hz	15	17	23
2000 Hz	28	34	38

Table 3: Number of iterations for different frequencies and number of subdomains.

4 CONCLUSION

We have presented transmission conditions which are intermediate between the local conditions on the boundary and domain conditions as provided by a PML layer. So it gives an equilibrium between the ease of implementation and the efficiency. It involves only modified

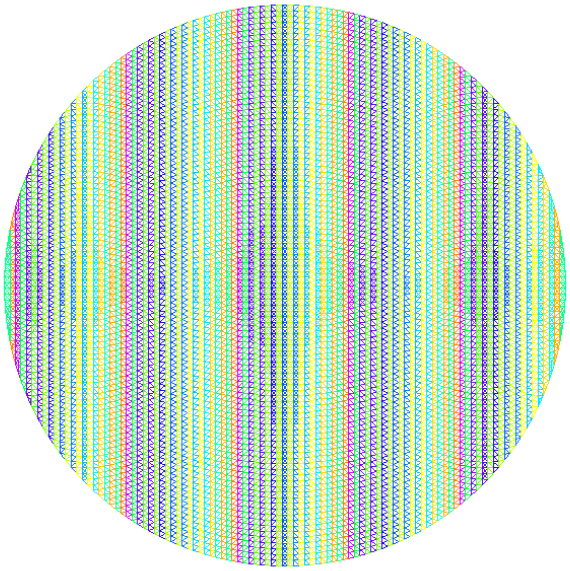

Figure 8: Disk domain with 100 subdomains

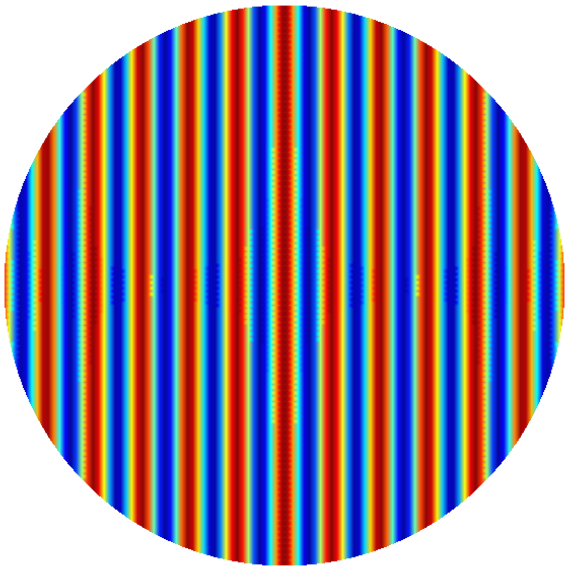

Figure 9: Solution at 2000Hz for 100 subdomains

matrices on the boundaries but no new matrix in the domains. Subsequent research should focus on the improvement of the boundary condition $\frac{\partial p}{\partial n} = ikp - \frac{i}{4k}\frac{\partial^2 p}{\partial \tau^2}$.

Keywords: Train-induced ground-vibration, moving frame of reference, Kirchhoff plate slab track.

Abstract. *To predict ground-borne vibration levels caused by railway traffic, models for estimating the load from the vibration source, as well as the vibration transmission through the ground, are needed. In the present paper, a finite element formulation in a frame of reference following the moving load, is used for modeling a railway slab track. The response of the underlying soil is represented through a dynamic stiffness matrix, obtained via the Green's function for a horizontally layered visco-elastic half-space in a moving frame of reference in the frequency–wavenumber domain. The track can be modeled as continuously connected beams, but the use of plate elements allows for more general stress and displacement distributions in the transverse direction of the slab to be resolved. Here, the free-field response due to a harmonic load moving along a slab track, is evaluated and compared using different modeling strategies for the slab.*

1 INTRODUCTION

To predict the level of ground-borne vibration caused by railway traffic, models are needed to estimate the load from the vibration source as well as the vibration transmission through the ground. A number of techniques have been developed in the past decades to study ground vibrations caused by a passing train, ranging from empirical methods to analytical and numerical schemes.

Numerical schemes are often based on either the finite element (FE) or the boundary element (BE) method or a combination thereof. The strength of these methods lies in their ability to model arbitrary geometries and discontinuities. The downside is the high computational cost. The computational cost can be reduced if the soil and track system is assumed to be invariant in the track direction, leading to so called 2.5D models [1, 2, 3, 4]. Further, if the soil stratification is assumed to consist of horizontally layered visco-elastic layers, a fundamental solution (Green's function) for the soil response can be found efficiently in frequency–wavenumber domain. Sheng et al [5, 6] proposed a semi-analytical model, with the track represented by an infinite layered beam resting on a layered ground, where both the ground and the beam is described in the frequency–wavenumber domain. Kaynia et al [7] coupled a series of FE beams, representing the railway track, to a dynamic stiffness matrix of the ground calculated from the Green's function of a layered half-space.

Modeling the track as a beam on a layered half-space is a common approach in the field of ground-borne vibrations due to railway traffic. This approach, however, constricts the track–soil interface stress distribution. Steenbergen et al [8] studied the influence of different interface conditions between a beam on a half-space, subjected to a dynamic moving load, on the free-field response, using a semi-analytical model in the frequency–wavenumber domain. Galvin et al [4] compared the free-field response of a high-speed train passage on a ballasted track on an embankment, calculated using a 2.5D continuum model, to a model with a beam representation of the track, finding large differences attributed to the rigid cross-section of the embankment in the beam model.

In the present paper, a FE model is used for representing a railway slab track. The response of the underlying soil is represented by a dynamic stiffness matrix obtained via the Green's function for a horizontally layered visco-elastic half-space. The model is formulated in a frame of reference following the moving load. The slab and rails can either be modeled as continuously connected beams or by using Kirchhoff plate elements for representing the track slab. Plate elements allow for more general stress and displacement distributions in the track transveral direction to be resolved. Here, the free-field response due to a harmonic load moving along the track at constant velocity, is calculated and compared using different modeling strategies for the track.

In Section 2 an overview of the model is given and the studied case is presented in Section 3. Finally, conclusions are given in Section 4.

2 CALCULATION MODEL

2.1 Overview

The slab track is shown principally in Figure 1. It consists of a supporting layer, a concrete slab, rails and rail pads. Full interaction is assumed between the slab and the supporting layer, so that a homogeneous section with equivalent mass and bending stiffness may be utilized in the calculations. This homogeneous section is simply referred to as the slab in the following.

Three models, model a)–c), with different assumptions regarding the slab and the slab–soil

interface conditions, are established:

a) The slab is modeled with Bernoulli-Euler beam elements. Displacement continuity of the beam and the soil is enforced only along the beam center line. A uniform stress distribution between the beam and the soil is assumed in the transverse direction of the slab.

b) The slab is modeled with Bernoulli-Euler beam elements. The slab–soil interface is assumed rigid in the transverse direction. This is enforced by coupling the beam kinematically to a number of soil DoFs in the transverse direction over the width of the slab.

c) The slab is modeled with Kirchhoff plate elements, allowing for a more general slab–soil interface stress and displacement distribution in the transverse direction of the slab than by the two other models.

In all three models, the rails are modeled as Bernoulli-Euler beams, connected to the slab via a continuous visco-elastic interface layer representing the rail pads. The loading is assumed identical on both rails, hence in model a) and b) the two rails are modeled as one. In model c) symmetry around the track center line is utilized so that only half the track is modeled. The track is coupled to a ground model, represented by a dynamic stiffness matrix. The dynamic stiffness matrix of the ground is derived from the Green's function for a horizontally layered visco-elastic half-space. Both the ground model and the FE model are expressed in a moving frame of reference, following the vehicle at a given speed v. The models a)–c) are shown schematically in Figure 2.

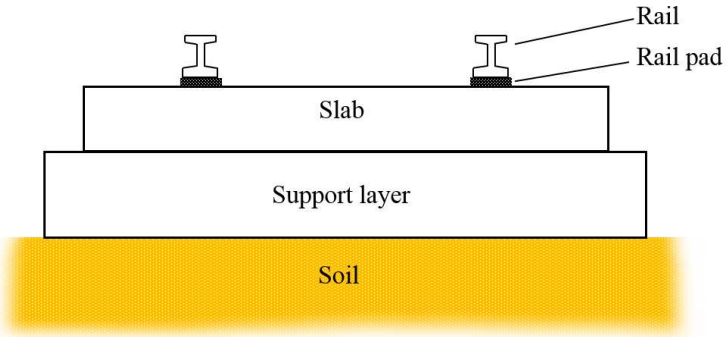

Figure 1: Section of slab track.

