PREFACE

This volume contains the full-length papers presented in the 7th International Conference on Computational Methods in Structural Dynamics and Earthquake Engineering (COMPDYN 2019) that was held on June 24-26, 2019 in Crete, Greece.

COMPDYN 2019 is one of the 32 Thematic Conferences of the European Community on Computational Methods in Applied Sciences (ECCOMAS) to be held in 2019 and is also a Special Interest Conference of the International Association for Computational Mechanics (IACM). The purpose of this Conference series is to bring together the scientific communities of Computational Mechanics, Structural Dynamics and Earthquake Engineering, to act as the forum for exchanging ideas in topics of mutual interests and to enhance the links between research groups with complementary activities. We believe that the communities of Structural Dynamics and Earthquake Engineering will benefit from their exposure to advanced computational methods and software tools which can highly assist in tackling complex problems in dynamic and seismic analysis and design, while also giving the opportunity to the Computational Mechanics community to be exposed to very important engineering problems of great social interest. The COMPDYN 2019 Conference is supported by the National Technical University of Athens (NTUA), the European Association for Structural Dynamics (EASD), the European Association for Earthquake Engineering (EAEE), the Greek Association for Computational Mechanics (GRACM).

The editors of this volume would like to thank all authors for their contributions. Special thanks go to the colleagues who contributed to the organization of the Minisymposia and to the reviewers who, with their work, contributed to the scientific quality of this e-book.

ACKNOWLEDGEMENTS

The conference organizers acknowledge the support towards the organization of the "7th International Conference on Computational Methods in Structural Dynamics and Earthquake Engineering", to the following organizations:

- European Community on Computational Methods in Applied Sciences (ECCOMAS)
- European Association for Structural Dynamics (EASD)
- European Association for Earthquake Engineering (EAEE)
- Greek Association for Computational Mechanics (GRACM)
- Hellenic Society for Earthquake Engineering (HSEE)
- School of Civil Engineering, National University of Athens (NTUA)
- Hellenic Republic-Region of Crete
- Municipality of Heraklion

Plenary Speakers and Invited Session Organizers

We would also like to thank the Plenary and Semi-Plenary Speakers and the Minisymposia Organizers for their help in the setting up of a high standard Scientific Programme.

Plenary Speakers: Michel Bruneau, Álvaro Cunha, Michael Fardis, Charbel Farhat, Christian Soize, Alexander Vakakis

Semi-Plenary Speakers: Christoph Adam, Gian Paolo Cimellaro, Eleni Chatzi, Geert Degrande, Boris Jeremic, Shinobu Yoshimura

MS Organizers: Günther Achs, Christoph Adam, Hamid Ahmadi, António Arêde, Rui Carneiro Barros, Michael Beer, Amadeo Benavent-Climent, Manuel Braz-Cesar, Alessandro Cabboi, Silvia Caprili, Claudia Casapulla, Serena Cattari, Nicola Cavalagli, Liborio Cavaleri, Jianbin Chen, Dimitris Chronopoulos, Alice Cicirello, Gian Paolo Cimellaro, Francesco Clementi, Marco Corradi, Flavia De Luca, Carlo Del Gaudio, Ciro Del Vecchio, Pedro Delgado, Raimundo Delgado, Raffaele Di Laora, Marco Di Ludovico, Luigi Di Sarno, Fabio Di Trapani, Francisco Alejandro Diaz de la O, Marco Domaneschi, Stefanos Dritsos, Hossein Ebrahimian, Antonio Formisano, Michalis Fragiadakis, Linda Giresini, Jose Gonzalez, Alexander Idesman, Alper Ilki, Maria Iovino, Fatemeh Jalayer, Hector Jensen, Andreas Kappos, Jin-Gyun Kim, Radek Kolman, Davide Lavorato, Guido Magenes, Charilaos Maniatakis, George Manos, Gabriele Milani, Stergios Mitoulis, Naoto Mitsume, Fabrizio Mollaioli, Paolo Morandi, Lukas Moschen, George Mylonakis, Jiri Naprstek, Ehsan Noroozinejad, Camillo Nuti, Roger Ohayon, Georgios S. Abstract

This study focuses on the development of a real-time damage detection technology based on statistical pattern recognition methods to detect damages in a complex structure, such as a cable-stayed bridge. Further, the performance of the proposed method is evaluated experimentally. The real-time damage detection method is devised on a statistical pattern recognition technology from a damage data assessment section and a simulation based on a non-damage data generation section. The damage data assessment section applies the improved Mahalanobis distance theory from among the available statistical pattern recognition technologies. Further, the non-damage data generation section comprises logic based on the state-space equation. To verify the performance of the technology developed, a damage detection test was conducted on the model structure of the cable-stayed bridge. The experiment confirms that the real-time damage detection technology determines the location of damages in the cable-stayed bridge in real time.

Keywords: Statistical pattern recognition, Real-time damage assessment, Mahalanobis distance, State-space equation, Maintenance, Cable-stayed bridge

1 INTRODUCTION

Owing to the development of modern society, human beings now live in more densely populated spaces. Structures that are built recently consider service loads, but old structures are always exposed to loads that exceed the serviceability limit of the structure itself. In addition, the safety of structures is always threatened by typhoons and earthquakes whose intensity increases with global climate changes.

Researchers have perceived such threats to the safety of structures and studied diverse technologies for the inspection and assessment of structure safety. Such an assessment technology is called structural health monitoring (SHM). SHM is a technology that can determine damages or unsafe elements in structures by conducting a statistical analysis of the data measured from the structures and clarifies the current conditions of the structures [1,2]. The method of statistical analysis on the current conditions of the structures is divided primarily into supervised learning and unsupervised learning. Supervised learning is a high-level damage detection method that can assess the current conditions of the structures using both non-damage data and damage data. For such a damage assessment, it is essential to secure non-damage data and a large volume of data learning is required. Unsupervised learning that has improved the problems of supervised learning is a convenient method of assessing the current conditions of structures without learning a damaged structure; however, the level and degree of damage assessment [2] are limited. Recently, such a limit of unsupervised learning is overcome by applying the data mining technology that extracts new information hidden in data by analyzing the correlation between data [3,4]. The Mahalanobis distance (MD) theory is a diverse data mining technology that has been studied by many researchers; it uses a simple method of perceiving the data pattern and can analyze a large data volume [5,6]. However, the Mahalanobis distance theory presents drawbacks even though it is an unsupervised learning, as it requires non-damage data for setting a threshold and is a post-treatment method that analyzes data only after the occurrence of a damage.

The objective of this study is to overcome the limit of the statistical analysis method used for the existing SHM method and to develop a technology that enables a real-time damage assessment. A real-time damage assessment technology was developed by offering non-damage data required for supervised learning as a simulation based on the information of a structure and by using a complex learning method that adopted the Mahalanobis distance for unsupervised learning. To verify the developed real-time damage assessment method, damage detection tests were performed on a cable-stayed bridge. The result proved that the real-time assessment method developed for this study can approximately yield the location of damages in a cable-stayed bridge.

2 REAL-TIME DAMAGE ASSESSMENT TECHNOLOGY

2.1 Statistical Pattern Recognition Technology

The assessment of damages in structures using the Mahalanobis distance theory was proposed in 2007 by Nair and Kiremidijian, who applied a specific vector obtained using the Gaussian mixture model (GMM) to calculate the Mahalanobis distance; this assessment method was verified using the ACSE benchmark structure's interpreted data [5]. Heo et al. proposed an improved Mahalanobis distance theory to resolve issues with the existing theory and verified it by conducting damage detection tests on a cable-stayed bridge [7].

This study used the improved Mahalanobis distance theory for real-time damage assessment. Equation (1) represents the improved Mahalanobis distance (IMD) that offsets the de-

crease following a substantial variability between data; this was a shortcoming of the existing MD. that the improved method can reduce large variability in data by utilizing the differences in the data before and after damage occurrence.

$$IMD = \sqrt{(\Delta x - m)^T R^{-1} (\Delta x - m)} \tag{1}$$

In the equation, x is the measurement value obtained from a structure; m is the average value of x; R is the covariance matrix of the measured x value. Δx is the difference between x before damage and x' after damage.

2.2 Simulation to Obtain Non-Damage Data

The most general technique of assessing damage in a structure is to compare the responses between the damaged and undamaged structures. However, the majority of structures built before the development of a monitoring system do not contain information about their initial condition. In this study, a simulation logic was created based on the basic information of a structure to obtain non-detection data for real-time damage assessment and was included in the real-time damage detection system. The simulation logic for obtaining the non-damage data was established based on the motion equation. Information on the mass, hardness, and damping obtained from a detailed finite element (FE) modeling and interpretation of the target bridge that used NX Nastran were used as the basic information of the structure. To ensure reliability of the obtained information, the modal assurance criteria (MAC) was used to compare the response data obtained from a model test with the target bridge, and the data was interpreted through FE analysis.

$$MAC(A, X) = \frac{\left| \sum_{j=1}^{n} (\Phi_X)_j (\Phi_A)_j^* \right|^2}{\left(\sum_{j=1}^{n} (\Phi_X)_j (\Phi_X)_j^* \right) \left(\sum_{j=1}^{n} (\Phi_A)_j (\Phi_A)_j^* \right)} \tag{2}$$

Here, Φ_X and Φ_A are the mode shapes calculated and obtained from interpretation and experiment, respectively, and the MAC value approaches 1 as the two compared modes correspond more with each other. The result of the FE interpretation of the target bridge indicated an approximately 4% of maximum error when compared to the result of the model test. To resolve such a problem, model updating was performed. Table 1 and Fig. 1 below indicate the MAC results for which model updating was performed.

		FE Analysis Modes (Updating)		
		1st	2nd	3rd
Exp. Modes	1st	1	0.016348	0.010044
	2nd	0.016091	1	0.003991
	3rd	0.010122	0.003648	1

Table 1: FE Interpretation and MAC Value from Modal Test

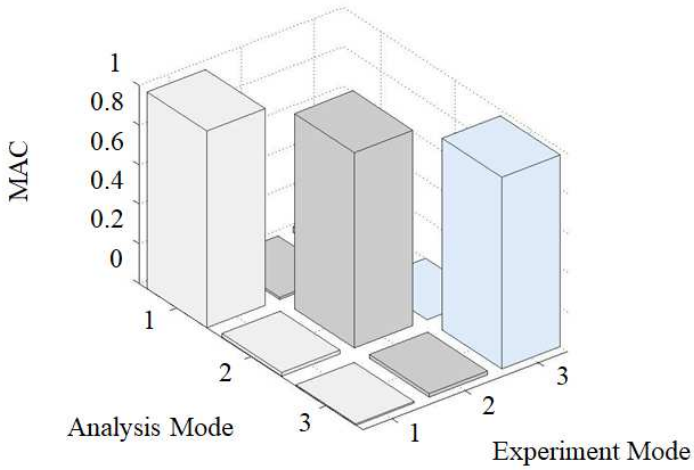

Figure 1: MAC Plot

2.3 Real-Time Damage Assessment Program

For the experimental verification of the developed real-time damage assessment technology, programming was performed using Matlab & Simulink, as shown in Fig. 2 below.

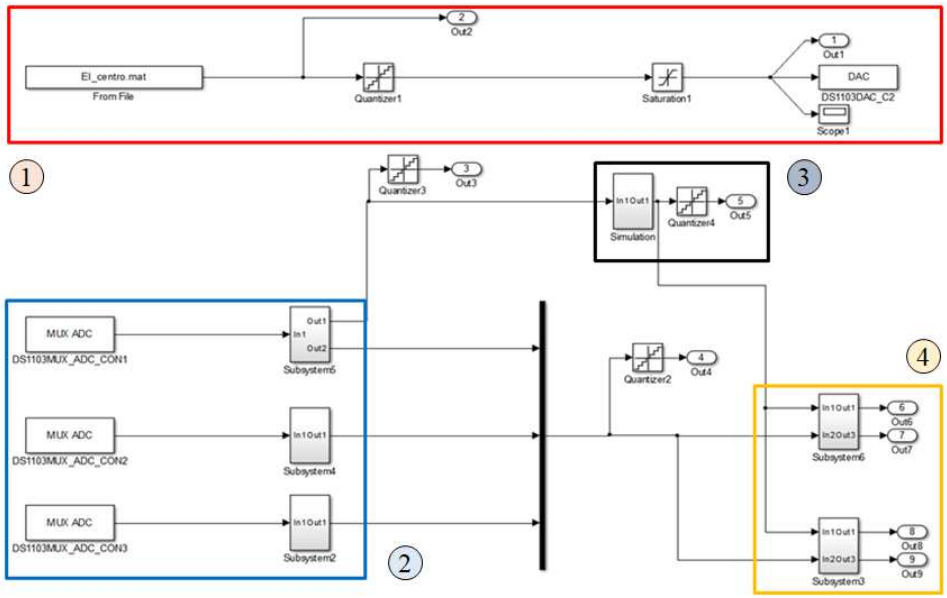

Figure 2: Real-Time Damage Assessment Program

For the real-time damage assessment program shown in Fig. 2, programming was performed separately for a seismic excitation signal output section for the vibration experiment, a measurement section that measures the response from the structure, and a damage detection section that is used to assess damages. Here, the damage assessment section is divided into a simulation section that provides the non-damage data of the structure based on measured seismic excitation signals and a statistical analysis section that compares the measured response from the structure and non-damage data by applying the IMD theory.

3 REAL-TIME DAMAGE ASSESSMENT TEST

3.1 Model Cable-Stayed Bridge for Damage Assessment Test

A model cable-stayed bridge that is a 1/200 replica of the Seohaedaegyo Bridge in Korea was used as the target for the verification of the developed real-time damage assessment method. The model bridge had 4,200 mm length, 170 mm width, and 1,000 mm pylon height, as displayed in Fig. 3. The seats at both ends of the bridge were of the roller type and the seat of the pylon was of the roller and hinge type.

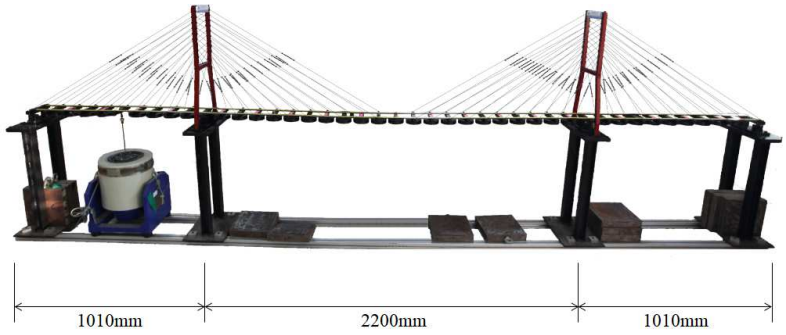

Figure 3: Model Cable-Stayed Bridge

As shown in Fig. 3, a shaker was located at the bottom of the left-side span to generate vibrations by imposing an external force to the cable-stayed bridge.

3.2 Damage Detection Test

Damage assessment tests were performed to assess the performance of the developed real-time damage assessment technology experimentally. For the output of the structure's seismic excitation signal and the measurement of its response, dSPACE 1103 was used. Control Desk based on Matlab & Simulink that is an operation-dedicated program was used for the operation of dSPACE 1103. Dytran's 3055B3 acceleration sensor was used for the measurement of the structure's response. Eight sensors were selected using kinetic energy optimization techniques, and one sensor on each of the left-side and right-side spans were positioned as illustrated in Fig. 4.

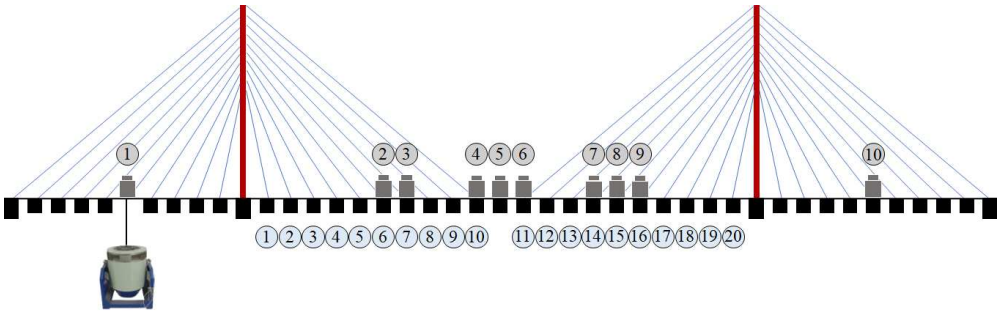

Figure 4: Measuring Instrument Locations and Cable Numbers

As shown in Fig. 4, the damage assessment test was implemented by removing the cables that support the span between two pylons in consecutive order. A set of cables in the front and back in the same section was removed together.

4 DAMAGE DETECTION PERFORMANCE OF DEVELOPED REAL-TIME DAMAGE ASSESSMENT TECHNOLOGY

Three damage tests were conducted for each case for the assessment of the damage detection performance of the newly developed real-time damage assessment technology to ensure the reliability of the test result. Fig. 5 below expresses the result of the response from the No.6 sensor out of the data obtained from the damage test in a graph.

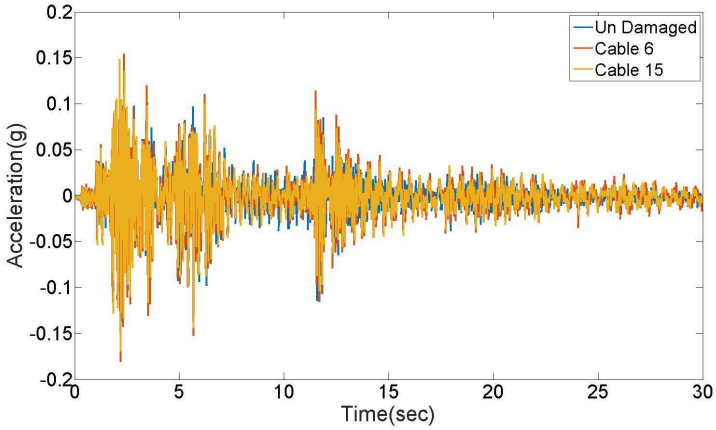

Figure 5: Acceleration Response Following Cable Damage

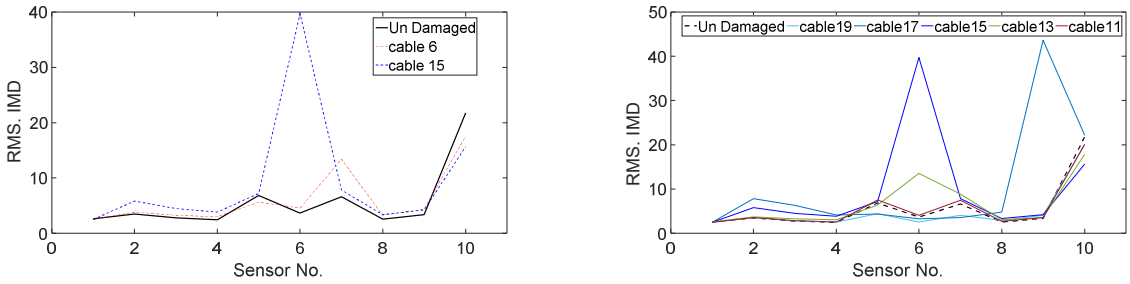
Fig. 5 compares the non-damage response and the acceleration response by damages in the No. 6 and No. 15 cables. As illustrated in the graph, the response following cable damage was similar to a non-damage response to the extent that the difference between the two could not be detected. Such results were observed in the other damage cases and sensors as well.

Subsequently, the result of damage detection that utilized the improved statistical pattern recognition technology was compared. IMD was calculated using data measured from ten sensors. Further, the root mean squared (RMS) value of each IMD was compared to detect the damage in 20 test cases. Fig. 6 below shows the result of damage detection using the improved statistical pattern recognition technology.



(a) A difference result (b) Indeterminate result

Figure 6: Result of Damage Detection that Utilizes Statistical Pattern Recognition Technology

As shown in Fig. 6(a), the IMD by cable damage was significantly different from non-detection IMD. However, a pattern that enables the damage location to be detected by simply comparing the IMD is not shown, as illustrated in Fig. 6(b).

Heo et al. compared the data obtained from one sensor to detect the degree of cable damage by utilizing the improved statistical pattern recognition technology [7] Such a data analysis method may be appropriate for assessing the degree of damage; however, it is not sufficient to detect the damage location in a bridge out of various responses from the bridge. In addition, as indicated by Fig. 6(b), the IMD calculated from each sensor did not offer a pattern for accurate damage detection.

Hence, the variability of the IMD and the RMS values of each test case are analyzed in this study to detect the damaged location from the IMD and RMS results from each sensor. As demonstrated in Fig. 6(b), the IMD and RMS values of each sensor did not indicate a significant variability for sensors No. 1 to 5; however, the variability between sensors was shown in sensors No. 6 to 10. Accordingly, the variability of the IMD and RMS values of sensors No. 6 to 10 were analyzed for each test case. Fig. 7 shows the variability of the IMD and RMS values in a graph.

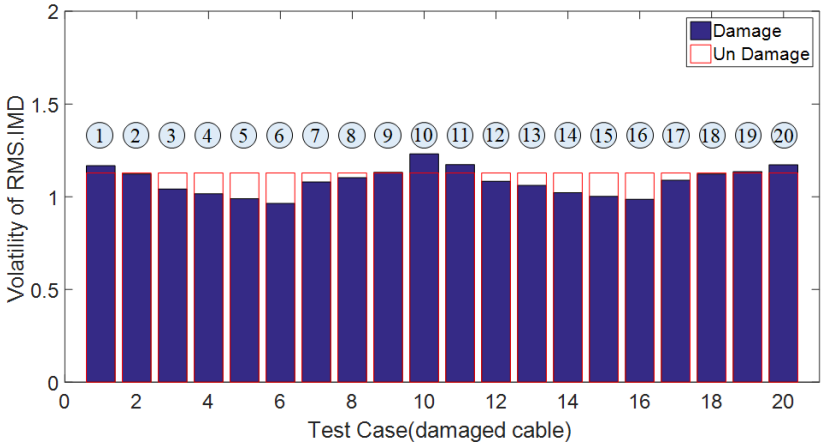


Figure 7: Detection of Damage in a Structure Using IMD Variability

Fig. 7 shows the RMS results from the IMD based on the data obtained from sensors No. 6 to 10 in 20 test conditions (cable damage) and the variability of each case. In Fig. 7, the red bars represent the result from a non-damage condition and the blues bars represent the result from damaged conditions. As the graph indicates, the variability of the damage is greater for the positions nearer to the pylon or the middle of the spans than the variability of the non-damaged conditions, while the variability was reduced at the 1/4 and 3/4 positions of the span.

5 CONCLUSIONS

Bridges are exposed to the threat of external loads frequently, even though they are critical in the transportation network. This study aimed at developing a technology that can perform a real-time damage assessment for bridges using a statistical pattern recognition technology. The real-time assessment technology was developed by applying a complex learning method that combined a simulation section offering non-detection data required for supervised learn-

ing and the Mahalanobis distance theory, which is the most well-known method of unsupervised learning. Notably, to overcome the limits of the newly improved Mahalanobis distance theory that resolved the shortcomings of the original version, a new method of analysis that considered the variability between the responses of a structure was proposed. Damage assessment tests were performed on a model cable-stayed bridge to verify the result of the study experimentally. The test result proved that the real-time damage assessment technology newly developed in this study could approximately detect the location of cable damage. The conclusion of this experimental study is as follows:

1) For the damage detection technology newly developed in this study, non-damage data were offered through simulations and the improved Mahalanobis distance theory utilizing such data was confirmed to demonstrate a difference by damage. However, the technology presented a drawback in that it did not exhibit a pattern that could detect the damage location;
2) This study proposed an analysis method that considered the variability between data for overcoming the limit in detecting the damage locations. The result of real-time damage assessment utilizing the proposed method proved its ability to approximately detect the location of cable damage.

Finally, it was confirmed that the real-time damage assessment technology and data analysis method developed in this study could perform the detection of damage location in a structure while non-damage data have not been obtained. However, the performance should be further verified on cases of damages in mass and in diverse structure types, as it was verified only on the cable of a cable-stayed bridge in this study.

Abstract

Motion Magnification (MM) is an emerging video processing methodology that acts like a microscope for motion in digital videos. Hardly visible motions are magnified leaving unchanged the general topology of the image. Therefore, the micro-displacements produced by vibrations can be amplified greatly and made available to the standard frequency domain analysis. The MM was recently successfully explored as a viable method to perform modal identification, at least in laboratory. In outdoor environment ambient vibration acquisitions are unavoidably affected by significant noise disturbing the modes identification. However, the first three or four modes, which are usually the most relevant to the dynamic behaviour of most structures, can be identified with little supervision, possibly reducing the calculation requirements as much as possible. All these tasks may be accomplished using MM together with the Blind Source Separation (BSS) algorithm. BSS allows the separation of mixed signals without previously known information about the mixture. MM provides the data while the BSS improves the identification of the modes by separating their contribution within the mixed noisy signals. A case-study is proposed to explore the application of the methodology to large ancient masonry structures, which represent very challenging objects for their structural complexities and heterogeneities. In particular, the studied structure was represented by an ancient bridge, the Ponte delle Torri, Spoleto. Due to the outdoor environmental difficulties, to the state of damage of the bridge and to the high level of noise in the video footages, this case-study has to be considered a very demanding one, nevertheless the modes were identified with good approximation in comparison to the results by Operational Modal Analysis (OMA) techniques, applied to ambient vibration data from seismographs equipped with accurate triaxial velocimeters.

Keywords: Motion Magnification, Blind Source Separation, Modal Identification.

1 INTRODUCTION

Monuments in the urban environment are affected by strong vibrations caused by anthropic activities, besides the natural events, therefore the health monitoring of these ancient constructions is required periodically. The standard procedure for the monitoring is the frequency domain analysis since a significant variation of the frequency response suggests that a damage has occurred, but expensive equipment, time-consuming elaborations and, last but not least, trained personnel are needed. Moreover, if the monument to be analysed is a large building, sensors have to be positioned to cover critical areas, but often is not possible to reach these points easily and sometimes it is impossible at all [1]. Even more important, since to perform reliable elaborations high density data should be collected, that is, the number of devices to be deployed to provide the full coverage of the building should be huge or alternatively, many measurement repetitions should be done. As a matter of fact, usually one chooses carefully some points, hoping that they will suffice to the analysis purpose. Once data have been collected, their processing and analysis may result in a long, hard and complex task.

To face these difficulties in the field of the mode identification, we propose the recently developed motion magnification (MM) digital video methodology [2] together with the Blind Source Separation (BSS) [3] algorithm. Motion magnification acts like a microscope for micro-motions in video sequences, saving the topology of the images but unveiling tiny visual patterns hardly visible with the naked eye. The magnification enables the spatial resolution of the videocamera to extract physical properties from images, to make inferences about the dynamical behaviour of the object no matter its dimensions, since any point on its surface can be considered a “virtual sensor”.

Recently, a number of laboratory experiments have ascertained the reliability of the MM methodology compared to standard techniques of modal identification, but regrettably, an extensive on-the-field experimentation for real buildings is still lacking.

On the other hand, the BSS original algorithm [3] allows the separation of randomly mixed signals, without previously known information about the mixture. Therefore, the MM provides the data, while the BSS (in the second-order statistical BSS formulated by McNeill’s [4]) improves the identification of the modes, separating their contributions within the mixed signals semi-automatically.

In the present paper, a case-study is proposed about the analysis of the *Ponte delle Torri*, a mediaeval bridge located in Spoleto, Italy. The McNeill approach properly adapted to the modal identification [4-6] was applied to video footages of the bridge processed through phase based MM. The analysis was limited to the first four modal frequencies and a comparison with the results obtained by Operational Modal Analysis (OMA) of velocimeters data is discussed.

Figure 1. The Ponte delle Torri of Spoleto.

2 THE PONTE DELLE TORRI OF SPOLETO

Our case study is the so-called *Ponte delle Torri* of Spoleto (Figure 1). It is a large historical construction that connects Colle Sant'Elia with Mount Monteluco in Spoleto, which used to be an important city in central Italy during the middle-ages.

The bridge superstructure is made up of a pedestrian deck, provided with a water canal on one side, supported by lancet arcades and stone piers known as "towers".

The bridge has a stone structure with shoulders and piers made up of rubble walls in a square matrix assembled by mortar and lime. The structure is only apparently regular. In fact, piers and arches have all different shapes and sizes, as well as the walls towards Colle Sant'Elia and Monteluco are also diverse in the masonry texture, due to their different construction timing and subsequent rebuilding interventions. The bridge has an overall length of about 230 m, while the highest tower is over 70 m. The bridge has a state of damage typical of historic masonry bridges. At the top of the arches, especially those on the slope of Monteluco, there are heavy water infiltrations resulting in losses of mortar binder and wall apparatus skiving. Moreover, a widespread damaged layer, especially in the lower part of the piers, was detected. This has caused the expulsion of some cornerstones of the piers, the disarticulation of the masonry texture and the collapse of portions of the outer layers. The bridge showed a widespread and extended state of damage already prior to the Central Italy sequence. The cracks present in the bridge seem mostly to be related to the heterogeneity of the construction materials, as usually befalls to ancient structures that are subjected to a series of structural interventions, architectural modifications and functional changes during their long history. The upper part of the piers is generally made up of better quality masonry with mortar of good consistency. In the lower piers, widespread damages caused the expulsion of some cornerstones, local dislocations of the masonry and some partial detachments of the outer layers. The fourth pier from West displayed two very large cracks that are clearly visible [1, 4].

3 THE MM AND BSS ALGORITHMS

Now we present briefly the two main algorithms used to perform the blind modal output-only identification, just the necessary to the comprehension of the proposed methodology, since the complete mathematical formalization is rather cumbersome.

3.1 The Magnified Motion algorithm

In the present work we have used the phase based version of the MM algorithm [7] to process the digital videos. It is important to observe that within the MM processing a band-pass derivation step is included, so that to magnify the motion displacements, either the initial Taylor's expansion or the amplification factor α do not have to be too large. In practice, slowly changing scenes and small amplifications permit to remain into the linearity bound needed.

Moreover, the algorithm implies a certain noise amplification too [8]. Physical sources of noise are lighting conditions, presence of shadows, camera unwanted vibrations, poor pixel resolution, presence of unexpectedly large motions, excessive camera-object distance. In particular, the scene lighting conditions should remain constant, as changing the background light could produce apparent motions. In general, the video duration heavily affects the computation time of the whole processing and may be a major problem. Obviously, according to the Shannon-Nyquist Theorem the frame rate should be appropriate as it represents the sampling frequency f_{fps} of the data. The general condition to be respected is given by:

$$f_{\text{fps}} \geq 2f_{\text{max}} \tag{1}$$

where f_{max} is the maximum frequency of interest.

3.2 The Blind Source Separation algorithm

The Blind Source Separation is an Independent Component Analysis (ICA) signal processing technique, that extracts n original signals $\boldsymbol{s}$ from their random mixtures $\boldsymbol{x}$, observed by a certain number m of sensors and possibly polluted by noise. Thus the *blind* source separation consists in identifying the mixing matrix $\mathbf{A}$ and retrieving the source signals $\boldsymbol{s}$ without resorting to any *a priori* information about $\boldsymbol{s}$, the mixing process, or the signals propagation medium. The only hypothesis is that the source signals are mutually statistically independent [4]. ICA algorithms are based on an objective function to be optimized according to a measure of independence of the source in the direction of the increasing independence. The physical phenomenon is represented by:

$$\boldsymbol{x}(t) = \mathbf{A}*\boldsymbol{s}(t) + \boldsymbol{\eta}(t) \tag{2}$$

where, given m sensors and n sources of signal, $\boldsymbol{x}$ is the observed signals vector that originate from the mixture, and vector $\boldsymbol{\eta}$ is the noise of unspecified distribution, $\mathbf{A}$ is the random "mixing matrix". The number of sensor m must be at least equal to the number of sources n, otherwise the reconstruction will be affected by very large errors. There are two important types of mixing models: instantaneous mixtures and convolutive mixtures. The first one is a mixing model which does not take into account any delays whereas the convolutive mixture involves some delays in the mixing process. In our case we admit no delays.

Originally, the BSS was developed to solve the "cocktail party" problem, whose simplest formulation is this: two people are speaking during a party, while two distant microphones record the overlapping voices amid noise. We want to separate voices $\boldsymbol{s}$ using only their registrations $\boldsymbol{x}$ from at least two microphones.

Thus, $m = n = 2$ and the mixing system is:

$$x_1(t) = a_{11}s_1(t) + a_{12}s_2(t) + \eta(t) \tag{3}$$
$$x_2(t) = a_{21}s_1(t) + a_{22}s_2(t) + \eta(t) \tag{4}$$

If the sources are statistically independent, the problem is solvable estimating the matrix $\mathbf{W} = \mathbf{A}^{-1}$, called the de-mixing matrix (up to some constants scaling factors):

$$\boldsymbol{s}(t) = \mathbf{W}* \boldsymbol{x}(t) \tag{5}$$

Today many ways to calculate $\mathbf{W}$ are known. Usually a cost function is chosen according to geometric information or theoretical considerations and minimized by the gradient descent, the simulated annealing or a genetic algorithm, resulting in an estimation of $\mathbf{W}$ [3].