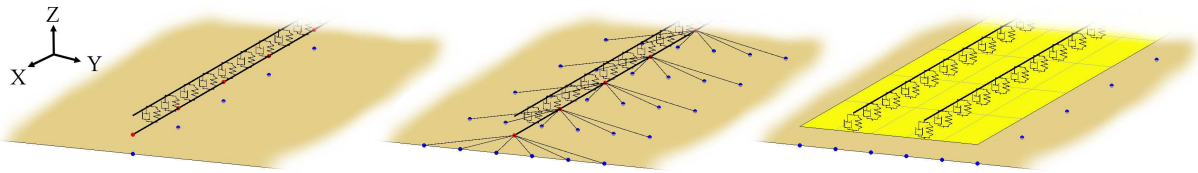

Figure 2: Finite element models of the slab track. From the left: Models a), b) and c). Blue points represent soil nodes at the slab–soil interface.

The soil model is described in Section 2.2. In Section 2.3 the governing equations for the beam, plate and interface finite elements are derived. The coupling between the finite elements and the soil is described in Section 2.4.

2.2 Soil model

The ground is assumed to be composed of horizontal visco-elastic layers. Neglecting body forces, the Navier equations for a single soil layer can be written as

$$(\lambda+\mu)\frac{\partial^2 u_j}{\partial x_i \partial x_j}+\mu\frac{\partial^2 u_i}{\partial x_j \partial x_j}=\rho\frac{\partial^2 u_i}{\partial t^2} \tag{1}$$

where $u_i = u_i(x_1, x_2, x_3, t)$ is the displacement in direction *i*. λ and μ are the Lame' parameters. Introducing a coordinate transformation as

$$(\tilde{x}_1, \tilde{x}_2, \tilde{x}_3) = (x_1 - vt, x_2, x_3), \tag{2}$$

where $\tilde{x}_1, \tilde{x}_2, \tilde{x}_3$ denotes the coordinates in the moving frame of reference, and v is the vehicle speed, transforms the Navier equations to

$$(\lambda+\mu)\frac{\partial^2 \tilde{u}_j}{\partial \tilde{x}_i \partial \tilde{x}_j}+\mu\frac{\partial^2 \tilde{u}_i}{\partial \tilde{x}_j \partial \tilde{x}_j}=\rho\Big(\frac{\partial^2 \tilde{u}_i}{\partial t^2}-2v\frac{\partial^2 \tilde{u}_i}{\partial t \partial \tilde{x}_1}+v^2\frac{\partial^2 \tilde{u}_i}{\partial^2 \tilde{x}_1}\Big), \tag{3}$$

where $\tilde{u}_i = \tilde{u}_i(\tilde{x}, \tilde{y}, \tilde{z}, t)$ is the displacement in the moving frame of reference [9].

Fourier transforming the Navier equations with respect to the horizontal coordinates and time, $(\tilde{x}_1, \tilde{x}_2, t)$, yields the Navier equations in frequency–wavenumber domain as

$$(\lambda+\mu)\tilde{\Delta} i\tilde{k}_1+\mu(\frac{d^2}{d\tilde{x}_3^2}-\tilde{k}_1^2-\tilde{k}_2^2)\tilde{U}_1=-\rho\tilde{\omega}^2\tilde{U}_1 \tag{4a}$$

$$(\lambda+\mu)\tilde{\Delta} i\tilde{k}_2+\mu(\frac{d^2}{d\tilde{x}_3^2}-\tilde{k}_1^2-\tilde{k}_2^2)\tilde{U}_2=-\rho\tilde{\omega}^2\tilde{U}_2 \tag{4b}$$

$$(\lambda+\mu)\frac{d\tilde{\Delta}}{d\tilde{x}_3}+\mu(\frac{d^2}{d\tilde{x}_3^2}-\tilde{k}_1^2-\tilde{k}_2^2)\tilde{U}_3=-\rho\tilde{\omega}^2\tilde{U}_3 \tag{4c}$$

where $\tilde{\Delta} = \tilde{\Delta}(\tilde{k}_1, \tilde{k}_2, \tilde{x}_3, \omega)$ is the Fourier transform, with respect to the horizontal coordinates and time, of the dilation $\Delta(\tilde{x}_1, \tilde{x}_2, \tilde{x}_3, t)$. The vibration frequency of a material point is $\tilde{\omega} = \omega - \tilde{k}_1 v$ and ω is the frequency of the moving load. The horizontal wavenumbers in the direction of $\tilde{x}_1$ and $\tilde{x}_2$ are $\tilde{k}_1$ and $\tilde{k}_2$, respecitvely.

As showed by Sheng [5, 6], the solution to Eq. 4 for an individual layer can be found analytically, and due to continuity of displacements and tractions over interfaces between layers, several layers can be assembled using the Thomson [10] and Haskell [11] layer transfer matrix approach, forming a relationship between the displacement and stresses at the top of the stratum and at the bottom of the stratum. With known boundary conditions at the lowest interface, a relationship between the traction and the displacement at the surface can be obtained as

$$\hat{\mathbf{u}} = \hat{\mathbf{G}}\,\hat{\mathbf{p}}, \tag{5}$$

where $\hat{\mathbf{u}} = \hat{\mathbf{u}}(\tilde{k}_1, \tilde{k}_2, \omega)$ and $\hat{\mathbf{p}} = \hat{\mathbf{p}}(\tilde{k}_1, \tilde{k}_2, \omega)$ are vectors containing the displacements and tractions respectively on the soil surface, $\hat{\mathbf{G}} = \hat{\mathbf{G}}(\tilde{k}_1, \tilde{k}_2, \omega)$ is the Green's function tensor, $\tilde{k}_1$ and $\tilde{k}_2$ are the horizontal wavenumbers. For certain frequencies and stratifications, the original Thomson and Haskell method suffers from loss-of-precision. To avoid these problems in the present work, the different soil layers are assembled in an orthonormalization procedure as proposed by Wang [12].

Equation 5 is evaluated for a set of discrete values of $\tilde{k}_1$ and $\tilde{k}_2$, and the displacement vector $\tilde{\mathbf{u}}(\tilde{x}_1, \tilde{x}_2, \omega)$ is obtained in Cartesian space through a double inverse Fourier transform of $\hat{\mathbf{u}}(\tilde{k}_1, \tilde{k}_2, \omega)$.

The procedure described above is used for calculating the response on the soil surface, due to a unit load with a rectangular spatial distribution, the size of which is determined by the element size in the connecting superstructure. From this single load case, a dynamic flexibility matrix $\mathbf{F}_g(\omega, v)$ is established for a set of DoFs where the superstructure interacts with the soil surface. These DoFs will be referred to as soil–structure interaction (SSI) DoFs. $\mathbf{F}_g$ is formed, column by column, by interpolating from $\tilde{\mathbf{u}}$. The flexibility matrix is then inverted to form the dynamic stiffness matrix of the soil, $\mathbf{D}_g(\omega, v) = \mathbf{F}_g^{-1}(\omega, v)$, which gives a relation between the steady-state displacements $\tilde{\mathbf{u}}_g$ and forces $\tilde{\mathbf{f}}_g$ for the SSI DoFs, at a certain load circular frequency ω and velocity v, as

$$\mathbf{D}_g\, \tilde{\mathbf{u}}_g = \tilde{\mathbf{f}}_g. \tag{6}$$

2.3 Finite element model of railway structure

The coordinate transformation used for expressing the governing FE equations in a moving frame of reference introduces convective terms in the damping and stiffness matrices. In Sections 2.3.1–2.3.3 below, the FE equations are derived for the beams, plates and visco-elastic interface elements, respectively.

2.3.1 Beam elements

The equilibrium equation for a Bernoulli-Euler beam reads

$$\frac{\partial^2 M}{\partial x^2} + q - m_b \frac{\partial^2 w}{\partial t^2} = 0, \tag{7}$$

where $M = M(x,t)$ is the bending moment. $q(x,t)$ is a loading force per unit length. m_b is the mass per unit length of the beam. $w = w(x,t)$ is the deflection. With the coordinate transformation described by Eq. 2, Eq. 7 can be written as

$$\frac{\partial^2 \tilde{M}}{\partial \tilde{x}^2} + \tilde{q} - m_b\left(\frac{\partial^2 \tilde{w}}{\partial t^2} - 2v\frac{\partial^2 \tilde{w}}{\partial \tilde{x}\partial t} + v^2\frac{\partial^2 \tilde{w}}{\partial \tilde{x}^2}\right) = 0, \tag{8}$$

where $\tilde{\cdot}$ denotes that a variable is expressed in the moving frame of reference. The weak form is obtained by multiplying Eq. 8 by an arbitrary weight function $g = g(\tilde{x})$ and integrating it over the region. It can be shown that the resulting weak form for the Bernoulli-Euler beam in a moving frame of reference is

$$\int_a^b \tfrac{\partial^2 g}{\partial \tilde{x}^2}\tilde{M}\,dx - [\tfrac{\partial g}{\partial \tilde{x}}\tilde{M}]_a^b + [g\tilde{V}]_a^b + \int_a^b g\tilde{q}\,dx - m_b\int_a^b g(\tfrac{\partial^2 \tilde{w}}{\partial t^2} - 2v\tfrac{\partial^2 \tilde{w}}{\partial \tilde{x}\partial t} + v^2\tfrac{\partial^2 \tilde{w}}{\partial \tilde{x}^2})\,dx = 0. \tag{9}$$

With the kinematic and constitutive assumptions for a Bernoulli-Euler beam, $\tilde{M}$ can be written as

$$\tilde{M} = -EI\frac{\partial^2 \tilde{w}}{\partial \tilde{x}^2}, \tag{10}$$

where EI is the bending stiffness. To obtain the FE formulation, the deflection $\tilde{w}(\tilde{x}, t)$ is approximated using the element nodal values $\mathbf{a}(t)$ and the shape functions $\mathbf{N}(\tilde{x})$, as $\tilde{w} = \mathbf{N}\mathbf{a}$.

Adopting the Galerking method, the mass, damping and stiffness matrices, as well as the load and boundary vectors, are identified as

$$\mathbf{K} = EI \int_a^b \Big(\frac{d^2\mathbf{N}(\tilde{x})}{d\tilde{x}^2}\Big)^T \frac{d^2\mathbf{N}(\tilde{x})}{d\tilde{x}^2}\, dx + m_b\, v^2 \int_a^b \mathbf{N}^T \frac{d^2\mathbf{N}}{d\tilde{x}^2}\, dx, \tag{11}$$

$$\mathbf{C} = -2m_b v \int_a^b \mathbf{N}^T \frac{d\mathbf{N}}{d\tilde{x}}\, dx, \tag{12}$$

$$\mathbf{M} = m_b \int_a^b \mathbf{N}^T\mathbf{N}\, dx, \tag{13}$$

$$\mathbf{f}_l = \int_a^b \mathbf{N}^T \tilde{q}\, dx, \tag{14}$$

$$\mathbf{f}_b = [\mathbf{N}^T\tilde{V}]_a^b - [\frac{\partial \mathbf{N}^T}{\partial \tilde{x}}\tilde{M}]_a^b. \tag{15}$$

A 2-node beam element with two DoFs per node (vertical displacement and one rotation), based on the above formulation, is implemented and used in the present work. Similar derivations for the convective Bernoulli-Euler beams can be found in e.g. [13, 14].

2.3.2 Plate elements

The equilibrium equation for a Kirchhoff plate reads, see e.g. [15],

$$\frac{\partial^2 M_{xx}}{\partial x^2} + 2\frac{\partial^2 M_{xy}}{\partial x \partial y} + \frac{\partial^2 M_{yy}}{\partial y^2} + q - \rho h \frac{\partial^2 w}{\partial t^2} = 0, \tag{16}$$

where $M_{xx} = M_{xx}(x, y, t)$, $M_{yy} = M_{yy}(x, y, t)$ and $M_{xy} = M_{xy}(x, y, t)$ are the bending moments in the x- and y-directions. $q(x, y, t)$ is a loading force per unit area. h and ρ is the plate thickness and the mass density respectively. $w = w(x, y, t)$ is the deflection of the mid-section. With the coordinate transformation described by Eq. 2, Eq. 16 can be written as

$$\frac{\partial^2 \tilde{M}_{xx}}{\partial \tilde{x}^2} + 2\frac{\partial^2 \tilde{M}_{xy}}{\partial \tilde{x} \partial \tilde{y}} + \frac{\partial^2 \tilde{M}_{yy}}{\partial \tilde{y}^2} + \tilde{q} - \rho h(\frac{\partial^2 \tilde{w}}{\partial t^2} - 2v\frac{\partial^2 \tilde{w}}{\partial \tilde{x}\partial t} + v^2\frac{\partial^2 \tilde{w}}{\partial \tilde{x}^2}) = 0. \tag{17}$$

The weak form is obtained by multiplying Eq. 17 by an arbitrary weight function $g = g(\tilde{x}, \tilde{y})$ and integrating it over the region. It can be shown that the resulting weak form for the Kirchhoff plate in a moving frame of reference is

$$\begin{aligned} &\textstyle\int_A (\tilde{\nabla} g)^T \tilde{\mathbf{M}}\, dA - \oint_{\mathscr{L}} \frac{dg}{dn}\tilde{M}_{nn}\, d\mathscr{L} + \oint_{\mathscr{L}} g(\tilde{V}_{nz} + \frac{d\tilde{M}_{nm}}{dm})\, d\mathscr{L} + \int_A g\tilde{q}\, dA \\ &\textstyle -\rho h \int_A (g\frac{\partial^2 \tilde{w}}{\partial t^2} - 2vg\frac{\partial^2 \tilde{w}}{\partial \tilde{x}\partial t} + v^2 g\frac{\partial^2 \tilde{w}}{\partial \tilde{x}^2})\, dA = 0, \end{aligned} \tag{18}$$

where the matrix differential operator $\tilde{\nabla}$ is defined as

$$\tilde{\nabla} = \begin{bmatrix} \frac{\partial^2}{d\tilde{x}^2} & \frac{\partial^2}{d\tilde{y}^2} & 2\frac{\partial^2}{d\tilde{x}d\tilde{y}} \end{bmatrix}^T, \tag{19}$$

and the moment vector $\tilde{\mathbf{M}}$ as

$$\tilde{\mathbf{M}} = \tilde{\mathbf{M}}(\tilde{x}, \tilde{y}, t) = \begin{bmatrix} \tilde{M}_{xx}(x, y, t) & \tilde{M}_{yy}(x, y, t) & \tilde{M}_{xy}(x, y, t) \end{bmatrix}^T. \tag{20}$$

The constitutive equation for the cross-section of a Kirchhoff plate can be written as $\tilde{\mathbf{M}} = -(h^3/12)\mathbf{D}\tilde{\nabla}\tilde{w}$ where $\mathbf{D}$ is the plane stress constitutive matrix for isotropic elasticity. To obtain the FE formulation, the deflection $\tilde{w}(\tilde{x},\tilde{y},t)$ is approximated using the element nodal values $\mathbf{a}(t)$ and the shape functions $\mathbf{N}(\tilde{x},\tilde{y})$, as $\tilde{w} = \mathbf{N}\mathbf{a}$.

Adopting the Galerking method, the mass, damping and stiffness matrices, as well as the load and boundary vectors, are identified as

$$\mathbf{K} = \frac{h^3}{12}\int_A (\tilde{\nabla}\mathbf{N})^T\mathbf{D}(\tilde{\nabla}\mathbf{N})\,dA \;+\rho h v^2\int_A \mathbf{N}^T\frac{\partial^2\mathbf{N}}{\partial\tilde{x}^2}\,dA\,, \tag{21}$$

$$\mathbf{C} = -2\rho h v\int_A \mathbf{N}^T\frac{\partial\mathbf{N}}{\partial\tilde{x}}\,dA, \tag{22}$$

$$\mathbf{M} = \rho h\int_A \mathbf{N}^T\mathbf{N}\,dA, \tag{23}$$

$$\mathbf{f}_l = \int_A \mathbf{N}^T\tilde{q}\,dA, \tag{24}$$

$$\mathbf{f}_b = \oint_{\mathscr{L}} \mathbf{N}^T(\tilde{V}_{nz} + \frac{d\tilde{M}_{nm}}{dm})\,d\mathscr{L} - \oint_{\mathscr{L}} (\nabla\mathbf{N})^T\mathbf{n}\tilde{M}_{nn}\,d\mathscr{L}. \tag{25}$$

A 4-node rectangular element with three DoFs per node (vertical displacement and two rotations), based on the above formulation, is implemented and used in the present work.