Here we use the McNeill BSS version [4], to obtain the separation of signals from noise and, at the same time, the output-only calculation of vibration modes. The underlying idea is quite simple: the physical responses $\boldsymbol{x}$ of the dynamic system are constructed from the modal response $\boldsymbol{q}$, through the modal matrix $\boldsymbol{\Phi}$:

$$\boldsymbol{x}(t) = \boldsymbol{\Phi} * \boldsymbol{q}(t) \tag{6}$$

hence using the BSS framework to calculate $\mathbf{W} = \boldsymbol{\Phi}^{-1}$:

$$\boldsymbol{q}(t) = \mathbf{W} * \boldsymbol{x}(t) \tag{7}$$

the modes $\boldsymbol{q}$ are obtained.

This decomposition allows for the estimation of the natural frequencies and damping ratios too. The modal matrix and modal responses are formed by real values if the topology of the damping matrix results in a proportional damping, otherwise are formed by complex values (for details see [4-6]).

4 APPLICATION TO THE PONTE DELLE TORRI

We validated the methodology on the case-study of the *Ponte delle Torri*, using the modal frequencies by OMA as a reference ground-truth. Besides the magnified motion that provides a very large number of "virtual sensors", the major advantages coming from the McNeill-BSS algorithm are the semi-automation of the mode calculations and the separation of the signals from most of disturbances. Two sets of time-series are used as inputs to the BSS: those from the MM and those from a velocimeter.

4.1 Modal identification by OMA of velocimeters data

Ambient vibration was measured by SL06 recorders (SARA Instruments) equipped with triaxial electrodynamic velocimeters, set to 200 Hz sampling frequency [8]. The instruments were positioned along the bridge deck, on top of each pier and in the middle between piers. Also the basis of the central pier and both abutments were recorded. All configurations were acquired for at least 20 minutes.

The OMA techniques implemented in the ARTeMIS Modal Pro software were used to elaborate the experimental data of the velocimeters. Among the several OMA techniques available, the Frequency Domain Decomposition (FDD), the Enhanced Frequency Domain Decomposition (EFDD) and the Stochastic Subspace Identification (SSI) were utilized. EFDD provides also an estimation of modal damping, SSI is a more sophisticated and automatic procedure based on time-domain approach. The results of the identification of the modal frequencies averaged over the OMA techniques are resumed in Table 1. Also a finite element analysis (FEM) has been carried out along with the experimental campaign, further confirming results of Table 1 [1, 4].

4.2 BSS with velocimeters data

We firstly applied the BSS to SARA velocimeters data in order to validate the algorithm efficiency by comparison with the OMA results of the same dataset. A velocimeter channel $y(t)$ was considered for the following processing steps. The segmentation can be expressed as follows:

$$\begin{aligned} y_1 &= y(t_i : t_{f1}); \\ y_2 &= y(t_{f1} : t_{f2}); \\ y_3 &= y(t_{f2} : t_{f3}); \\ y_4 &= y(t_{f3} : t_f); \end{aligned} \tag{8}$$

The above segmentation is correct only if the ergodic hypothesis holds, otherwise the BSS error could be quite large. It is not easy to demonstrate the ergodicity of the system under consideration, however, as a matter of fact, the errors with respect to OMA modes are small

(Figure 2, Table 1). This reduced error could be quite predictable by means of specific tests and will be the object of future investigations.

In the Fast Fourier Transform (FFT) of the velocimeter signal, the peaks are well defined and separated, allowing a clear identification of modes (Figure 3). This is clearly due to the good quality of the high-performance velocimeters mounted on the SARA recorder. Therefore, BSS proved to be an effective tool for frequencies identification with good-quality vibration data.

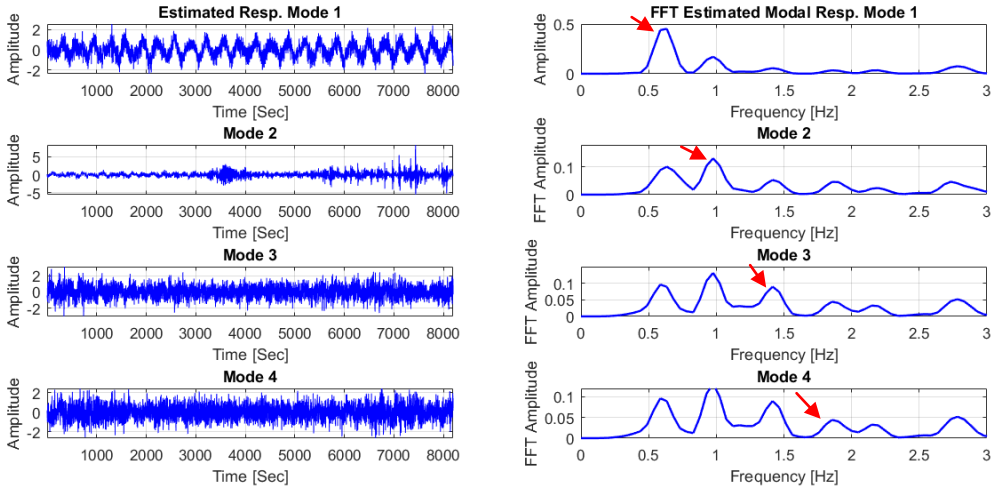

Figure 2. The first four vibration modes indicated by the red arrows (right column) and on the left their amplitude time-series. Each subgraph shows the related peak, according to the mode order. Here the signal is from a velocimeter, direction y.

Mode	BSS-vel (Hz)	OMA (Hz)	% error
1	0.635	0.632	-0.44
2	0.977	1.011	-3.40
3	1.416	1.496	5.34
4	1.855	1.975	-6.08

Table 1. Modal frequencies calculated by BSS of velocimeter data (BSS-vel), the reference values of OMA, and the percentage errors with respect to the OMA values.

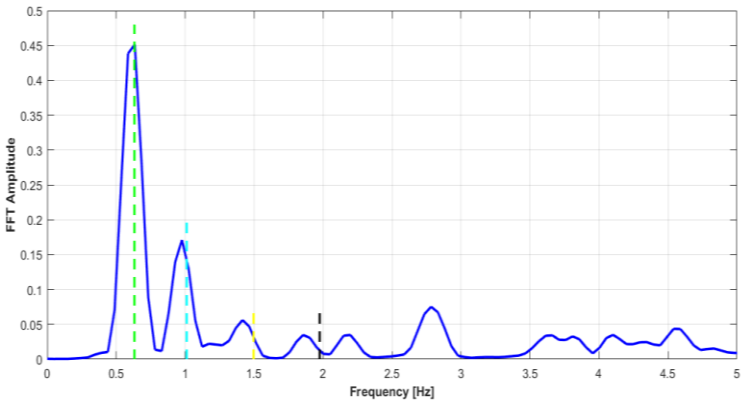

Figure 3. FFT amplitude of the velocimeter signal processed by BSS. Dotted coloured vertical lines represent the modes identified by OMA. The peaks are well defined and separated, allowing a clear identification of modes.

4.3 The Magnified Motion data

A video footage of the bridge was recorded contemporarily to the ambient acquisition of velocimeters data during the campaign of 29th May 2017. Large motions, such as people passing by in front of the camera and swinging objects, were avoided [10]. The presence of large motions is one of the most important sources of noise for the MM, requiring the experimenter to isolate part of the image, although usually this is not a feasible option. Video footage was recorded by means of a commercial low-cost camera (pixel resolution 360 x 445, frame rate of 50 fps). The basic methodology is to take advantage of the large number of pixels contained in the camera view. Theoretically, we could have 160,200 "virtual sensors", meaning that each pixel provides a time history of intensity variation (colour or grey scale), from the first frame to the last one. These time series contain the information about the displacements of the physical points related to the pixels (although they are not real displacements). Of course, not all the surface of the structure generates useful information, therefore we identify a small area with high signal-to-noise ratio (SNR). The identification of the region of interest (ROI) is a crucial point of the procedure.

In Figure 4 the first frame of the MM video, note also the field of view. The red box enlarged on the right is the selected region of interest used to extract the MM intensity time-series and finally the average over all the pixel time series (bottom).

It is not mandatory to perform the PSD on this averaged signal, but it is useful to exploit the low-passing action of the mean to reduce noise disturbances. The main source of vibrations is the wind, although a road flanks the monument on the right side. In any case, man-made vibrations may be considered of low intensity. The camera is positioned on the road near the monument hence wind and traffic affect its stability too [11].

To run the MM algorithm [3] we need to set some parameters. In particular, the magnification band and the amplification factor are the most important. We chose a band of 0.5-2.5 Hz and an amplification factor of 140. Similar values would be also acceptable, nevertheless, since the MM acts as a pass-band filter, choosing a band close to the actual modes gives better results. In our case we have been supported by the previous analysis [1], but generally one must rely on experience to decide a suitable band. After the MM phase based magnification step [3], we have to select the region of interest of the virtual sensors, meaning to pick some pixels whose time history of colour variation will be translated into the frequency domain. We choose the area as in the red box of Figure 5, because it is morphologically different from the wall and provides some edges to the algorithm.

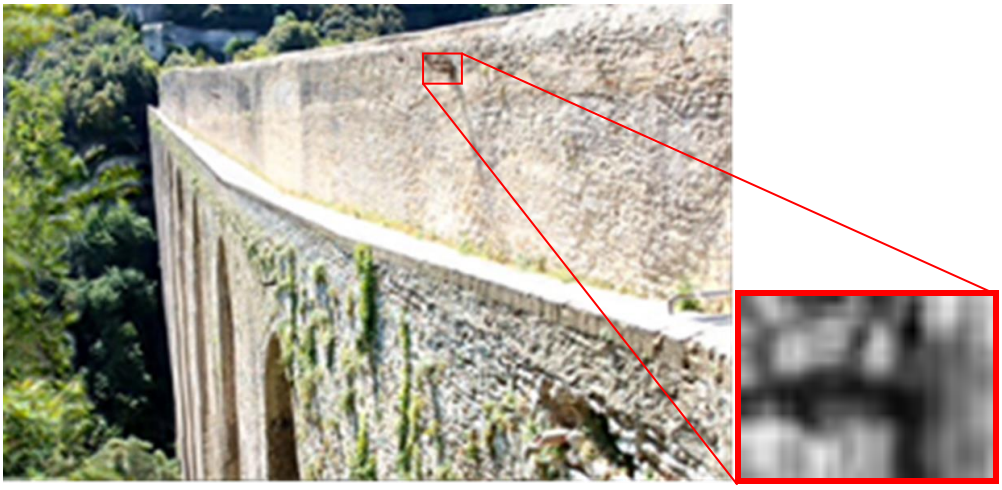

Figure 4. The camera view of the bridge. The red box enlarges the lamppost selected for analysis.

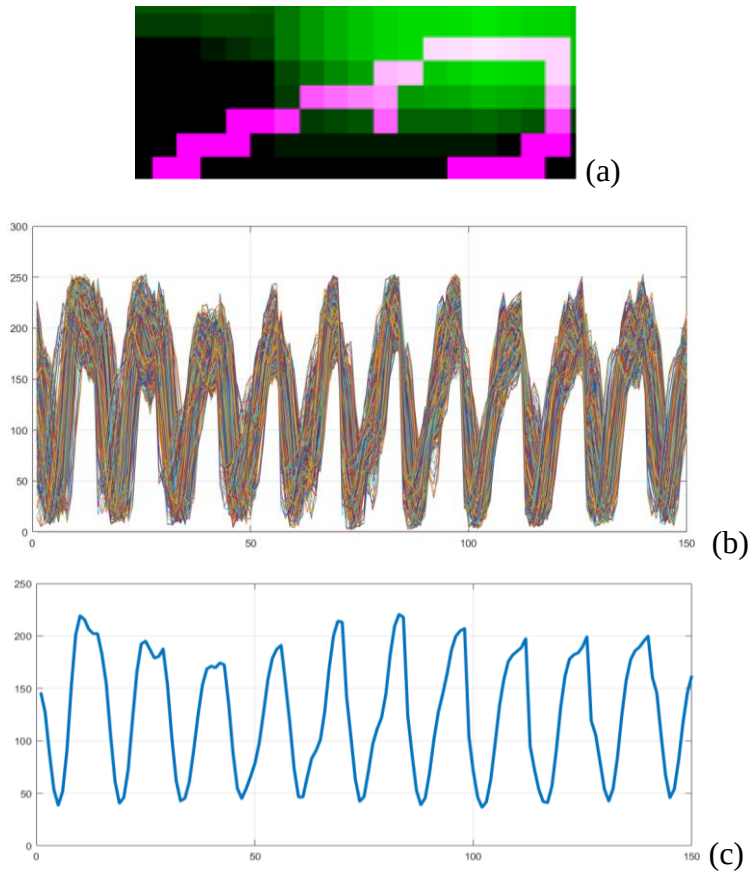

Figure 5. Signals time histories (b) from the selected pixels (a) and the related average signal (c).

The presence of marked edges or texture would be very helpful for the MM, but unfortunately the surface of the monument is rather homogeneous. These circumstances produce a large amount of noise, to be added to other disturbances. Also the angle of the camera is much less than 90° (Figure 4), therefore the magnification will be affected by a distortion. Also the air refraction and the wind provide a substantial source of noise, affecting the algorithm. No attempt to compensate for these distortions has been made.

The ROI is part of a lamppost, in-built to the wall about 40 m from the camera; however only the red box pixels are able to supply low-noise information, because are close to the structure. In fact, the upper part of the lamppost spreads spurious frequencies, due to its own resonances. Other choices of the ROI have not improved the measurements.

Signals provided by MM do contain displacement information, but they cannot be used immediately as real displacements. Anyway, acceleration may be calculated just like it can be done with the velocimeter displacement measurements, and the PSD obtained as well.

The ROI area of Figure 4 may be identified qualitatively by trial and error considering the number of peaks in the PSD and their inter-distance; a dense presence of peaks suggests a high level of noise and of course is misleading, therefore only PSD spectra with identifiable frequencies are acceptable. In practice, to avoid a biased choice, one may select manually the area several times, repeat the calculation and average the results. In our case, we find that ten iterations of the MM-PSD procedure is a good trade-off between speed and precision (intended as closeness to the mean value). The smooth appearance of the MM-PSD depends on the short time span of the video that decreases the PSD frequency resolution. Another selection criterion of the ROI could be based on the entropy calculation for the single pixel time-series, choosing the high information content suggested by the entropy.

4.4 BSS with Magnified Motion data

Having extracted the time-series from the digital video as described above, we take the temporal average on four sets of selected pixels to simulate the signal obtained from four sensors, in order to match the basic BSS requirement, then we apply the McNeill calculation to unveil the modes [5-6]. Focusing on the first four modes, we must consider at least 4 signals, thus $m = 4$.

$$m = n = 4 \tag{9}$$

where eq. 9 is the BSS requirement condition. To such purpose we took four segments of the original averaged MM signal s (Figure 3, bottom) as follows:

$$\begin{aligned} s_1 &= s(t_i \ : t_{f1}); \\ s_2 &= s(t_{f1} : t_{f2}); \\ s_3 &= s(t_{f2} : t_{f3}); \\ s_4 &= s(t_{f3} : t_f); \end{aligned} \tag{10}$$

The eq. 10 is the formalization of the signal segmentation of s, in analogy to eq. 8. Each of the above four signals can be considered as the measurement time-series received from some "virtual sensors" (i.e. a group of pixels, see Figure 3), acting as input to the second order-BSS algorithm [9]. The first four modes obtained are shown in Figure 6. Each subgraph shows the related peak, according to the mode order. The smoothness of the peak depends on the particular choice of the algorithm parameters, which introduce a certain amount of unwanted arbitrariness. From the FFT amplitude of signal s (Figure 7), it can be noted that the peaks are ,ore noisy and not as well-separated as in the case of velocimeters data. Here the noise is introduced mostly by the MM mechanism, but usually noise sources may be related also to a variety of factors, and anyway they are hardly avoidable. In such cases, the McNeill's algorithm contributes to resolve the hardly distinguishable frequency peaks. In fact, the first four modes could be identified with interesting accuracy with respect to the modes identified by OMA (Table 2). Therefore, integrating the MM with the BSS proved interesting potential as a vibration measurement technique for fundamental frequency identification. It must be remarked that this achievement was due to the proper choice of the pixels to process by MM.

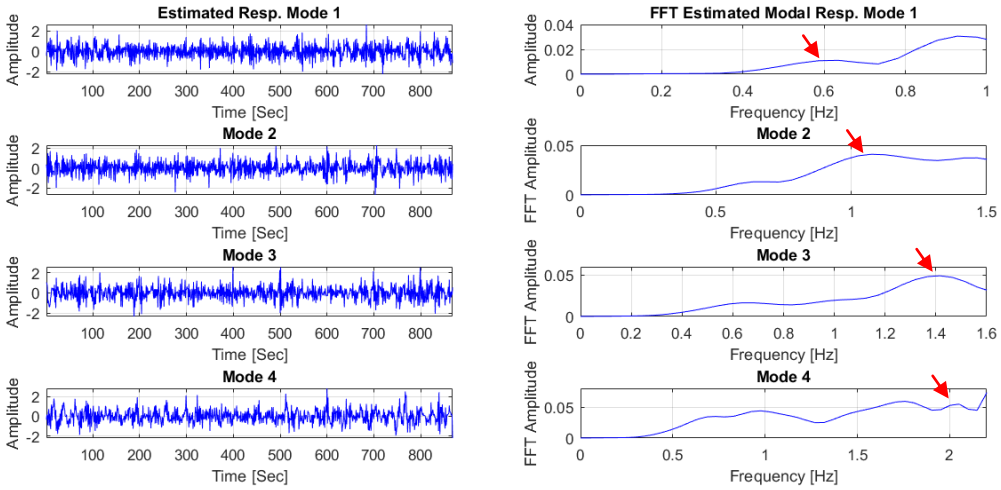

Figure 6. The first four vibration modes indicated by the red arrows (right column) and on the left their amplitude time-series. Each subgraph shows the related peak, according to the mode order.

Mode	MM (Hz)	OMA (Hz)	% error
1	0.635	0.632	-0.44
2	1.074	1.011	-6.23
3	1.416	1.496	5.34
4	2.051	1.975	-3.85

5 CONCLUSIONS

Ambient vibration monitoring of large buildings is a difficult task both in terms of data collection and elaboration. Several sensors must be deployed on the structure, which is quite expensive and often demand specialized operators. After on-the-field collection, vibration data must be pre-processed, elaborated and finally analysed. In the presented case-study, about the *Ponte delle Torri*, the data were collected also as video footages for the application of MM technique. The large number of virtual sensors extracted from the acquired scene were processed with a semi-automatic procedure through the second order BSS to identify the modes of the analysed structure. Although the used McNeill algorithm for BSS still needs a complete automatization, the number of parameters to be set is limited, making it already quite easily usable for non-expert operators. On the other hand, it proved to be very stable and well-integrated with the MM. Moreover, it must be stressed that the proposed case-study was particularly tricky with regard to the noise/disturbance issues. Nevertheless, the overall procedure performed well in terms of speed, simplicity and accuracy of modal frequencies identification (6%-error accuracy with respect to the frequencies obtained with velocimeters data processed by OMA techniques). Improvements of both the basic MM and the BSS algorithms are definitely within reach, paving the way to the perspective of very easy, speedy and low-cost data acquisition for modal identification of monitored structures.

Abstract

The SHM has a very important role in the diagnostic process of cultural heritage buildings, for which generally, the identification of the structural behaviour is affected by many uncertainties. The use of ambient vibration tests allow to characterize the dynamic behavior of the structures, providing also information to validate numerical modeling. Moreover, continuous monitoring allows to record streams of seismic ambient noise for long time intervals in order to retrieve the temporal evolution of the structural characteristics and to highlight the response of them to seasonal variations of environmental parameters (temperature, humidity) and the stresses due to the human activities or to the rapid (daily or weekly) changes in the ambient conditions (temperature, wind velocity and intensity).
Three seismic monitoring experiments were performed in 2012, 2013 and 2014 at the Asinelli and Garisenda Towers, two masonry leaning tower built in the center of Bologna (Italy). The aim of this work is to present the results of the analysis of the data recorded by seismic monitoring that allowed to clearly identify the normal modes of oscillation of the Two Towers. A particular attention was devoted to the identification of transient that, propagating inside the structures, produce beating effects at the top stations. Implication to the structural modeling and to the State of health monitoring are discussed.

Keywords: Dynamic Structural Health Monitoring, Masonry tower, Ambient vibration

1 INTRODUCTION

The assessment of the structural heath of the historical buildings, through non-destructive techniques, is fundamental in order to preserving their cultural integrity. For this purpose, Structural Health Monitoring (SHM) plays a crucial role in providing information both on the dynamic properties of the structures and the damage caused by earthquakes, impacts or traffic loads. In the last decade, the number of SHM systems designed and implemented on historic structures increased considerably. SHM perfectly meets principles and guidelines of Italian and European seismic codes concerning the historical buildings, which require the preservation of the structural architectural integrity, promoting removable, non-invasive and compatible solutions in the knowledge process, restoration and strengthening [1], [2]. The data obtained from a dynamic monitoring system shall provide information regarding the intrinsic properties of the structure that can be used to develop more accurate models and thus to plan effective strengthening interventions. Vibrations are one of the main factors for fatigue in structures. For this reason, with the increase of heavy traffic in the cities the study of the effects of the road traffic vibrations induced on the historical buildings is becoming another important issue. Continuous monitoring allows to record streams of seismic ambient noise for long time intervals in order to retrieve the temporal evolution of the structural characteristics, the influence on them of the ambient conditions (temperature, wind velocity and intensity) and the stresses due to the human activities (traffic loads). Three seismic monitoring experiments were performed in 2012, 2013 and 2014 at the Asinelli and Garisenda Towers, two masonry leaning tower built in the center of Bologna (Italy). The aim of this work is to present the results of the analysis of the data recorded by seismic monitoring, that allowed to identify the dynamic properties of the Two Towers, and to investigate the effects of the vibrations induced by the traffic loads on the Towers. The information obtained from the monitoring are also used to calibrate FEM models with the purpose of identify models able to better simulate the real behavior of the Towers. Particular attention was paid to the evidence of particular signals propagating inside the Towers that point out clear effects of beatings at the top.

2 GARISENDA AND ASINELLI TOWER

Garisenda and Asinelli Towers, commonly referred to as “The Two Towers”, are the main monument of the city of Bologna, North Italy (Figure 1). The Asinelli Tower is the taller one (97 m) and was built between 1109 -1119. During the Second World War, the Tower was used as a watchtower. It tilts toward South-West of 2.23 m [3]. The external walls were built using solid bricks for the outer skins and rubble masonry fill. The total thickness of the masonry decreases almost linearly from 3.15 m at the base to 0.45 m at the top. Three main discontinuities are present at 11.5 m, 34.0 m and 56.0 m (Figure 1b) [4]. The Garisenda, the older one, can be dated around the last two decades of the eleventh century. During the construction phases, the foundation soil underwent important subsidence phenomena, which caused a visible tilt of the tower [5]. The tower is 48 m high and has a slope of 3.40 m towards South-East. The base of the Garisenda tower presents an external selenitic layer that cover the external wall for the first 3.5 m. The Tower cross section above the selenitic base (built using solid bricks for outer skins and rubble masonry fill) reduces with height as the common construction practice at the time of construction (Figure 1c) [6]. The knowledge of actual state of health the towers is a crucial issue in order to preserve these monuments. For this reason, at the beginning of the 2011 the Municipality decided to installed a static SHM systems in both the Towers [7], [8]. In addition, following the Emilia earthquakes (20th May 2012 and 29th May 2012, respectively 5.8 and 5.6 Mw), seismic monitoring experiments were commissioned to the Istituto Nazionale di Geofisica e Vulcanologia (INGV) in conjunction with the

University of Bologna with the purpose of obtaining information on the dynamic behaviour of the Two Towers.

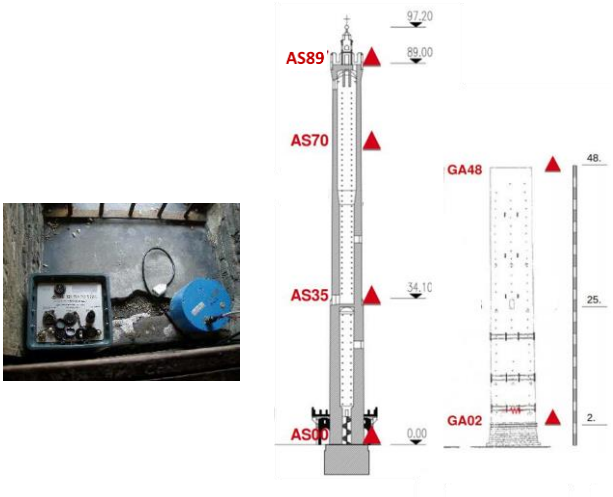
2.1 The monitoring system and the tests developed

The Towers' vibrations induced by natural or artificial sources (ambient noise) have been recorded in order to evaluate their dynamic properties. The first experiment [9] was performed from June 2012 to September 2012. Six seismic stations, equipped with three-axial seismometers (Lennartz Le3d5s coupled to 24-bit digitizers Reftek 72A-07/08) were installed along the height of each Towers (4 in the Asinelli, 2 in the Garisenda), see Figure 2. A second experiment was repeated the year after, from September 2013 to March 2014 (Lennartz Le3d5s coupled to 24-bit digitizers Reftek 130). A third experiment was performed from August to October 2014 (three seismic stations in the Asinelli, SS20 2Hz seismometer coupled to a SL06 24 bit DAS from Sara Electronics S.r.l.).



(a) (b)

At the end of the third experiment (October 2014) additional experimental measurements have been carried out in order to study the effects of the transit of a heavy vehicle on the Asinelli tower, at the end of the monitoring period. For this aim, the oscillations produced by the transit of an heavy truck at different speed along Strada Maggiore (the road at the base of the Asinelli Tower, Figure 3) were recorded by the three seismometric stations, installed at the base, at 35 m high and at the top of the Asinelli Tower.

3 AMBIENT MODAL FREQUENCIES IDENTIFICATION AND MODELING

Recording natural vibration on built structures gives a way to identify their fundamental frequencies of vibration. Since the use of these techniques allows to make measurements without any damage to the building and without interfering with its normal use, it appear particularly suitable for the analysis of structures of historical and monumental interest. Also, from the spectral-analysis point of view, taking into account the wide frequency band covered by the natural vibration, it is possible to recognize the principal modal frequencies in a single step.
Figure 4 and 5 show the average spectra computed over the entire monitoring period of 2013 for the three components of the top station for the Asinelli and Garisenda, respectively [7, 8]. The first three fundamental flexural frequencies (indicated as F1, F2, F3 in the spectrum of figure 4a) of the Asinelli Tower fall within the range of 0.32-0.33 Hz, 1.3-1.5 Hz and 3.0-3.3 Hz. The third peak (indicated as R1 in figure 4a) of the spectrum of the horizontal components may be associated with a torsional motion. The first three fundamental frequencies of the Garisenda tower, instead, fall within the range of 0.71- 0.73 Hz, 3.7-4 Hz and 8.8 9.0 Hz respectively (Figure 5). It can be noticed that these peaks are split and characterised by different amplitudes between the two horizontal components (figure 4b and 5b). The frequency splitting, not existing in a symmetrical structure, is probably due to the asymmetry in building characteristics and to the leaning angle of the Towers.
A more detailed observation of the spectral response of the Garisenda Tower (Figure 5a) allows to capture a quite interesting phenomena, that is the presence of two small spectral peaks at frequencies corresponding to the fundamental frequencies of the Asinelli Tower. Such phenomena can be interpreted as a mutual induction effect of oscillation. The same effect, on the other hand, is visible only on the vertical average spectrum of the Asinelli Tower that exhibits in this frequency band the minimum spectral amplitude (Figure 4a).
In the last years, the assessment of the structural health was mostly focused on the Asinelli Tower rather than on the Garisenda Tower, mainly because being the larger height of that would probably make it more vulnerable to the effects of lateral vibrations, such as those in-

duced by earthquakes. In the past, some of the authors have conducted numerical studies based on the use of Finite Element Method (FEM) to asses to seismic response of the Tower. FE models of increasing complexity (mono and bi- dimensional models considering different base conditions) have been developed and the results of modal analysis were compared with the data recorded by the dynamic monitoring. Details are available in [10].

In this work, to investigate the phenomenon of frequency splitting and of beating (that will be presented in the next sections), a further FE model of the Asinelli Tower has been developed. considering isotropic shells elements using the commercial softwareSAP2000. The model reflects faithfully the geometry in the following aspects: inclination, thickness of the walls at the differed sections, windows, holes used to install the scaffolding during the construction phases and steel ties installed during the years to confine the masonry walls. In particular, the openings could influence the structural response of the Tower and could be a possible cause of the frequency splitting detected through the dynamic monitoring. Figure 4c displays the mode shapes obtained by the FE model. It can be noticed that the fundamental periods obtained from the model analysis are in good agreement with those obtained from the measurements. Time history analyses, using the recorded data at the base of the Tower as input, are under development to better investigate the cause of the beating phenomenon observed.

In 2018, a possible material degradation at the base of the Garisenda tower has been revealed pointing out the necessity to assess its current structural health. Several models (bi-dimensional and three-dimensional finite element models) of the Garisenda have been developed. Particular attention has been paid to the modelling of the base of the Tower composed by an external and internal perimeter of selenitic stones (thickness of around 50-60 cm) and an internal filling. The measured frequencies have been used to calibrate these models, which will be used to investigate the consequences of the natural decay of material properties in terms of safety and stability. For sake of brevity, only the mode shapes as obtained by the bi-dimensional model are reported in Figure 4c. The material properties used in the models of both Towers, characterized through in situ tests (both destructive and non-destructive), are summarized in Table 1.

4 CHANGES IN THE OSCILLATION DUE TO VARIATION OF AMBIENT CONDITION

Dynamic monitoring, if performed continuously and for a long period, can be an effective tool to describe the health status of a built structure. The recording of long data flows allows to follow the variation of the modal parameters with time and to correlate it to the changes in the environmental conditions, natural or artificial, that can influence the behavior of the structure and can produce fatigue or rapid modification of the mechanical-physical properties. It is the case of the Two Towers, which have been monitored for several months over several years, allowing not only to depict a snapshot of the modal parameters but also to observe how the Towers are solicited by the variation of ambient parameters.

A first aspect taken into account was to measure the variation of the amplitude of oscillation with the variation of anthropic noise due to the daily increment of the vehicular traffic at the base of the Towers. As representative example of an average behaviour for both Asinelli and Garisenda Tower, Fig. 6 shows the daily oscillation recorded at the Asinelli top station during August 2012 between 1–20 Hz, the frequency band where the seismic ambient noise is known to be dominated by “cultural sources”. It is clear the similarity of the trend during the working days, showing a sharp increment in the amplitude of oscillation when the human activity rises (about at 6: am, local time), a reduction during the evening and an almost instant decrease in the night, after the 01 a.m. (local time). On the other hand, also during holidays (15, 17, 18 August 2012) the pattern is similar but the interval when the oscillation amplitude is increasing reduces its duration only in the central part of the day.