2.3.3 Visco-elastic interface elements

The rail pads are modeled by visco-elastic interface elements, representing continuous springs and dashpots. In the following derivation of the equations for the interface elements, an interface element is assumed to be located between two beam elements parallel with the x-axis. The loads on the upper and lower beams due to the visco-elastic interface are written

$$q_u(x,y,t) = -k(w_u - w_l) - c(\frac{\partial w_u}{\partial t} - \frac{\partial w_l}{\partial t}) = 0, \tag{26}$$

$$q_l(x,y,t) = -k(w_l - w_u) - c(\frac{\partial w_l}{\partial t} - \frac{\partial w_u}{\partial t}) = 0, \tag{27}$$

where $w_u = w_u(x,t)$ and $w_l = w_l(x,t)$ is the deflection in the upper and lower beam respectively, k is the spring stiffness and c is the damping coefficient. With the coordinate transformation described by Eq. 2,

$$\tilde{q}_u(\tilde{x},t) = -k(\tilde{w}_u - \tilde{w}_l) - c\Big\{(\frac{\partial\tilde{w}_u}{\partial t} - \frac{\partial\tilde{w}_l}{\partial t}) - v(\frac{\partial\tilde{w}_u}{\partial\tilde{x}} - \frac{\partial\tilde{w}_l}{\partial\tilde{x}})\Big\}, \tag{28}$$

$$\tilde{q}_l(\tilde{x},t) = -k(\tilde{w}_l - \tilde{w}_u) - c\Big\{(\frac{\partial\tilde{w}_l}{\partial t} - \frac{\partial\tilde{w}_u}{\partial t}) - v(\frac{\partial\tilde{w}_l}{\partial\tilde{x}} - \frac{\partial\tilde{w}_u}{\partial\tilde{x}})\Big\}. \tag{29}$$

The displacements of the upper and lower beam, w_u and w_l, are approximated using the shape functions $\mathbf{N}_u$ and $\mathbf{N}_l$ and element nodal displacements $\mathbf{a}_u(t)$ and $\mathbf{a}_l(t)$ for the upper and lower beams, respectively. With Eq. 14 the load vectors for the respective beams can be written

$$\begin{aligned}&\mathbf{f}_{l_u} = \textstyle\int_a^b \mathbf{N}_u^T\tilde{q}_u\,dx = -k\Big\{\int_a^b \mathbf{N}_u^T\mathbf{N}_u\,dx\,\mathbf{a}_u - \int_a^b \mathbf{N}_u^T\mathbf{N}_l\,dx\,\mathbf{a}_l\Big\} - \\ &c\Big\{\int_a^b \mathbf{N}_u^T\mathbf{N}_u\,dx\,\dot{\mathbf{a}}_u + \int_a^b \mathbf{N}_u^T\mathbf{N}_l\,dx\,\dot{\mathbf{a}}_l\Big\} + c\,v\,\Big\{\int_a^b \mathbf{N}_u^T\tfrac{\partial\mathbf{N}_u}{\partial\tilde{x}}\,dx\,\mathbf{a}_u - \int_a^b \mathbf{N}_u^T\tfrac{\partial\mathbf{N}_l}{\partial\tilde{x}}\,dx\,\mathbf{a}_l\Big\},\end{aligned} \tag{30}$$

$$\begin{aligned}&\mathbf{f}_{l_l} = \int_a^b \mathbf{N}_l^T \tilde{q}_l \, dx = -k\Big\{ \int_a^b \mathbf{N}_l^T \mathbf{N}_l \, dx \, \mathbf{a}_l - \int_a^b \mathbf{N}_l^T \mathbf{N}_u \, dx \, \mathbf{a}_u \Big\} - \\ &c\Big\{ \int_a^b \mathbf{N}_l^T \mathbf{N}_l \, dx \, \dot{\mathbf{a}}_l + \int_a^b \mathbf{N}_l^T \mathbf{N}_u \, dx \, \dot{\mathbf{a}}_u \Big\} + c\,v \Big\{ \int_a^b \mathbf{N}_l^T \tfrac{\partial \mathbf{N}_l}{\partial \tilde{x}} \, dx \, \mathbf{a}_l - \int_a^b \mathbf{N}_l^T \tfrac{\partial \mathbf{N}_u}{\partial \tilde{x}} \, dx \, \mathbf{a}_u \Big\}.\end{aligned} \tag{31}$$

With the shape function vectors $\tilde{\mathbf{N}}_u$ and $\tilde{\mathbf{N}}_l$ and the displacement vector $\mathbf{a}$ defined as

$$\begin{aligned}&\tilde{\mathbf{N}}_u(\tilde{x},\tilde{y}) = \begin{bmatrix}\mathbf{N}_u & 0\mathbf{N}_l\end{bmatrix}, \tilde{\mathbf{N}}_l(\tilde{x},\tilde{y}) = \begin{bmatrix}0\mathbf{N}_u & \mathbf{N}_l\end{bmatrix} \\ &\tilde{\mathbf{f}}_{l_u}(t) = \begin{bmatrix}\mathbf{f}_{l_u} & 0\mathbf{f}_{l_l}\end{bmatrix}, \tilde{\mathbf{f}}_{l_l}(t) = \begin{bmatrix}0\mathbf{f}_{l_u} & \mathbf{f}_{l_l}\end{bmatrix}, \mathbf{f}_L(t) = \begin{bmatrix}\mathbf{f}_{l_u} & \mathbf{f}_{l_l}\end{bmatrix}^T \\ &\tilde{\mathbf{a}}_u(t) = \begin{bmatrix}\mathbf{a}_u & 0\mathbf{a}_l\end{bmatrix}, \tilde{\mathbf{a}}_l(t) = \begin{bmatrix}0\mathbf{a}_u & \mathbf{a}_l\end{bmatrix}, \mathbf{a}(t) = \begin{bmatrix}\mathbf{a}_u & \mathbf{a}_l\end{bmatrix}^T\end{aligned} \tag{32}$$

it is possible to write the load vector as

$$\begin{aligned}&\mathbf{f}_L(t) = \tilde{\mathbf{f}}_{l_u}(t) + \tilde{\mathbf{f}}_{l_l}(t) = \\ &-k\Big\{ \int_a^b \tilde{\mathbf{N}}_u^T \tilde{\mathbf{N}}_u \, dx + \int_a^b \tilde{\mathbf{N}}_l^T \tilde{\mathbf{N}}_l \, dx - \int_a^b \tilde{\mathbf{N}}_u^T \tilde{\mathbf{N}}_l \, dx - \int_a^b \tilde{\mathbf{N}}_l^T \tilde{\mathbf{N}}_u \, dx \Big\} \mathbf{a} \\ &-c\Big\{ \int_a^b \tilde{\mathbf{N}}_u^T \tilde{\mathbf{N}}_u \, dx + \int_a^b \tilde{\mathbf{N}}_l^T \tilde{\mathbf{N}}_l \, dx + \int_a^b \tilde{\mathbf{N}}_u^T \tilde{\mathbf{N}}_l \, dx + \int_a^b \tilde{\mathbf{N}}_l^T \tilde{\mathbf{N}}_u \, dx \Big\} \dot{\mathbf{a}} \\ &+c\,v \Big\{ \int_a^b \tilde{\mathbf{N}}_u^T \tfrac{\partial \tilde{\mathbf{N}}_u}{\partial \tilde{x}} \, dx + \int_a^b \tilde{\mathbf{N}}_l^T \tfrac{\partial \tilde{\mathbf{N}}_l}{\partial \tilde{x}} \, dx - \int_a^b \tilde{\mathbf{N}}_u^T \tfrac{\partial \tilde{\mathbf{N}}_l}{\partial \tilde{x}} \, dx - \int_a^b \tilde{\mathbf{N}}_l^T \tfrac{\partial \tilde{\mathbf{N}}_u}{\partial \tilde{x}} \, dx \Big\} \mathbf{a}.\end{aligned} \tag{33}$$

The vector $\mathbf{f}_L(t)$ collects the forces on the upper and lower beam, caused by the interface element. The forces on the interface element are therefore $\mathbf{f}_i(t) = -\mathbf{f}_L(t)$, and the stiffness and damping matrices of the interface element can be identified from Eq. 33 as

$$\begin{aligned}\mathbf{K} = &k\Big\{ \int_a^b \tilde{\mathbf{N}}_u^T \tilde{\mathbf{N}}_u \, dx + \int_a^b \tilde{\mathbf{N}}_l^T \tilde{\mathbf{N}}_l \, dx - \int_a^b \tilde{\mathbf{N}}_u^T \tilde{\mathbf{N}}_l \, dx - \int_a^b \tilde{\mathbf{N}}_l^T \tilde{\mathbf{N}}_u \, dx \Big\} \\ &-cv\Big\{ \int_a^b \tilde{\mathbf{N}}_u^T \tfrac{\partial \tilde{\mathbf{N}}_u}{\partial \tilde{x}} \, dx + \int_a^b \tilde{\mathbf{N}}_l^T \tfrac{\partial \tilde{\mathbf{N}}_l}{\partial \tilde{x}} \, dx - \int_a^b \tilde{\mathbf{N}}_u^T \tfrac{\partial \tilde{\mathbf{N}}_l}{\partial \tilde{x}} \, dx - \int_a^b \tilde{\mathbf{N}}_l^T \tfrac{\partial \tilde{\mathbf{N}}_u}{\partial \tilde{x}} \, dx \Big\},\end{aligned} \tag{34}$$

$$\mathbf{C} = c\Big\{ \int_a^b \tilde{\mathbf{N}}_u^T \tilde{\mathbf{N}}_u \, dx + \int_a^b \tilde{\mathbf{N}}_l^T \tilde{\mathbf{N}}_l \, dx - \int_a^b \tilde{\mathbf{N}}_u^T \tilde{\mathbf{N}}_l \, dx - \int_a^b \tilde{\mathbf{N}}_l^T \tilde{\mathbf{N}}_u \, dx \Big\}. \tag{35}$$

The above expressions are also valid for an interface element between a beam element overlying a plate element in the xy-plane, such as in model c), with the shape functions for the plate evaluated at the y-coordinate of the beam.