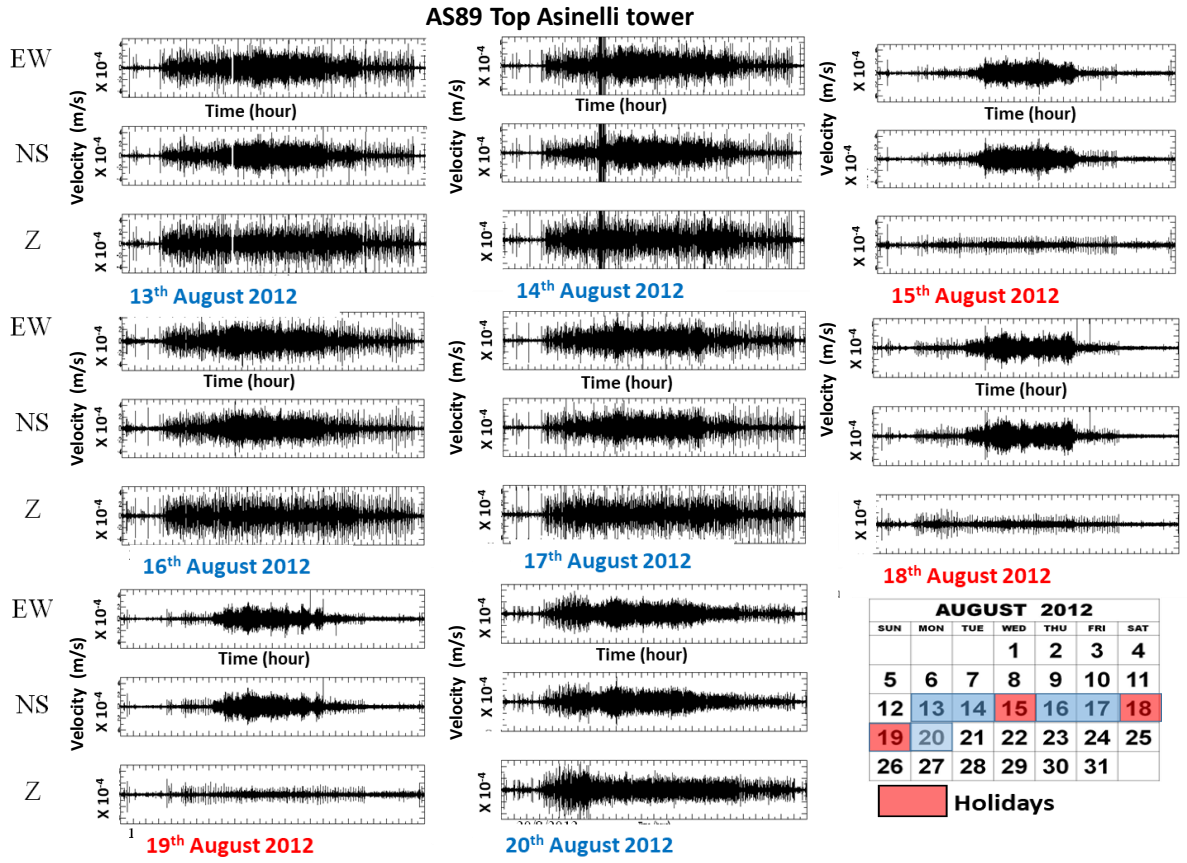

Figure 6- Daily trend of the oscillation recorded by the top station of the Asinelli Tower from 13th to 20th August 2012. The signal has been filtered in the 1-20 Hz frequency band, in order to point out the content associated with the anthropic noise surrounding the Tower.

To evaluate the amplitude ratio of the oscillation between night and day periods and between weekdays and holidays, the trends of the maximum amplitudes of oscillation in the different periods have been calculated, performing the averages of the maximums. It can be noticed that the oscillation between day and night is between 2 and 6 times greater on weekdays and doesn't exhibit evident differences between weekday and holidays.

The continuous monitoring has allowed recognizing the propagation inside the Towers of transients that trigger beatings at the top of the Asinelli Tower. Figure 7 shows the time history of the three components of recorded signals (200 s) recorded by the three stations. The signals recorded by the station at the top clearly show beatings. The phenomenon has been investigated by some of the authors Palermo et al [11] using a simplified eccentric planar model with an equivalent eccentric and torsional stiffness. The results indicated that the equivalent eccentricity could be compatible with some partial wall disconnections due to cracks propagating along the openings.

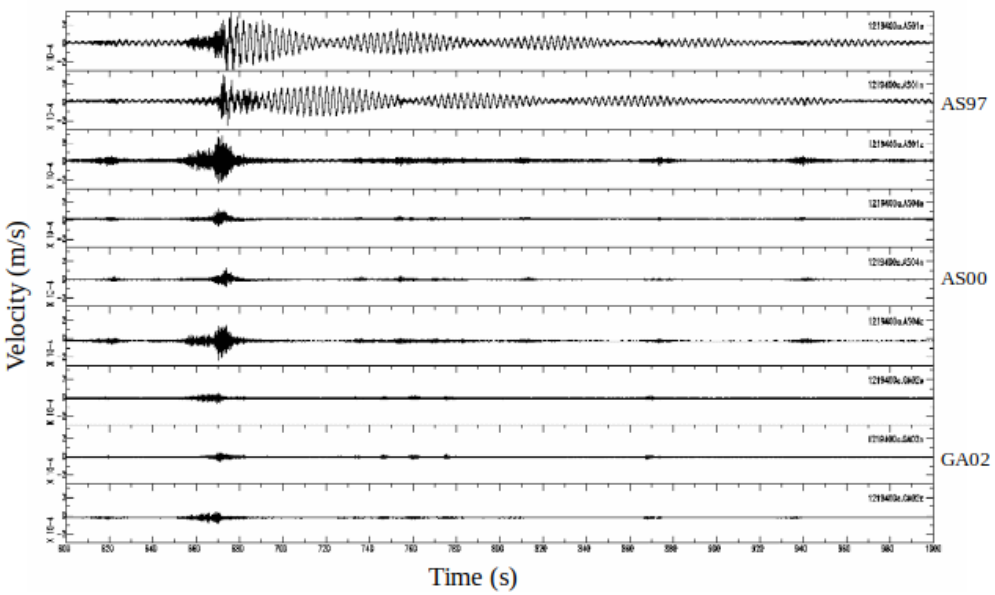

Figure 7. Example of transient propagating inside the Towers and triggering beatings at the Top level of Asinelli Tower. Each set of three signals are the waveforms on the Z, NS, EW directions, from down to top respectively for GA02, AS00 and AS97 measurements point.

In order to individuate the possible source of the impulse at the base, a horizontal particle motion analysis of the signal recorded at the base of the Two Towers has been performed. Figure 8 shows that the cross point of the composition of the horizontal components, taking into account the position of the instrumentation inside the Towers, points toward the intersections of roads “Via Rizzoli” and “Strada Maggiore”, daily traveled by heavy vehicular traffic.

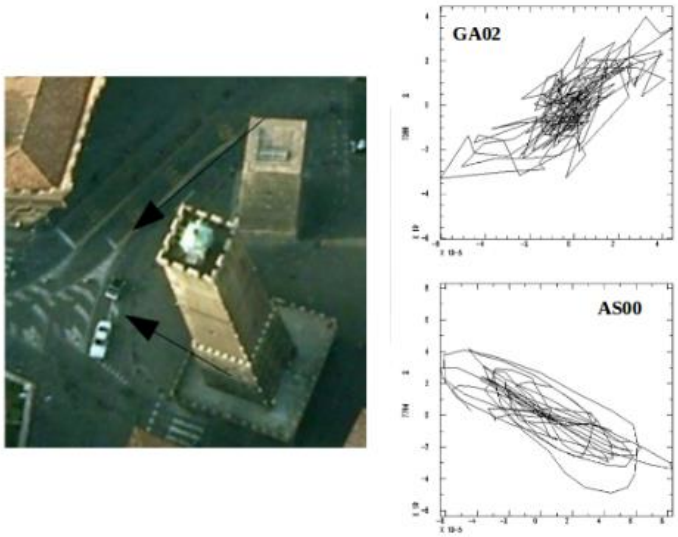

Figure 8. Particle motion analysis along the horizontal directions for the two seismic stations installed at the base of the Two Towers

5 VIBRATION INDUCED BY HEAVY TRAFFIC: EXPERIMENTAL TEST

In October 2014, during the execution of some maintenance works along road "Strada Maggiore" that required the road closure, an experimental test has been performed in order to record the Asinelli Tower vibrations induced by the passage of a heavy truck along the road (Figure 3). Three seismic station equipped with three-axial seismometrs (SARA SS20 and SL06) were installed at the base, at 35 m and at the top level of the Tower. The signal was sampled at 100 sps. The truck made five passages at different speeds (10, 20, 30 km / h). The presence of a sudden discontinuity in the pavement was also accounted for by placing an obstacle in the road, namely a wooden beam in the direction perpendicular to the road. For each measurement, the following tests have been conducted (Figure 9):

A. truck moving at 20km/h with no obstacle
B. truck moving at 30km/h with no obstacle
C. truck moving at 10km/h in correspondence of the storm drain
D. truck moving at 30km/h with obstacle
E. truck moving at 10km/h with obstacle

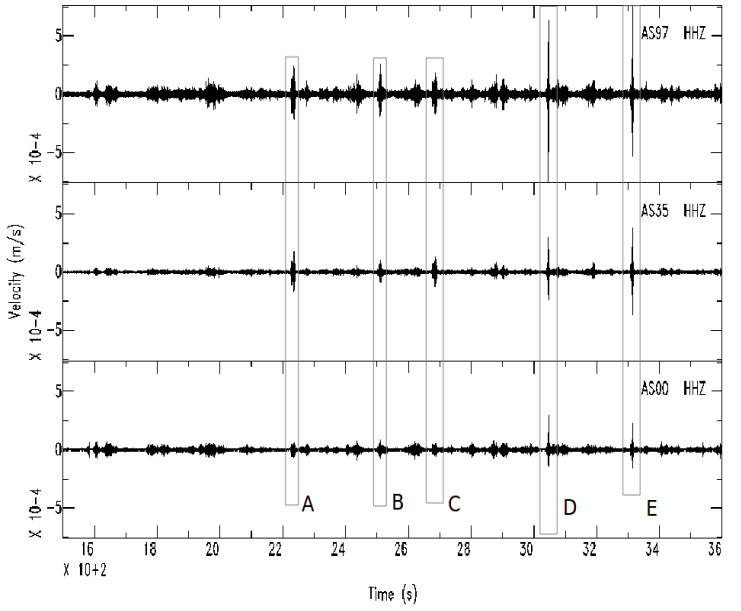

Figure 9. Vertical component waveforms recorded at the three measurement points during the five passages of the truck.

As is evident from Figure 9, during the first three passages (A,B,C) the amplitude of motion along the vertical component of the base didn't exceed the maximum average vibration recorded in absence of input. During the last two tests (D and E), the input at the base was significantly stronger. In these cases at both the stations inside the Tower beatings were recorded, similar to those observed during the continuous monitoring (Figure 10). This seems to confirm that the input at the base produced by heavy traffic along the roads surrounding the Towers is responsible for the observed beatings. The acceleration and displacement peak values (PGA and PGD) recorded during the tests were computed and collected in Table 2. The maximum values of PGA and PGD recorded at the top along the horizontal direction refer, as expected, to the two most energetic tests (D, E). They are equal to 3 mg and 0.4 mm respectively (Table 2).

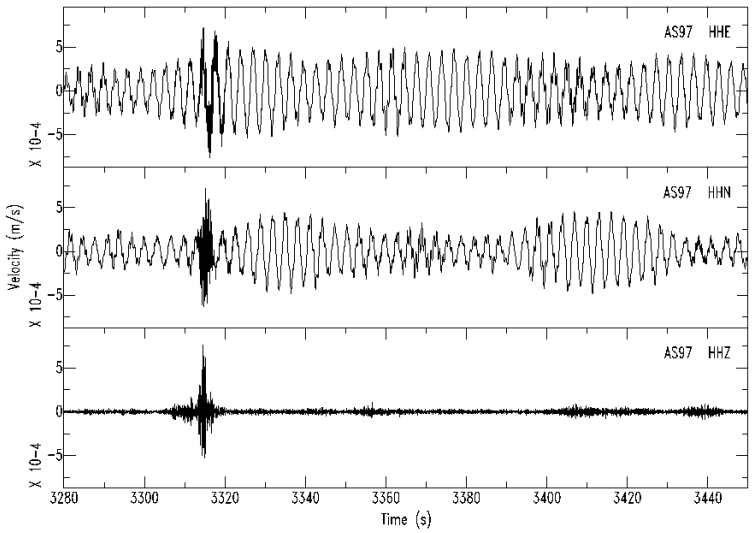

Figure 10. Waveforms recorded during the most energetic test (E) at the top level station, from top to down respectively EW, NS and Z components.

Acceleration		Test A	Test B	Test C	Test D	Test E
		mg	mg	mg	mg	mg

CONCLUSIONS

The main conclusions of the study can be summarized as follows:

- The experimental modal frequencies determined from the dynamic monitoring performed between 2012 and 2014 result in good agreement with those obtained from modal analysis performed on the FE models.
- The long duration and the repetition over several years of the survey allowed to recognize a typical trend of the vibration of the Towers that at high frequency (1-20 Hz) seems to be strongly correlated to the surrounding anthropic sources. In particular, some specific transients propagating inside the Asinelli Towers triggered beatings that are evident at the top of the Tower.
- The passage of an heavy truck monitored during one specific experiment induced beatings that resulted to be similar to those evidenced during the long term monitoring.
- Further analyses are necessary to better interpret the observed beatings in order to identify possible relations between structural and material irregularities and the peculiar dynamic response.

ACKNOWLEDGEMENT

The authors gratefully acknowledge Dott. Ing. Gilberto Dallavalle who provided valuable information related to geometrical and material properties. The experimental activities have been partially funded by a collaboration contract between Bologna Municipality and INGV.

Abstract. *Vibration-based Structural Health Monitoring (SHM) is receiving increasing attention due to the high technological level that the developed methodologies are nowadays reaching, together with the increasing quest for the implementation of effective, but ideally of low-cost, monitoring instrumentation. The latter is relatively easy to deploy and allows for the recording of the structural vibration response at multiple locations, which, for large strategical infrastructures, such as high-rise buildings, bridges, wind farms, etc. may be of critical importance. On the other hand, low-cost instrumentation may typically be accompanied by high Noise-to-Signal (N/S) ratios, contaminating the structural response, increasing the induced uncertainties and rendering the implementation of SHM methods more difficult. This calls for appropriate and effective denoising processes. In tackling such an associated denoising problem, several methods have been proposed and are currently under further development. Among specific variants, the utilization of multi-rate filter banks, especially the one based on Discrete Wavelet Transform (DWT), as well as the application of Singular Value Decomposition (SVD), have revealed to be rather effective. Yet, they have mostly been applied to problems where structural vibration response signals originate from specific behavioral classes, as, e.g., in monitoring applications of rotating machinery. In this study, the aforementioned methods are reconsidered and reimplemented; then, assessed on noise-corrupted vibration response signals related to civil engineering applications. Different Noise-to-Signal (N/S) ratios and excitation types are considered, i.e. earthquake and ambient vibration input. Advantages and limitations of both denoising approaches are presented and discussed, with a critical comparison. The outcomes prove the effectiveness of the considered methods in clarifying earthquake response signals, yet also their difficulty in purifying ambient vibration signals, motivating further specific research on the filtering of this latter common class of structural response.*

1 INTRODUCTION

Due to ever increasing structural requirements and loading condition magnitudes to which civil engineering structures are continuously subjected, an effective and accurate evaluation of the safety of existing structures, as well as an appropriate estimation of their remaining lifetime, become more and more necessary. In particular, in the last few years, the increasing interest in predicting the potential deterioration and collapse of such critical infrastructures by collocating on them various sensors for detecting data related to their dynamic response, has led to the emergence of the field of Structural Health Monitoring (SHM). Many case studies in which the structural vibration response has been employed as a critical and directly measurable quantity for evaluating structural safety, may be found in the literature [1–4]. From all these examples, the availability of reliable data on structural safety, usability and fatigue resistance, represents an essential point for efficient SHM, aiming at preserving structural integrity over time. However, often either no updated information on the structural characteristics is available or it may result incomplete, or even noise affecting the signals may considerably alter the useful information embedded within the response signals themselves. Consequently, in many cases, the application of denoising techniques aiming at enhancing the data quality by removing the noise affecting the signals, might become necessary.

Several denoising approaches for dealing with signals have been developed and reported in the literature [5–7]. In particular, the application of band pass filters, such as high-pass and low-pass filters, may be considered as a most simple and rudimentary denoising method. The Fourier Transform might also be employed for denoising purposes [8]. However, all these mentioned approaches are ineffective when the noise is concentrated in a frequency band similar to that of the useful part of the signal, and this occurs in several real cases. In fact, this would mean removing not only the noise but also a relevant portion of the meaningful signal, which instead should be preserved.

In the last two decades, this has led to search for alternative denoising approaches able to overcome this issue, by removing the contaminated part of the signal without losing the important information contained within it. In particular, two important denoising approaches are identified, as focus herein, i.e., one based on a Discrete Wavelet Transform (DWT) implementation [9] and one based on a Signal Value Decomposition (SVD) algorithm [10]. In addition, a further interesting approach to the problem of signal denoising is the effectuated use of a Kalman Filter (KF), as a powerful tool to enhance noise-corrupted data, as presented in recent publications [11–13]. Specifically, in Ravizza et al. [13], a KF algorithm has been integrated into a Heterogeneous Data Fusion (HDF) scheme, aiming at improving the quality of displacement response signals detected on a numerical dynamic system.