2.4 Coupling to soil

Assuming steady-state conditions, the governing equation for the railway track structure can be written as

$$(-\omega^2 \mathbf{M}_r + i\omega \mathbf{C}_r + \mathbf{K}_r)\tilde{\mathbf{u}}_r = \tilde{\mathbf{f}}_r, \tag{36}$$

or

$$\mathbf{D}_r \tilde{\mathbf{u}}_r = \tilde{\mathbf{f}}_r, \tag{37}$$

where $\mathbf{M}_r$, $\mathbf{C}_r$ and $\mathbf{K}_r$ is the mass, damping and stiffness matrix respectively. $\mathbf{D}_r = (-\omega^2 \mathbf{M}_r + i\omega \mathbf{C}_r + \mathbf{K}_r)$ is the dynamic stiffness matrix, and $\tilde{\mathbf{u}}_r$ and $\tilde{\mathbf{f}}_r$ is the displacement and force vector for the track structure, respectively.

The track and soil is coupled in a standard FE manner. Only the vertical DoFs of the track structure and the soil are coupled. A global system of equations for the soil and the railway structure is formed by combining Eqs. 6 and 37, yielding

$$\mathbf{D}_t \tilde{\mathbf{u}}_r = \tilde{\mathbf{f}}_r, \tag{38}$$

where $\mathbf{D}_t$ represents the total dynamic stiffness matrix for the track structure and soil.

Once the track displacements $\tilde{\mathbf{u}}_r$, and thereby also the displacement in the soil DoFs $\tilde{\mathbf{u}}_g$, have been obtained by solving Eq. 38, the corresponding forces on the soil surface, $\tilde{\mathbf{f}}_g$ are calculated by Eq. 6. A second flexibility matrix $\mathbf{F}_{gf}(\omega, v)$ is established, in the same manner as $\mathbf{F}_g(\omega, v)$ as described in Section 2.2, expressing the displacements in free-field due to forces on the soil–structure interface. The free-field displacements, $\tilde{\mathbf{u}}_f$, are then calculated as

$$\tilde{\mathbf{u}}_f = \mathbf{F}_{gf}\tilde{\mathbf{f}}_g. \tag{39}$$

3 MODEL COMPARISON

To compare the effect of the three different modeling strategies for the track on the free-field response, each model is used for evaluating the response to a moving unit harmonic point load acting on the rail. The track properties are given in Table 1. The track rests on a 14 m deep layer of clay overlaying a half-space, with properties according to Table 2. An element length of 0.3 m is used, meaning that 12 elements are used in the transverse direction of the slab in model c). For model b) the slab is rigidly connected to 13 soil DoFs in the transverse direction. In all three models, the number of elements in the track direction is 500, yielding a total track length of 150 meters, which has been found to be sufficient to avoid problems with reflecting waves at the boundaries of the FE model in the studied case. The track gauge is 1.435 m.

Figure 3 shows the wavefield and the track deformation due to a harmonic point load with frequency $f = 50$ Hz traveling at $v = 60$ m/s, as obtained with the three different models. The difference in the slab deformation in the transverse direction due to the different modeling approaches is clearly visible. The displacements shown in Figure 3 are in the moving frame of reference, following the load at speed $v = 60$ m/s. In this frame of reference, the displacements are in steady state with the loading frequency $f = 50$ Hz. For a fixed point in the free-field, however, the response is transient and contains a broad band of frequencies due to the Doppler effect. A higher load speed results in a broader frequency content of the response in a fixed point. This can be seen in Figure 4 that shows the displacement spectrum for a fixed point 10 m and 25 m from the track, due to a harmonic 50 Hz load travelling at $v = 30$ m/s and $v = 60$ m/s. All three models yield similar results, however, the response obtained with model c) using plate elements is slightly higher than obtained with the other two models, for this particular load frequency.

To compare the three models for a range of excitation frequencies, a moving rms-value of the vibration velocity in a fixed point is calculated for each excitation frequency f, as

$$v_{rms}(t) = \sqrt{\frac{1}{T}\int_t^{t+T} \dot{u}(t)^2 dt}, \tag{40}$$

where $\dot{u}(t)$ is the velocity time history response for a fixed point. T is the window length and is here set to $T = 1$ s. In Figure 5 the maximum of $v_{rms}(t)$ is shown for each excitation frequency for the three models, for a fixed point located 10 and 25 m from the track respectively and the load speeds $v = 30$ and $v = 60$ m/s. For both load speeds, and both distances, the free-field response is very similar for all three models up to about $f = 50$ Hz. At higher frequencies, both models a) and b) underestimate the response. However, the underestimation with model b) is modest. For model a) the maximum underestimation is almost 10 dB at 70 Hz.

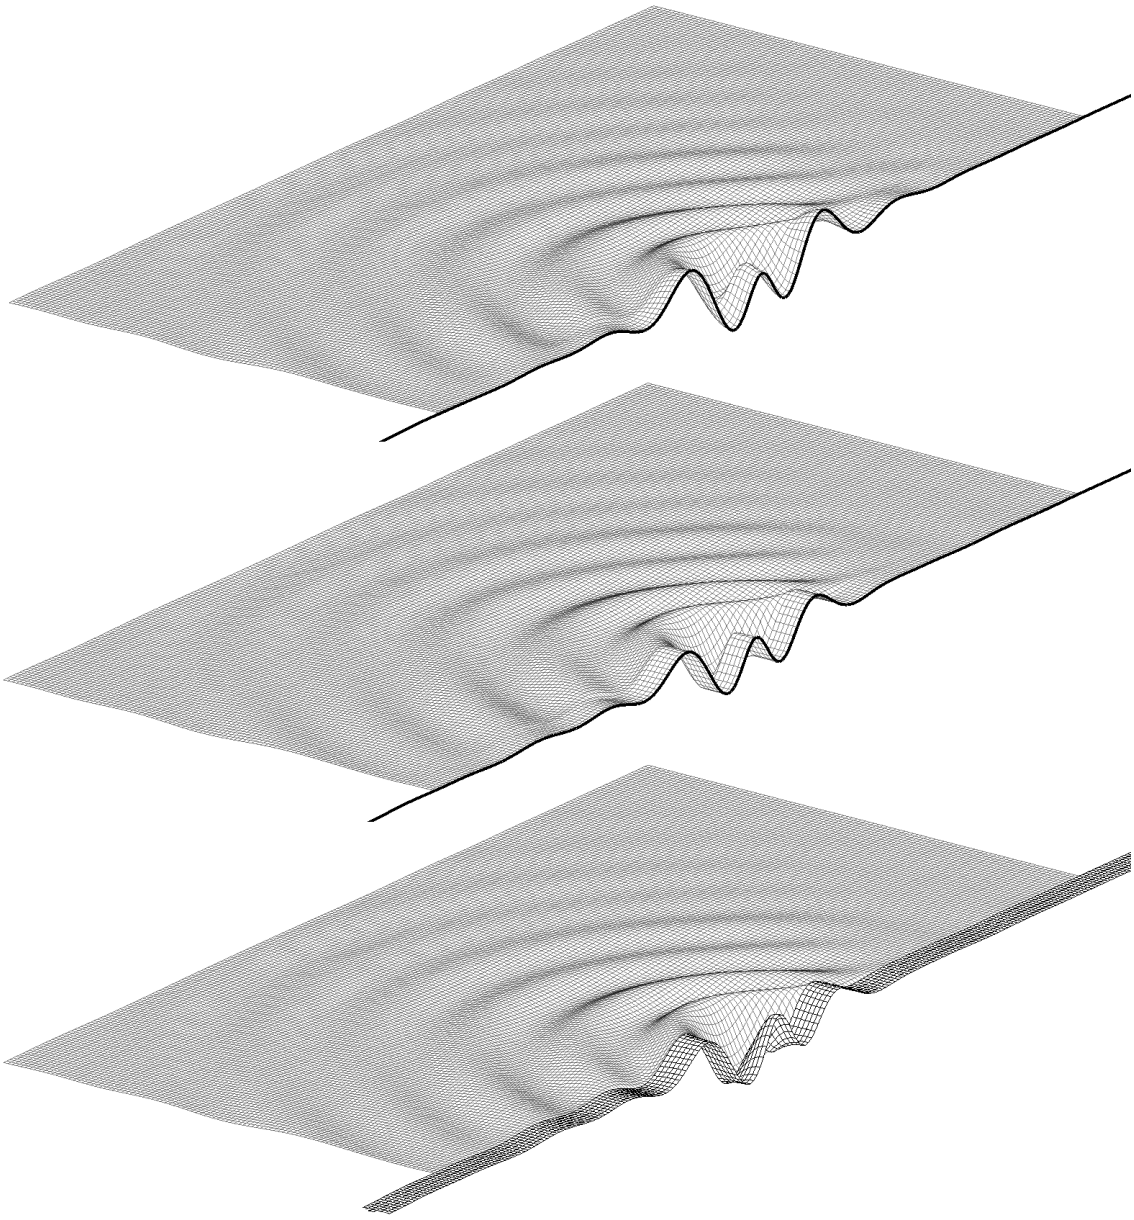

Figure 3: Soil and slab displacements in models a)–c), from top to bottom, when subjected to a harmonic load with frequency $f = 50$ Hz moving along the track at speed $v = 60$ m/s. The size of the displayed area is 60 m$\times$ 30 m.

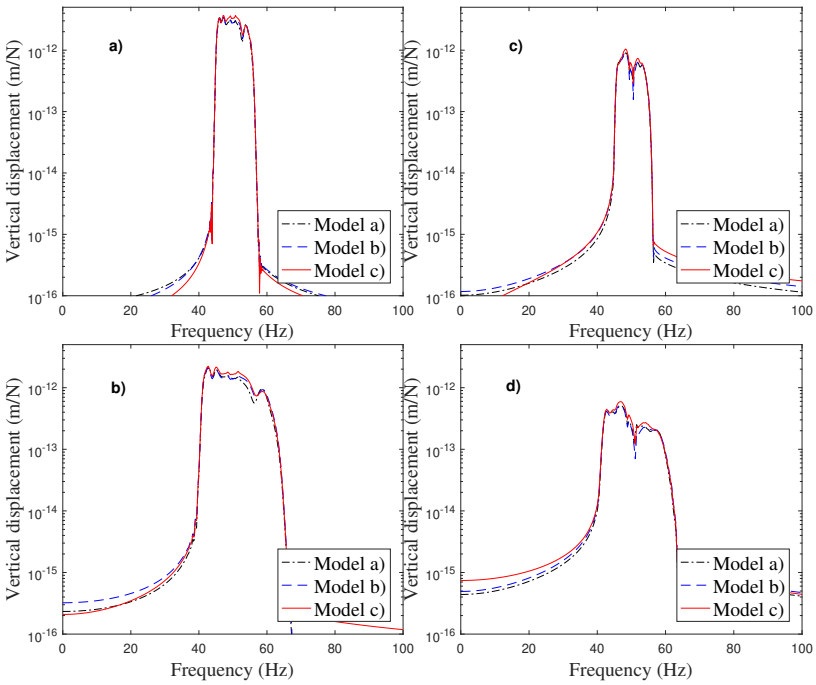

Figure 4: Response of a fixed point in the free-field due to a 50 Hz load traveling on the track. a) and b) show the results for a fixed point 10 meters from the track, with a load speed of $v = 30$ and $v = 60$ m/s, respectively. c) and d) are for a point 25 meters from the track.

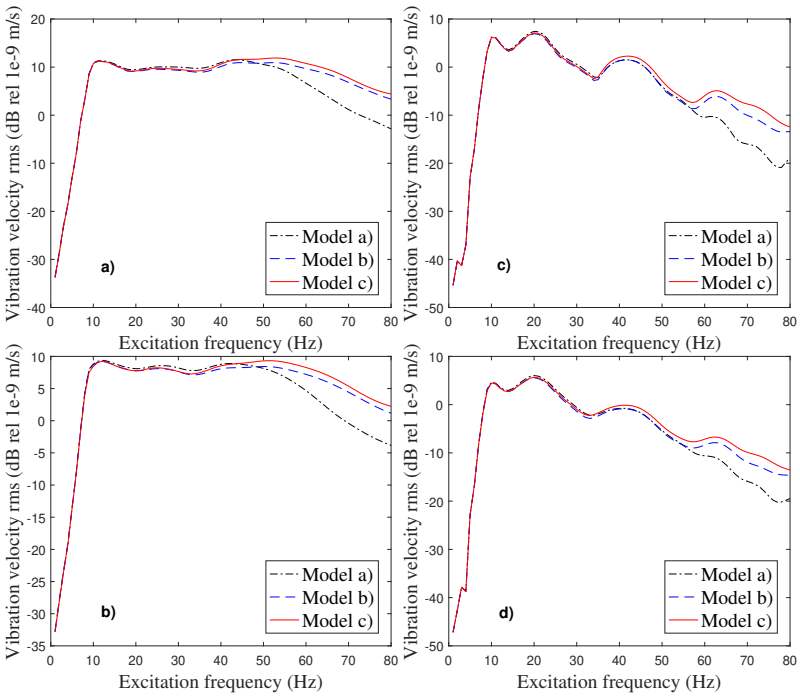

Figure 5: Velocity rms-value of a fixed point in the free-field due to a harmonic load traveling on the track. a) and b) show the results for a fixed point 10 meters from the track, with a load speed of $v = 30$ and $v = 60$ m/s, respectively. c) and d) are for a point 25 meters from the track.

	Parameter	Value
Rail	Mass (kg/m)	60
	Young's modulus (GPa)	210

4 CONCLUSIONS

In the paper a numerical prediction model for train-induced ground-vibration has been presented. The model is formulated in a frame of reference following the moving load, which offers some advantages over conventional FE models using a fixed frame of reference. Using a fixed frame of reference, the computational domain must be large for the moving load to stay within the model during the time of analysis. In the moving frame of reference following the load, on the other hand, the load stays at the same location in the model throughout the analysis, allowing a smaller model. Furthermore, frequency domain methods can be used for analyzing the moving load. A drawback of the model is that it is not suitable for analyzing load cases where the resulting wavelengths are very short, such as moving loads approaching the soil shear wave velocity. Short wavelengths, making the current approach inappropriate, may also result from non-moving loads, depending on the soil and track stiffness and the frequency of the load.

Three different models of a railway slab track have been established and compared. In the first two models, the railway track is modeled as a Bernoulli-Euler beam on a layered half-space, with different assumptions regarding the displacement and stress distribution at the track–soil interface. In the third model, the track slab is modeled using Kirchhoff plate elements, enabling a more general displacement and stress distribution in the track transverse direction to be resolved. It is shown that in the case studied here, the beam model where the track–soil interface is considered rigid over the width of the slab, only slightly underestimates the response, at higher frequencies. The beam model where a uniform traction is assumed at the track–soil interface, on the other hand, underestimates the response significantly at frequencies above 50 Hz.

Keywords: Textile composite structures, Wave propagation, Periodic Structure Theory, Experimental validation, B-scan.