In this paper, DWT- and SVD-based denoising approaches are reconsidered and independently implemented, in order to explore their effectiveness in dealing with signal typologies typical of civil engineering contexts, namely structural vibration response signals. This may open up to new perspectives in the post-processing of such signals; in fact, although these techniques have been already tested, for instance, on gravity and magnetic signals, biological signals such as electrocardiograms (ECG) or electroencephalograms (EEG), or even acoustic signals and pressure signals, their application on structural vibrational signals, typical of the civil engineering field, has not been deeply inspected yet. Furthermore, structural response data are crucial for SHM purposes, as their observation over time, also supported by the wide development of modal identification techniques for the acquisition of the structural modal features [14–16], may reveal variations in the physical properties of the monitored structure. This

might be related to the possible appearance of damage and, consequently, it could lead to a decay of the structural performance characteristics.

In particular, within the present analysis, seismic response and ambient vibration signals, in terms of acceleration, will be considered. This choice is motivated by the fact that, since these signals display a very different nature, i.e., non-stationary (seismic excitation) vs. stationary (ambient vibration), they could bring out different aspects inherent to the process of denoising, depending on the performed approach. A ten-story shear-type building is assumed as a benchmark reference structure, in order to generate simulated response signals, which are then subsequently contaminated with different levels of noise, and further denoised by means of the proposed techniques.

The main goal which this study aims to achieve is twofold:

- to inspect the effectiveness of denoising methods in dealing with response signals which are typical of the civil engineering context, i.e., ambient vibration and seismic acceleration response signals, through the assessment of their performance based on the comparison between the reconstructed denoised signal and the original clean one;
- to shed light on strengths and limitations of DWT- and SVD-based denoising approaches, depending on the amount of noise that affects the data, and as referring to the type of the response signal (ambient vs. seismic).

The paper is organized as follows. In Section 2 a brief description of the analysis procedure is provided, through the presentation of the benchmark dynamical system, the synthetic generation of last-floor's acceleration response signals (considering both seismic excitation and ambient vibration), and the process of their distortion by adding a Gaussian white noise. In Section 3, DWT- and SVD-based denoising approaches are performed on data affected by increasing noise levels, and results are presented and commented on. A critical comparison based on the performance evaluation of the two considered techniques is also presented. Conclusions and global remarks are finally outlined in Section 4, together with some possible future research perspectives.

2 ANALYSIS PROCEDURE

2.1 Problem statement

The traditional formulation of a generic signal denoising problem may be expressed according to the following relation:

$$\mathbf{y} = \mathbf{x} + \mathbf{n} \tag{1}$$

where $\mathbf{y} = (y_1, ..., y_i, ..., y_n)$ is the noise-affected signal which has to be processed, and that may be interpreted as the sum of a clean (noise-free) signal $\mathbf{x} = (x_1, ..., x_i, ..., x_n)$, which embeds the useful information to be preserved, and an additive noise signal $\mathbf{n} = \sigma(n_1, ..., n_i, ..., n_n)$, of intensity given by standard deviation σ, which may be modeled as a stationary independent zero-mean Gaussian term [17, 18], superimposed on the useful signal and altering its content.

The application of each numerical denoising technique aims at achieving a best approximation $\widehat{\mathbf{x}} = (\widehat{x}_1, ..., \widehat{x}_i, ..., \widehat{x}_n)$ of original (noise-free) signal $\mathbf{x}$, starting from noise-affected signal $\mathbf{y}$, removing most of the unwanted noise without losing the useful information. It is

worth mentioning that, at least at this preliminary stage of research, all signals involved within the analyses are constituted by *synthetic signals*, since this assumption allows to more deeply explore all possible strengths and limitations of the two studied denoising methods, rather than and before eventually considering *real signals*.

Several approaches have been presented in the literature in order to assess the effectiveness of denoising techniques [19–21]. Here, since both original (clean) signal $\mathbf{x}$ and denoised signal $\widehat{\mathbf{x}}$ are available, the Percentage Root Mean Square Difference (PrmsD) [22] value can be employed toward such purposes:

$$\text{PrmsD} = 100 \cdot \sqrt{\frac{\sum\limits_{i=0}^{n}(x_i - \widehat{x}_i)^2}{\sum\limits_{i=0}^{n} x_i^2}} \tag{2}$$

Small values of PrmsD are desirable for achieving a reliable approximation of original signal $\mathbf{x}$. In this study, PmrsD is considered as an evaluation term to compare the performances of DWT- and SVD-based denoising approaches in processing both stationary and non-stationary response signals.

2.2 Description of benchmark structure

In order to generate simulated acceleration response signals, a one-bay ten-story shear-type building is taken as a reference structure. For making the analysis as truthful as possible, realistic values of mass, stiffness and damping are assumed. In particular, for the first-floor, values of mass $m_1 = 100$ t and stiffness $k_1 = 4 \cdot 10^6$ kN/m are considered, while the upper floors are characterized by values of mass $m_i = 80$ t and stiffness $k_i = 3 \cdot 10^6$ kN/m, with $i = 2, ..., 10$. Furthermore, a modal damping ratio $\zeta_i = 5\%$, as typical of reinforced concrete structures, is assumed, for all the modes.

During the analysis, two different input typologies are considered acting on the structure, i.e. an earthquake acceleration excitation, acting at the base, and an ambient vibration force distribution, applied along the structure with a linear variation (increasing from bottom to top of the building). In both cases, the last-floor acceleration response signal is solely monitored, as it shall be associated to the most critical response values and, consequently, it may be enough to well characterize the whole structural response of the analyzed building.

2.3 Generation of noise-affected response signals

In this section, the procedure of generation of noise-affected response signals is shown. In particular, a zero-mean Gaussian white noise is added to the original (noise-free) signals, aims at simulating the intrinsic error characterizing the sensor technology, as well as the errors which might occur *"in situ"* at the signal acquisition stage. The fact that the added Gaussian white noise affects each single frequency component indifferently over the whole length of the signal, makes its removal always a challenging task. Here, the Noise-to-Signal (N/S) ratio is used to quantify the amount of noise, in relation to the useful signal. Although in today's sensor technology N/S ratios greater then 20% might be considered as unrealistic, or extremely rare, for a complete understanding of the limitations of the explored denoising techniques, in the present analysis N/S ratios up to 50% are taken into account. Two different types of excitation

are considered as acting on the benchmark structure, i.e., seismic input and ambient vibration input; whereupon, performing a classic direct analysis, the dynamic response of the system is obtained.

The analyzed non-stationary input is the earthquake excitation that struck Kalamata (Greece) in 1986, characterized by a Peak Ground Acceleration (PGA) of 0.24 g, magnitude of $M = 5.9$ and focal depth of 22 km. Such a seismic excitation has been assumed acting at the base of the reference building. The numerically-determined acceleration response signal related to the tenth floor is first obtained and then contaminated by adding a white Gaussian noise level of 25% N/S ratio, as depicted in following Fig. 1.

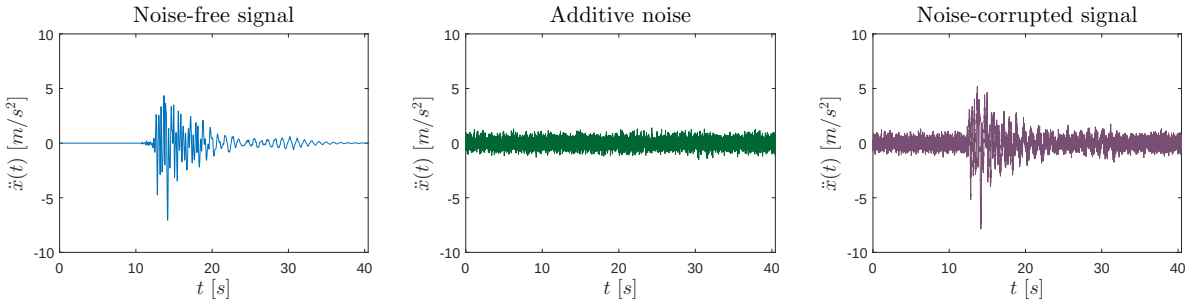

Figure 1: *10th-floor acceleration response signal of the benchmark structure under earthquake excitation input and subsequent noise addition process (25% N/S ratio).*

Ambient vibration, instead, represents the stationary excitation to which the structure is subjected to during its regular operating condition, and is commonly associated to environmental loads like wind, traffic load or wave motion. The last-floor dynamic acceleration response of the benchmark structural system under ambient vibration input is represented in Fig. 2, as well as the process of data corruption through the addition of a Gaussian white noise characterized by a N/S ratio of 25%.

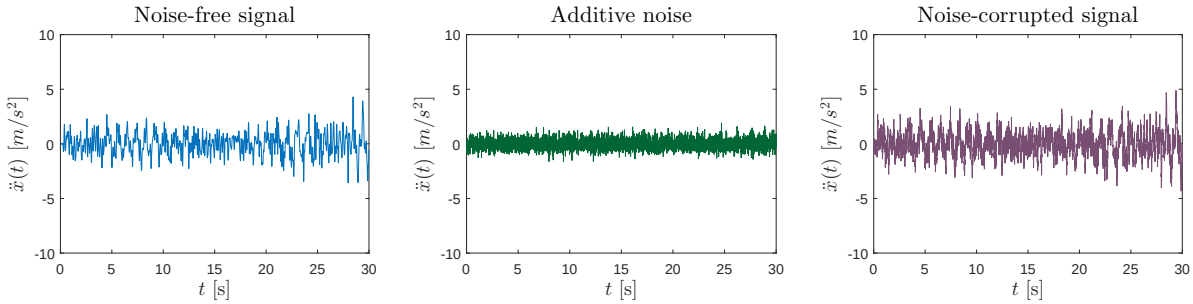

Figure 2: *10th-floor acceleration response signal of the benchmark structure under ambient vibration input and subsequent noise addition process (25% N/S ratio).*

The so generated noise-corrupted signals are now processed within a denoising implementation based on the application of DWT and SVD. The outcomes of the analysis are presented in next Section 3.

3 ANALYSIS RESULTS

3.1 DWT-based denoising application

The optimal calibration of the DWT-based denoising approach for dealing with seismic response signals has been first investigated through a criterion of minimization of the PmrsD index between the original (noise-free) signal and the denoised one. For this purposes, several mother wavelets (i.e. *Symlet, Coifet, Daubechies, Biorthogonal, Reverse Biorthogonal* and *Discrete Meyer*) and thresholding rules (i.e. *Heuristic SURE, Sqtwolog, Minimax* and *Rigorous SURE*) have been explored, with the optimal solution being identified in the adoption of *Smylet* with two oscillations in its mother wavelet combined with *Heursure* hard thresholding, at decomposition level 2. The results of the DWT-based denoising performed on a seismic acceleration response signal corrupted with a 25% N/S ratio are shown in Fig. 3. The small error which may be appreciated between the original signal and the denoised one reveals the effectiveness of the method in the clarification of such a non-stationary signal.

A similar procedure has then been applied for the denoising of an ambient vibration response signal. However, even though the denoising method based on DWT has been suitably recalibrated for dealing with this specific class of signals, in this latter case, the error which occurs between the original signal and the denoised one becomes more visible, as observed in the last graph in Fig. 4. In particular, here, the combination of *Coifet*, featuring two oscillations in its mother wavelet and *Minimax* hard thresholding at decomposition level 3 is adopted. The difficulty in the denoising of stationary signals and, in general, the relevant discrepancy in the obtained results seems to clearly show how the typology of the processed signal strongly affects the performances of the DWT-based denoising technique.

3.2 SVD-based denoising application

The SVD-based implementation exploited in this study for denoising purposes is based on the computing of the singular values associated to so-called Hankel matrix $\mathbf{A}$, which contains the noise-corrupted signal components that ought to be denoised. Since it has been shown that the noise mainly affects the small singular values of the signal, it follows that by removing those lower than a selected threshold, a new matrix $\hat{\mathbf{A}}$ (of a lower rank) containing solely the denoised signal components, may be obtained. Thus, in this process, the critical point is represented by the choice of the threshold value. To this end, here, a criterion based on the minimization of the PrmsD index between the noise-free and denoised signal has been adopted, which has led to the selection of a threshold value of 10.

In Fig. 5, the results of the SVD-based denoising approach performed on the non-stationary seismic response signal are shown. It may be asserted that, through the proposed SVD implementation, and despite the considered significant level of noise (i.e. 25% N/S ratio), the original signal has been almost completely reconstructed, as demonstrated by the very small error that can be appreciated.

A similar analysis has then been performed on the stationary ambient vibration response signal and, contrary to what was seen for the denoising approach based on DWT, in this case, satisfactory outcomes may still be achieved, as represented in Fig. 6. Thus, the SVD-based denoising technique seems to better fit the different nature of the considered input, providing a more stable solution and, thus, leading to a more reliable estimate of the original reference signal.

3.3 DWT- vs. SVD-based denoising techniques

In this section, a critical comparison based on the performance evaluation of the two analyzed denoising approaches in clarifying noise-affected response signals is presented. The effectiveness of both methods is assessed, depending on the typology of the processed signal (non-stationary vs. stationary) and on the level of Gaussian white noise added to the source data. For academic purposes, N/S ratios up to 50% are considered within the analysis, and a PrmsD value between the reference signal and the denoised one is computed for each noise level. Results are summarized in following Table 1, and depicted in Fig. 7.

N/S ratio [%]			**5**	**10**	**15**	**20**	**25**	**30**	**35**	**40**	**45**	**50**
PrmsD [%]	Seismic excitation	DWT	0.06	0.13	0.18	0.20	0.88	1.18	1.23	1.39	2.11	2.69
		SVD	0.23	0.34	0.46	0.55	0.44	0.69	0.59	0.55	0.60	0.71
	Ambient vibration	DWT	0.59	1.25	2.64	3.80	4.58	4.93	5.23	5.90	6.21	6.82
		SVD	0.15	0.07	0.21	0.39	0.57	0.53	0.66	1.19	2.33	2.88

Table 1: *PrmsD [%] index between original and denoised signal for different signal typologies and N/S ratios: DWT vs. SVD.*

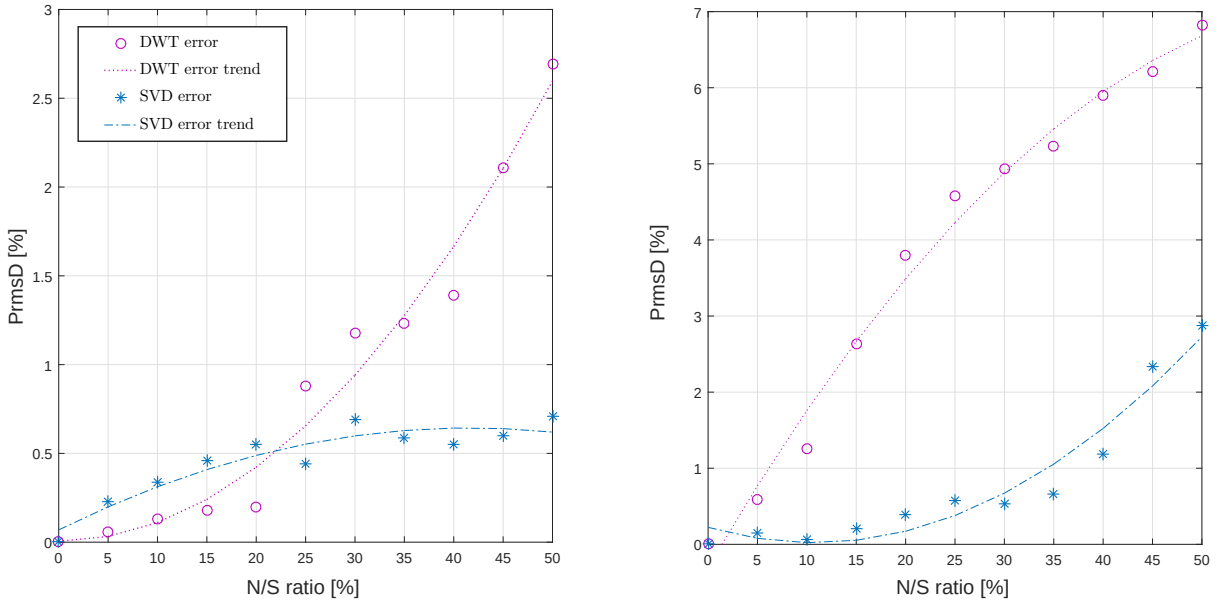

Figure 7: *Effectiveness evaluation of DWT- and SVD-based denoising techniques for increasing N/S ratios and different signal typologies: (a) earthquake excitation; (b) ambient vibration. Notice that scales on the PrmsD axes are different, almost twice for (b). Indicated trends come from a polynomial fit of degree 2.*

From the obtained outcomes it may be deduced that both considered denoising approaches seem to be well suited for dealing with non-stationary signals, and in particular for seismic response. However, the analysis performed on ambient vibration response has shown that, for the denoising of stationary signals, only the SVD-based technique leads to reliable estimates. This technique seems less affected by the level of noise considered in the source signals, in comparison to the DWT-based approach. Its robustness may also be better appreciated by the

graphs in Fig. 7, which plot the data in Table 1, where the error trends (in terms of PrmsD index) of the two denoising approaches are compared, considering the two studied typologies of source response signals.