Abstract. *In this article, an attempt is made toward the experimental validation of a numerical method allowing vibroacoustic and ultrasonic wave propagation analysis of complex woven composites. For this validation, plates with a complex woven architecture were manufactured using Resin Transfer Molding (RTM) process. These composites can be considered as periodic structures composed of unit cells repeated in two directions. The unit cells of these three different woven patterns are modelled realistically at a mesoscopic scale, using information from micrographic cross-sections and the mechanical properties of the fibres and matrix materials provided by the various manufacturers. The numerical method combining the mode-based Component Mode Synthesis (CMS) and the Wave Finite Element (WFEM) methods allows for computing the dispersion relations of the modelled samples. Experimentally, a few dispersion relations are extracted from the samples by the mean of B-scan. These experimental results are compared with the numerical results. It is shown that this methodology has a good accuracy for determining the dispersion relations of complex woven composites. It is efficient time wise and provides more information on the dispersion relations than experimental testing.*

1 INTRODUCTION

Textile composites are increasingly used in modern industry due to their excellent mechanical properties [1] and especially for aerospace applications thanks to a low weight. These composite structures considered as an infinite assembly of identical elements called unit cells. The wide application of these periodic structures have attracted a lot of research for more than a decade [2, 3, 4, 5, 6]. 3D woven composites in particular are getting more and more interest over 2D laminates as they provide higher resistance in out-of-plane loading while 2D laminates are easily subjected to delamination. Textile composites are prone to many modes of failures such as fiber breakages, cracks and delamination. In the process of Structural Health Monitoring (SHM) - which consists of performing Non Destructive Evaluation (NDE) [7] - the earliest possible detection of damage is important. At present, approximately 27% of an average aircraft's life cycle cost is spent on maintenance [8]. To avoid that, a technique finding increasing popularity for 'on-line' inspection is ultrasound guided waves spectroscopy [9]. As guided wave propagation in thin plates is dispersive, the velocity of wave propagation depends on the frequency and the dispersion relations need to be known. These guided waves techniques are very efficient in traditional isotropic or even orthotropic materials as their wave propagation characteristics have been thoroughly investigated [10]. However in strongly anisotropic composites, such as woven composites for example, these properties are not straightforward to obtain. This paper proposes and experimentally validates a methodology for obtaining these dispersion relations for 3D woven composites.

2 SAMPLES MANUFACTURING

A 3D woven fabric of complex architecture was used [11] to manufacture plaque samples by resin transfer molding (RTM) (see Fig1). This process was chosen because it allows to have smooth surfaces which is extremely important for the experimental measurements using a laser Doppler vibrometer.

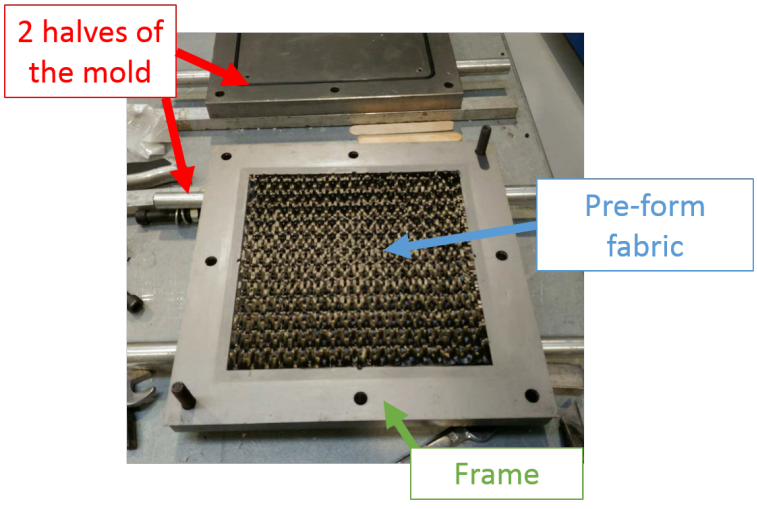

Figure 1: Photography showing the two halves of the mold, with the frame placed on on half and the pre-form fabric sheet fitted inside the frame

The plaques measure 250 x 250 x 2 mm. The fabric is an angle interlock weave. The fabric is made of carbon fibers while the matrix is made of epoxy resin. The dry preforms were given courtesy of Dr. Andreas Endruweit.

3 EXPERIMENTAL DETERMINATION OF THE DISPERSION RELATIONS

When performing a quantitative measurement of the dispersion relations in a thin structure , more than one mode can exist and propagate for any given frequency. That is why the two-dimensional fast Fourier transform (2D FFT) is used [12]. It allows for calculating the amplitude in the frequency-wavenumber domain from displacements or velocities amplitude in the space-temporal domain.

A broadband excitation signal (Fig.2 is transmitted to the studied structure by the mean of a glued piezoelectric transducer (PZT).

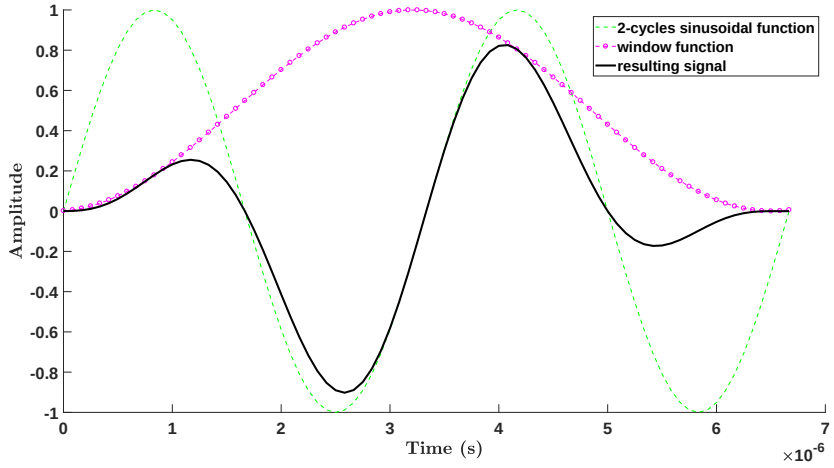

Figure 2: Broadband excitation signal, '- -' 2 cycles of a sinusoidal function mixed with a window function '-o-' gives the broadband signal '–'

Two cycles of a sinusoidal function are modulated by a window function.

The set-up (see Fig.3) is composed of a waveform generator that is used to generate the electrical waveform that will be transmitted to the piezoelectric transducer. The transducer is glued on the surface of the tested textile composite sample. Finally, the scanning laser Doppler vibrometer is programmed to measure the displacement at a set of discrete position on a straight line (B-scan). The B-scan is performed once in every direction of interest.

This output signal is transmitted to the oscilloscope for each discrete position along the defined line. A Fourier transform of the time history of the response at each discrete position is carried to compute the frequency spectrum for each position. A spacial Fourier transform is then applied to compute the amplitude-wavenumber-frequency information.

4 NUMERICAL METHOD

4.1 Microscale: Matrix and yarn mechanical properties

The mechanical properties of the fibers and matrix are provided by the supplier. A square arrangement of the fiber is assumed to calculate the mechanical properties of the yarn [13, 14, 15]. The homogenization from microscale (fibers & matrix) to mesoscale (yarn) gives us the following properties for the yarns (Tab.4.1)

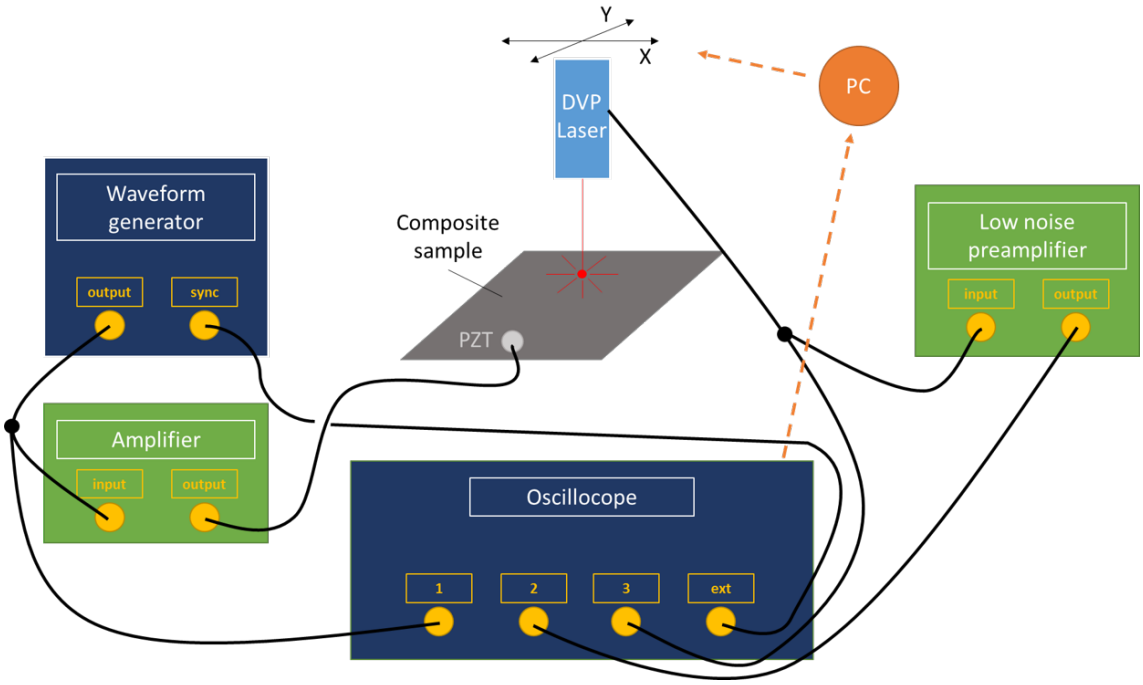

Figure 3: Experimental set-up for B-scan measurements

	Fibre	**Resin**	E_1	$E_{2,3}$	$G_{12,13}$	G_{23}	$\nu_{12,13}$	ν_{23}	**density**
Yarn - Mat1 V_f=0.41	TC33	IN2	116.3	7.40	2.87	2.31	0.27	0.37	1.450
	TC35	IN2	124.5	7.41	2.87	2.31	0.27	0.37	1.451

4.2 Mesoscale: Geometric modelling

The modelling of the textile is performed with TexGen which is a software developed by the Composites Research Group at the University of Nottingham [16, 17]. The geometric modeling is compared to micrographic cross sections of the actual composite (see Fig.2). This helps for an accurate modelling of the geometric shapes [18, 19].