4 CONCLUSIONS

In this paper, two different approaches for the denoising of (acceleration) structural response signals have been presented, i.e. one based on Discrete Wavelet Transform (DWT) and one based on Singular Value Decomposition (SVD). These two denoising techniques have been implemented with reference to simulated response signals typical of the civil engineering context, such as earthquake excitation and ambient vibration response signals. A ten-story shear-type building has been assumed as a benchmark structure, in order to generate the source noise-affected signals, and the last-floor acceleration response has been monitored.

Salient research contributions which this study is bringing to light may be briefly summarized as follows:

- stationary signals proved more problematic to purify than non-stationary ones, due to their almost constant distribution in time and frequency;
- the effectiveness of the SVD-based denoising method has been fully proven. It can be stated that it constitutes a rather robust technique, which is able to return reliable estimates of the original (noise-free) signal, despite for the significant amount of additive noise assumed on the source data. Moreover, this technique seems to be suitable for both non-stationary and stationary signals;
- The DWT-based approach may be considered as useful for the denoising of non-stationary signals, such as seismic response signals, especially for N/S ratios lower than 20%, where it may provide even better results than those for the SVD-based approach. However, the performed analysis has proven also its limitations in the processing of stationary signals, for which the application of the denoising method based on SVD is instead suggested.

Finally, after this first necessary phase of effectiveness assessment of the two denoising methods, in which only simulated signals have been considered, future developments shall concern the employment and denoising of real response signals (accelerations but also displacements), within the developed denoising procedure.

Abstract

Roads and railway tracks are a major focus of interest in transport infrastructure monitoring. Settlement in a road or railway track profile changes the dynamic excitation applied to passing vehicles. This, in turn, results in a changed dynamic response in the original source of loading, such as a passing vehicle. These changes in dynamic excitation make it possible to detect damage in transport infrastructure from the vehicle response. In this paper, the profile is calculated using accelerations in a passing vehicle and used to monitor transport infrastructure.

Keywords: Direct Integration, Drive-by, Profile, Railway Track, Acceleration, SHM.

1 INTRODUCTION

Roads and railway tracks are critical parts of transport infrastructure. They routinely become damaged with features emerging such as potholes in the roads and 'soft spots' in the railway track. These damages may influence the serviceable and safe operation of the transportation network. Therefore, infrastructure monitoring is an important area of research.

Railway tracks are subject to reductions in stiffness due to deteriorating foundations and to permanent fatigue deformations that result in a change in the track profile. The objective of this research is to identify local reductions of profile or stiffness that can help with the identification of problems related to track settlement, vehicle-ride comfort, track geometry and even ground-borne vibrations [1]. Railway track stiffness can currently be measured using specialised medium-speed vehicles or stationary equipment. A track recording vehicle (TRV) is a traditional method used by railway infrastructure managers to assess the condition of their network. A TRV is a specialised, instrumented train which periodically collects geometric data of the railway track including track gauge, longitudinal profile, alignment, super-elevation irregularity (cross level or cant) and twist. European Standard EN13848 defines the method of measurement of railway track using TRVs in Europe [2]. TRVs are the current preferred method of measurement for these parameters. However, they are expensive to operate and may disrupt regular services during operation. Using in-service vehicles to determine at least some of these parameters represents a possible alternative that can provide much more frequent measurements at much less cost [3].

In this method, sensors mounted on in-service vehicles collect accelerations and possibly other dynamic parameters. Improvements in band-width of wireless communications, reductions in sensor and data acquisition electronics cost have allowed the development of unattended track geometry inspection systems that are compact and robust enough to be mounted on in-service vehicles [4]. This concept of using trains in regular service to measure track stiffness has the potential to provide inexpensive daily 'drive-by' track monitoring to complement data collected by other less frequent (but more accurate) monitoring techniques.

Railway track longitudinal profile is also regard as indicator of serviceability condition. Perfectly level track profiles can minimise dynamic responses of the vehicle, which can increase passenger comfort, reduce power consumption and reduce wear on vehicle components. A reduction in vehicle dynamics also reduces the vehicle load on the track. Therefore, keeping a good vertical longitudinal profile helps maintain overall track condition through a reduction in vehicle dynamic effects [5].

Accelerometer(s) mounted on a vehicle also provide a way to measure road profile which is of low cost. González et al identify the relationship between vehicle accelerations and the power spectral densities of road surfaces using a transfer function [6]. The road condition is accurately classified by Fourier analysis which is used to calculate the power spectral density (PSD) function of the surface. OBrien et al present a drive-by method to monitor transport infrastructure (such as bridges and pavements) by analysing vehicle accelerations [7]. An algorithm is proposed to identify the dynamic vehicle-bridge interaction forces using the vehicle response. It is suggested that this method could be used to identify the global bending stiffness of the bridge and to predict the pavement roughness. This paper will use a new direct integration approach to calculate track and/or road profiles using vehicle accelerations. Points of low stiffness in the track are also determined as it is loaded track profile that is measured which is a combination of permanent deformation/profile and deflection in response to the weight of the train.

2 MODEL DESCRIPTION

2.1 Vehicle Model

The vehicle is represented by a 4 degree-of-freedom half-car model travelling on a beam-on-elastic-foundation track (Figure 1(a)) and rigid road (Figure 1(b)). The four independent degrees of freedom correspond to sprung mass bounce displacement, u_s, sprung mass pitch rotation θ_s and axle hop displacements of the unsprung masses at axles 1 and 2, u_{u1} and u_{u2} respectively. The vehicle body is represented by sprung mass, m_s. The axle components are represented by unsprung masses, m_{u1} and m_{u2}. The sprung mass connects to the axle masses via a combination of springs and dampers. The damping coefficients of viscous dampers are $C_{s,i}$ and stiffnesses of springs are $K_{s,i}$ which represent the suspension components for the front and rear axles ($i = 1,2$). The axle masses connect to the road or railway track surface via springs with linear stiffnesses, $K_{t,i}$ which represent the tyre components for the front and rear axles ($i = 1,2$). Finally, I_s is the sprung mass moment of inertia and the distances of the axles to the centre of gravity are D_1 and D_2. Table 1 gives the property values of the half-car.

Property	*Unit*	*Symbol*	*Half-Car and track model*	*Half-Car and road model*
Body mass	kg	m_s	16 200	16 200
Axle mass	kg	m_{u1}	700	700
		m_{u1}	1100	1100
Suspension stiffness	N/m	$K_{s,1}$	4×10^5	4×10^5
		$K_{s,2}$	1×10^6	1×10^6
Suspension damping	N s/m	$C_{s,1}$	1×10^4	1×10^4
		$C_{s,2}$	2×10^4	2×10^4
Tyre stiffness	N/m	$K_{t,1}$	1.75×10^6	1.75×10^6
		$K_{t,2}$	3.5×10^6	3.5×10^6
Pitch moment of inertia	kg m^2	I_s	111 193	93 457
Distance of axle to centre of gravity	m	D_1	4.13	2.375
		D_2	4.13	2.375

Table 1: Vehicle model properties.

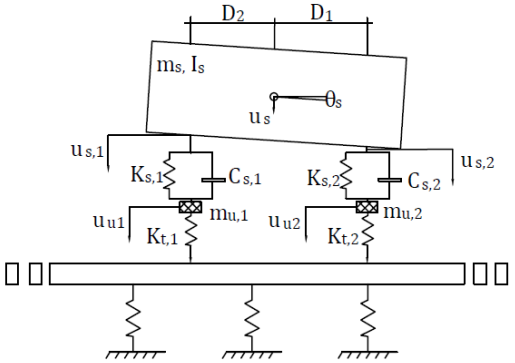

Figure 1(a): Half-Car and track model.

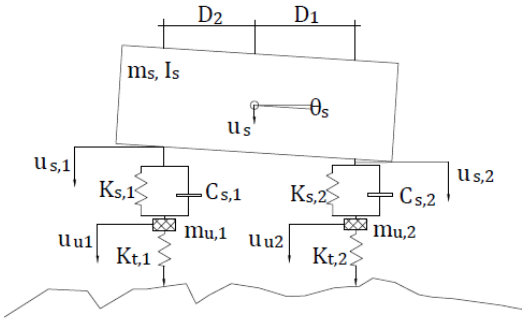

Figure 1(b): Half-Car and road model.

The equations of motion of the vehicle are obtained by imposing equilibrium of all forces and moments acting on the vehicle:

$$\mathrm{M}_v\ddot{u}_v + C_v\dot{u}_v + \mathrm{K}_v u_v = f_v \tag{1}$$

where M_v, C_v, and K_v are the mass, damping and stiffness matrices of the vehicle respectively. The vehicle accelerations, velocities and displacements are represented by vectors, $\ddot{u}_v$, $\dot{u}_v$ and u_v respectively, where the displacement vector of the vehicle is,

$$u_v = \{u_s, \theta_s, u_{u1}, u_{u2}\}^T \tag{2}$$

The time-varying dynamic interaction force vector is,

$$f_v = \{0,0,F_{t1},F_{t2}\}^T \tag{3}$$

The dynamic interaction force at wheel *i* is,

$$F_{ti} = K_{t,i} \times y_i \tag{4}$$

$i = 1,2$, where y_i is the road or track profile. The mass, damping and stiffness matrices are:

$$\mathrm{M_v} = \begin{bmatrix} m_s & 0 & 0 & 0 \\ 0 & I_s & 0 & 0 \\ 0 & 0 & m_{u,1} & 0 \\ 0 & 0 & 0 & m_{u,2} \end{bmatrix} \tag{5}$$

$$\mathrm{C_v} = \begin{bmatrix} C_{s,1}+C_{s,2} & D_1C_{s,1}-D_2C_{s,2} & -C_{s,1} & -C_{s,2} \\ D_1C_{s,1}-D_2C_{s,2} & {D_1}^2C_{s,1}+{D_2}^2C_{s,2} & -D_1C_{s,1} & D_2C_{s,2} \\ -C_{s,1} & -D_1C_{s,1} & C_{s,1} & 0 \\ -C_{s,2} & D_2C_{s,2} & 0 & C_{s,2} \end{bmatrix} \tag{6}$$

$$\mathrm{K_v} = \begin{bmatrix} K_{s,1}+K_{s,2} & D_1K_{s,1}-D_2K_{s,2} & -K_{s,1} & -K_{s,2} \\ D_1K_{s,1}-D_2K_{s,2} & {D_1}^2K_{s,1}+{D_2}^2K_{s,2} & -D_1K_{s,1} & D_2K_{s,2} \\ -K_{s,1} & -D_1K_{s,1} & K_{s,1}+K_{t,1} & 0 \\ -K_{s,2} & D_2K_{s,2} & 0 & K_{s,2}+K_{t,2} \end{bmatrix} \tag{7}$$

2.2 Road model

In this paper, a 100 m road profile is generated by Monte Carlo simulation according to the ISO standard [8]. It simulates a class 'A' road which is a 'very good' profile, typical of a well-maintained highway. The geometric spatial mean is 8×10^{-6} m^3/cycle. A moving average filter

is applied to the generated road profile heights, y_i. It is over a distance of 0.24 m to simulate the attenuation of short wavelength disturbances by the tyre contact patch [7,9].

2.3 Track Model

In past work, the railway track is represented using a beam-on-elastic-foundation model [1]. This model features a single layer of discrete elastic springs. Figure 1(a) shows the beam-on-elastic-foundation track model. It features an elastic beam (the rail) supported on some springs with different stiffness, k. Track supports have regular interval spacing, L_s, representing the spacing between the sleepers. A UIC60 rail is simulated as a finite element Euler-Bernoulli beam with one beam element per sleeper spacing. Each track element has 2 nodes with 2 degrees of freedom (DOF), vertical translation and rotation, at each node. Rail irregularities are not considered in this research which means the track profile is entirely from deflection of the springs under the loaded train.

3 DIRECT SOLUTION OF PROFILE CALCULATION

The forward problem and the inverse problem are features of any profile calculation. The forward problem is to find vehicle accelerations, velocities and displacements for a given profile. The inverse problem, in contrast, uses given $\ddot{u}$ and $\dot{\theta}_s$to find the profile. In previous research, the inverse problem is solved using a complex optimisation procedure [10]. It repeatedly solves the problem for thousands of trial profiles, until a good match is achieved between measured and theoretical accelerations. It also should repeat this for each segment of track/road. In this paper, the direct integration approach is proposed to solve the inverse problem directly to find the profile.

The forward problem is solved first. In the forward problem calculation, a 'true' profile is used to generate the 'measured' sprung mass accelerations and sprung mass pitch rotational velocity. Then, to test the method of solving the inverse problem, the profile y_i is calculated with these 'measured' sprung mass accelerations and sprung mass pitch rotational velocities. All problems are solved here using the Newmark-Beta integration scheme and simulated in MATLAB.

In the Newmark-Beta integration scheme, a value of γ=0.5 is used to ensure unconditional stability of the algorithm. In the Newmark-Beta method, the integration constants are chosen as:

$$\text{Time step } \Delta t,\ \ \gamma = 0.5, \beta = \ 0.25 \times (0.5 + \gamma)^2$$

$$a_0 = \frac{1}{\beta \times \Delta t^2},\ a_1 = \frac{\gamma}{\beta \times \Delta t},\ a_2 = \frac{1}{\beta \times \Delta t}, a_3 = \frac{1}{\beta \times 2} - 1, a_4 = \frac{\gamma}{\beta} - 1, \tag{8}$$

$$a_5 = \frac{\Delta t}{2} \times \left(\frac{\gamma}{\beta} - 2\right), a_6 = (1 - \gamma) \times \Delta t, a_7 = \ \gamma \times \Delta t$$

The profile is calculated step by step in the process as follows: The sprung mass bounce acceleration, $\ddot{u}$ and the sprung mass pitch rotational velocity, $\dot{\theta}_s$ are taken to be known at first. Then the sprung mass bounce displacement, u_s, and velocity, $\dot{u}_s$, sprung mass pitch rotational displacement, θ_s, and accelerations, $\ddot{\theta}_s$, can be calculated using the Newmark-Beta integration scheme:

$$u_{s,t+\Delta t} = (\ddot{u}_{s,t+\Delta t} + a_2 \times \dot{u}_{s,t} + a_3 \times \ddot{u}_{s,t})/a_0 + u_{s,t} \tag{9}$$

$$\dot{u}_{s,t+\Delta t} = \dot{u}_{s,t} + a_6 \times \ddot{u}_{s,t} + a_7 \times \ddot{u}_{s,t+\Delta t} \tag{10}$$

$$\theta_{s,t+\Delta t} = (\dot{\theta}_{s,t+\Delta t} + a_4 \times \dot{\theta}_{s,t} + a_5 \times \ddot{\theta}_{s,t})/a_1 + \theta_{s,t} \quad (11)$$

$$\ddot{\theta}_{s,t+\Delta t} = a_0 \times (\theta_{s,t+\Delta t} - \theta_{s,t}) - a_2 \times \dot{\theta}_{s,t} - a_3 \times \ddot{\theta}_{s,t} \quad (12)$$

According to Equations (1) to (7), the equations of motion of the sprung mass can be found:

$$m_s \times \ddot{u}_{s,t+\Delta t} + (C_{s,1} + C_{s,2}) \times \dot{u}_{s,t+\Delta t} + (D_1 C_{s,1} - D_2 C_{s,2}) \times \dot{\theta}_{s,t+\Delta t} - C_{s,1} \times \dot{u}_{u1,t+\Delta t} - C_{s,2} \times \dot{u}_{u2,t+\Delta t} + (K_{s,1} + K_{s,2}) \times u_{s,t+\Delta t} + (D_1 K_{s,1} - D_2 K_{s,2}) \times \theta_{s,t+\Delta t} - K_{s,1} \times u_{u1,t+\Delta t} - K_{s,2} \times u_{u2,t+\Delta t} = 0 \quad (13)$$

$$I_s \times \ddot{\theta}_{s,t+\Delta t} + (D_1 C_{s,1} - D_2 C_{s,2}) \times \dot{u}_{s,t+\Delta t} + ({D_1}^2 C_{s,1} + {D_2}^2 C_{s,2}) \times \dot{\theta}_{s,t+\Delta t} - D_1 C_{s,1} \times \dot{u}_{u1,t+\Delta t} + D_2 C_{s,2} \times \dot{u}_{u2,t+\Delta t} + (D_1 K_{s,1} - D_2 K_{s,2}) \times u_{s,t+\Delta t} + ({D_1}^2 K_{s,1} + {D_2}^2 K_{s,2}) \times \theta_{s,t+\Delta t} - D_1 K_{s,1} \times u_{u1,t+\Delta t} + D_2 K_{s,2} \times u_{u2,t+\Delta t} = 0 \quad (14)$$