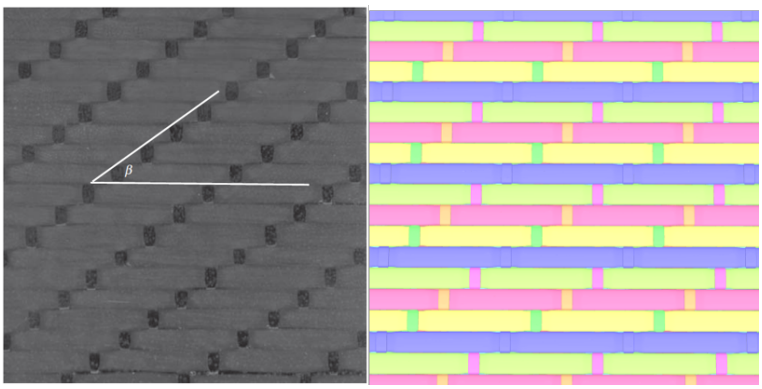

Figure 4: Top view of the material

The dispersion curves are calculated using the geometric model and the methodology presented in [20] that combines the WFEM and the CMS methods.

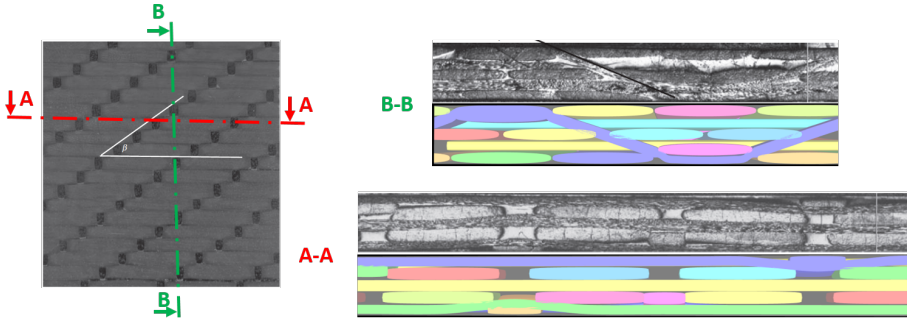

Figure 5: Cross sections of the material

4.3 WFE/CMS method

The nodal DOFs of the unit cell are partitioned in the following way: bottom, top, left, right, left-bottom corner, right-bottom corner, left-top corner, right-top corner and internal DOFs, which gives:
$\mathbf{q} = \left\{\mathbf{q_B^T} \quad \mathbf{q_T^T} \quad \mathbf{q_L^T} \quad \mathbf{q_R^T} \quad \mathbf{q_{LB}^T} \quad \mathbf{q_{RB}^T} \quad \mathbf{q_{LT}^T} \quad \mathbf{q_{RT}^T} \quad \mathbf{q_I^T}\right\}^T$. The equation of motion of the unit cell can be written as

$$\left[\mathbf{K} + \mathrm{i}\omega\mathbf{C} - \omega^2\mathbf{M}\right]\mathbf{q} = \mathbf{F} \tag{1}$$

In order to reduce the complexity of the structural dynamic model, a Component Mode Synthesis (CMS) method is applied. It is mostly used to reduce the use of CPU time and memory.
The key to this method is the reduction of the relative DOFs (internal nodes), whereas the boundary DOFs are kept as physical coordinates [21]. In the fixed interface CMS, a set of 'fixed boundary modes', also called component modes are selected among a subset of the local modes of the unit cell when the boundary DOFs are fixed and no force is acting on the internal nodes.
Once this reduction method has been applied, the periodic structure theory (PST) is employed. The PST states that when a free wave travels along a waveguide, the displacements between two opposite boundary sides of a cell differ only by a propagation factor. The unit cell needs however to be meshed in a similar way on its opposite boundaries, so that continuity in displacements and forces equilibrium is respected [22].
In our case the wave motion is in the Oxy plan, which gives

$$\begin{gathered}\mathbf{q_R} = \lambda_x\mathbf{q_L}; \qquad \mathbf{q_T} = \lambda_y\mathbf{q_B} \\ \mathbf{q_{RB}} = \lambda_x\mathbf{q_{LB}}; \quad \mathbf{q_{LT}} = \lambda_y\mathbf{q_{LB}}; \quad \mathbf{q_{RT}} = \lambda_x\lambda_y\mathbf{q_{LB}}\end{gathered} \tag{2}$$

λ_x and λ_y being respectively the propagation factors along the axis x and y.
The propagation factors are calculated using the following formula

$$\lambda_x = e^{-\mathrm{i}k_x\Delta}; \quad \lambda_y = e^{-\mathrm{i}k_y\Delta} \tag{3}$$

and the direction of propagation θ is computed using the following relations

$$k_x = kcos(\theta); \quad k_y = ksin(\theta) \tag{4}$$

Combining the CMS reduction method with the periodicity relation, allows us to reduce drastically the number of unknown in the equations and thus the calculation time.

5 RESULTS

A comparison is presented in Fig.6.

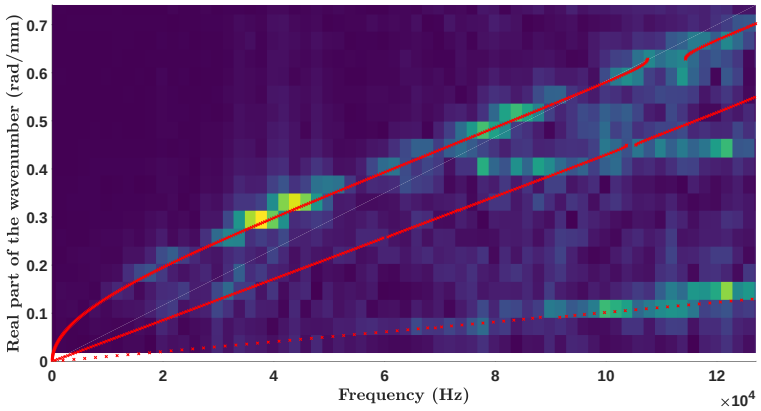

Figure 6: Dispersion curves of the material in the y-direction - background image results from the experimental B-scan - 'x' numerical results computed with the methodology presented in [20] - '+' numerical results computed with a classic WFE method and homogenised mechanical properties

A good agreement can be observed betweeen the numerical results and the experimental results. However the resolution of the experimental results doesn't allow to conclude wether the agreement is excellent or not. Also both numerical methods seem to give similar results.

6 CONCLUSIONS

- It is shown that this methodology has a good accuracy for determining the dispersion relations of complex woven composites.
- It is efficient time wise and provides more information on the dispersion relations than experimental testing.
- It is difficult to conclude whether the methodology provides more information than using a standard WFE method on a model with homogenized mechanical properties.

7 ACKNOWLEDGEMENT

- This work is funded by the INNOVATIVE doctoral programme. The INNOVATIVE programme is partially funded by the Marie Curie Initial Training Networks (ITN) action (project number 665468) and partially by the Institute for Aerospace Technology (IAT) at the University of Nottingham.
- We are grateful for access to the University of Nottingham High Performance Computing Facility.
- Special thanks go to the Composites Research Group members and especially to Louise Brown who gave us advices on TexGen, to Andreas Endruweit who gracefully provided us the dry fabrics and to the lab technicians Paul and Harry who helped us manufacture the composite samples.
- These experiments were conducted at the CEA List in France and we want to thank them for the help and opportunity provided on these.