The terms, $\dot{u}_{u2,t+\Delta t}$ and $u_{u2,t+\Delta t}$ can be removed by combining Equations (14) with Equations (13), scaled by D_2:

$$D_2 m_s \times \ddot{u}_{s,t+\Delta t} + D_2(C_{s,1} + C_{s,2}) \times \dot{u}_{s,t+\Delta t} + D_2(D_1 C_{s,1} - D_2 C_{s,2}) \times \dot{\theta}_{s,t+\Delta t} + D_2(K_{s,1} + K_{s,2}) \times u_{s,t+\Delta t} + D_2(D_1 K_{s,1} - D_2 K_{s,2}) \times \theta_{s,t+\Delta t} + I_s \times \ddot{u}_{s,t+\Delta t} + (D_1 C_{s,1} - D_2 C_{s,2}) \times \dot{u}_{s,t+\Delta t} + ({D_1}^2 C_{s,1} + {D_2}^2 C_{s,2}) \times \dot{\theta}_{s,t+\Delta t} + (D_1 K_{s,1} - D_2 K_{s,2}) \times u_{s,t+\Delta t} + ({D_1}^2 K_{s,1} + {D_2}^2 K_{s,2}) \times \theta_{s,t+\Delta t} = (D_2 C_{s,1} + D_1 C_{s,1}) \times \dot{u}_{u1,t+\Delta t} + (D_2 K_{s,1} + D_1 K_{s,1}) \times u_{u1,t+\Delta t} \quad (15)$$

In the Newmark-Beta method,

$$\dot{u}_{u1,t+\Delta t} = a_1 \times (u_{u1,t+\Delta t} - u_{u1,t}) - a_4 \times \dot{u}_{u1,t} - a_5 \times \ddot{u}_{u1,t} \quad (16)$$

Substituting (16) into (15), the unsprung mass displacement can be calculated:

$$u_{u1,t+\Delta t} = (D_2 m_s \times \ddot{u}_{s,t+\Delta t} + I_s \times \ddot{\theta}_{s,t+\Delta t} + (D_2 C_{s,1} + D_1 C_{s,1}) \times \dot{u}_{s,t+\Delta t} + (D_2 D_1 C_{s,1} + {D_1}^2 C_{s,1}) \times \dot{\theta}_{s,t+\Delta t} + (D_2 K_{s,1} + D_1 K_{s,1}) \times u_{s,t+\Delta t} + (D_2 D_1 K_{s,1} + {D_1}^2 K_{s,1}) \times \theta_{s,t+\Delta t} + (D_2 C_{s,1} + D_1 C_{s,1}) \times (a_1 \times u_{u1,t} + a_4 \times \dot{u}_{u1,t} + a_5 \times \ddot{u}_{u1,t}))/(D_2 K_{s,1} + D_1 K_{s,1} + (D_2 C_{s,1} + D_1 C_{s,1}) \times a_1) \quad (17)$$

Unsprung mass acceleration and velocity can be calculated using the Newmark-Beta method:

$$\ddot{u}_{u1,t+\Delta t} = a_0 \times (u_{u1,t+\Delta t} - u_{u1,t}) - a_2 \times \dot{u}_{u1,t} - a_3 \times \ddot{u}_{u1,t} \quad (18)$$

$$\dot{u}_{u1,t+\Delta t} = \dot{u}_{u1,t} + a_6 \times \ddot{u}_{u1,t} + a_7 \times \ddot{u}_{u1,t+\Delta t} \quad (19)$$

This is used to calculate $f_{v,t+\Delta t}$ at time step, $t + \Delta t$,

The effective stiffness matrix is:

$$\bar{K} = K_v + a_0 \times M_v + a_1 \times C_v \quad (20)$$

The effective force is:

$$\bar{f}_{v,t+\Delta t} = \bar{K} \times u_{v,t+\Delta t} \quad (21)$$

and,

$$f_{v,t+\Delta t} = \bar{f}_{v,t+\Delta t} - \mathrm{M}_v \times (a_0 \times u_{v,t} + a_2 \times \dot{u}_{v,t} + a_3 \times \ddot{u}_{v,t}) - C_v \times (a_1 \times u_{v,t} + a_4 \times \dot{u}_{v,t} + a_5 \times \ddot{u}_{v,t}) \quad (22)$$

According to Equation (3), $f_{v,t+\Delta t} = \{0,0,F_{t1,t+\Delta t},F_{t2,t+\Delta t}\}^T$, so $F_{ti,t+\Delta t}$ is known, and the profile can be found according to Equation (4):

$$y_{i,t+\Delta t} = F_{ti,t+\Delta t}/K_{t,i} \tag{23}$$

The calculated road profile and track profile are shown in the Figure 2(a) and Figure 2(b) respectively. The results show that the profiles are found with a great degree of accuracy. This direct integration approach allows the calculation to be completed in a very short time which is massively more efficient than an optimisation approach.

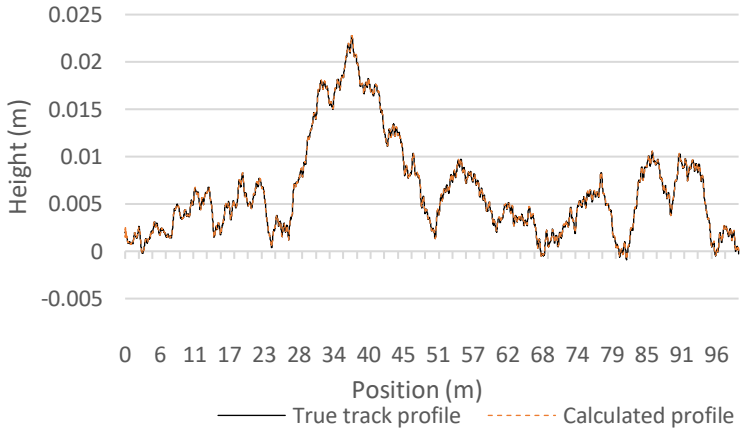

Figure 2(a): Calculated road profile and true profile.

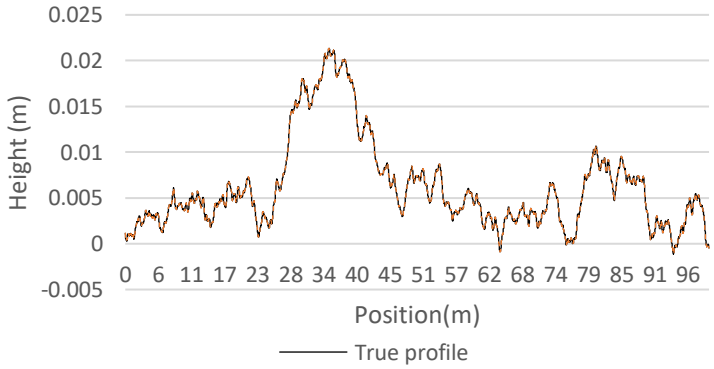

Figure 2(b): Calculated track profile and true profile.

4 DAMAGE IN RAILWAY TRACK

Local variations in the track stiffnesses can be detected from the calculated track profile which is effectively a combination of profile and deformations under load. In this example, there is a 50% loss in the track stiffness from 60 m to 65 m. This changes the 'measured' accelerations and rotational velocities. Using these changed signals, the new deflected profiles are calculated. The calculated track profile with and without a local reduction in railway track stiffness are shown in Figure 3. The results show that calculating track profile is a good means of identifying defects in the track.

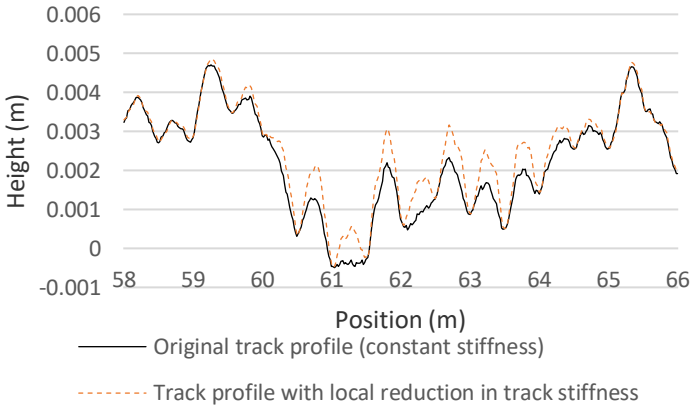

Figure 3: Calculated track profile with variations in railway track stiffness.

5 CONCLUSIONS

This paper introduces a new method of monitoring transport infrastructure. A direct integration approach is proposed to calculate road and railway track profiles using measured accelerations from vehicles. The direct method is used to calculate profiles using these 'measured' accelerations. The results show that the calculated profiles are the same as the 'true' profiles which are from the forward problem (used to generate the accelerations). What is more, direct integration is much more efficient and allows the calculation to be completed much more quickly in comparison to the optimisation procedure used by previous researchers. Also, the calculated track profile can be used to detect local variations in railway track stiffness. It has good potential as a means of detecting areas where railway tracks have suffered a reduction in stiffness.

Abstract

Continuous vibration-based structural monitoring is increasingly used to assess the state of health of existing structures and infrastructures in environmental conditions through non-invasive methods that allow, in most cases, an early identification of damage. To date, the innovative wireless smart sensor networks are the subject of numerous researches in the field of structural health monitoring, but their use on real structures is still limited, due to problems related to energy consumption and algorithmic optimization. In fact, most of the traditional identification algorithms work in centralized topology and are not suitable for electronic elements with low computational capacity. Nevertheless, the high energy consumption of wireless communication does not allow continuous data transmission for centralized processing in real time. However, the limited costs of new technologies, compared to traditional wired acquisition systems, shifts the interest towards innovative solutions, both from an algorithmic and hardware point of view, in order to provide innovative monitoring systems that can also be used on minor structures, for which traditional systems would be inaccessible. This paper presents a first practical application of a structural identification algorithm specifically designed for low-cost embedded electronic systems on a scaled laboratory model. The proposed solution consists of a single sensing node able to identify natural frequencies in real time, even in conditions of non-stationary excitation and variable structural characteristics. The estimated parameters are periodically uploaded to a cloud platform, where a preliminary real-time damage detection takes place.

1 INTRODUCTION

In order to ensure the reliability and efficiency of existing civil structures, they have to be properly maintained. Because of the strict constraints of architectural conservation, the preservation of historical buildings mainly means monitoring [1]. For this reason, in recent decades, infrastructures and buildings of strategic and monumental importance have been equipped with advanced vibration-based structural health monitoring systems that allow to detect any changes in the dynamic characteristics potentially connected with ongoing damage [2-3]. Nevertheless, recent news has highlighted the fact that maintenance, and then monitoring, is of the utmost importance also for minor structures and infrastructures, which could undergo fatigue load cycles or other forms of degradation during their rated life time. However, providing each viaduct or building of traditional monitoring systems would be difficult due to the prohibitive costs of traditional sensors and related equipment.

Nowadays, by using the most recent Micro Electro-Mechanical Systems (MEMS) sensors combined with low-cost microcontrollers and wireless transmission modules, it is possible to design innovative monitoring solutions having less impact from the visual and economic point of view with respect to the traditional configurations based on wired piezoelectric sensors [4-5]. Furthermore, thanks to the computational capacity of the microcontrollers, part of the processing activities can be performed directly on board, making the system particularly suitable for applications in the Internet of Things (IoT) [6-11].

However, these systems have important limitations related with the weak computational abilities of processing units [5]. It is therefore of fundamental importance that the operational algorithms are simple and use few resources, both in terms of memory and energy consumption. For this reason, most of the traditional techniques used for modal identification and damage estimation are not suitable for applications through the innovative low-cost systems.

In this paper, we propose a variant of a structural identification algorithm previously presented for multi-node monitoring networks [12]. This variant is specifically designed for single-node embedded systems and is able to estimate the first natural frequencies of the monitored structure in real time, in order to notice any changes that could be related with damage.

A first application on a scaled laboratory model is also presented. In particular, two acceleration channels collected by a single triaxial sensor are analyzed in order to compute the instantaneous natural frequencies of the first three vibration modes of the structure. The results are automatically uploaded to the cloud through a platform that allows the real-time visualization of data from any device connected to the Internet. Moreover, a simple procedure for measuring frequency variations with respect to the initial condition is implemented within the online platform in order to perform an early damage detection.

2 MONITORING SYSTEM

In this section, a brief description of the hardware and software parts is given. Both these aspects have been designed in order to exploit the computational capabilities of the implemented low-cost electronic devices.

2.1 Hardware configuration

The hardware implemented in this study consists of a sensing node and a gateway (Fig. 1). The node is an embedded system composed of a MEMS triaxial accelerometer connected to a microcontroller on which the preliminary signal processing procedures take place through the proposed identification algorithm. In the presented application, the node communicates via a wired one-to-one connection with the gateway, consisting of a single board computer with a

microprocessor that performs the modal identification. The gateway is wirelessly connected to the Internet in order to upload the identification results to a programmable data-logging application that allows simple post-processing activities, mainly aimed at data representation.

The sensor implemented in the proposed system is the digital low-power and low-noise-density ADXL-355 triaxial MEMS accelerometer by Analog Devices, with incorporated 20-bit analog-to-digital converter. An amplitude limit of ±2g has been selected, corresponding to a sensitivity of 256000 LSB/g and noise density of 20 μg/√Hz for an output data rate of 500 Hz. The accelerometer is connected via the serial peripheral interface (SPI) to an ARM Cortex-M3 microcontroller unit with 64 kB of flash memory and 20 kB of Random Access Memory (RAM). Some additional LEDs are connected to the microcontroller for debugging purposes.

The sensing node is connected via the Universal Asynchronous Receiver-Transmitter (UART) interface to the gateway, consisting of a Raspberry Pi 3 model B.

The overall cost of the hardware used in this study is very low, and much lower than the cost of traditional piezoelectric sensors, which are usually connected to onerous external monitoring stations.

In order to evaluate the quality of the signal collected through the implemented MEMS sensor, two mono-axial piezoelectric accelerometers 333B40 by PCB Piezotronics have been installed, with a sensitivity of 500 mV/g and noise density equal to 0.4 μg/√Hz for an output data rate of 1 kHz.

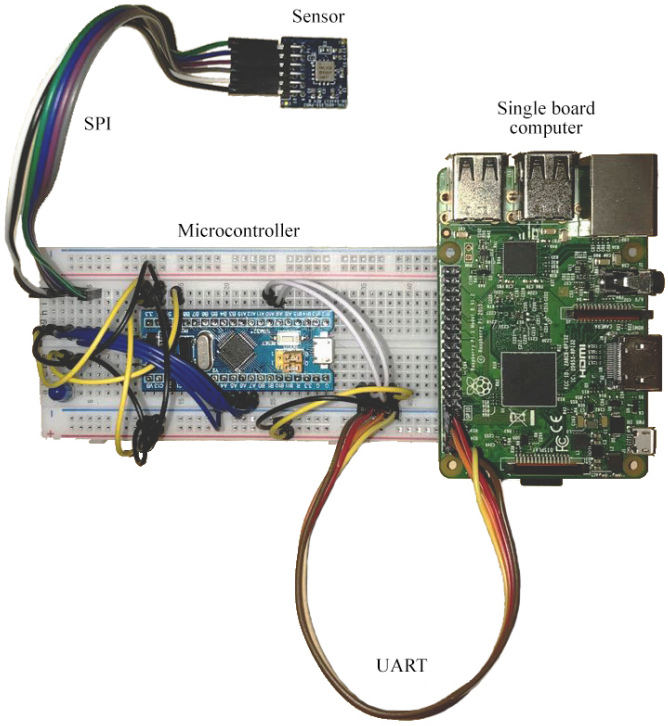

Figure 1: Hardware setup.

2.2 Algorithm description

The identification algorithm consists of two steps that are recursively performed to generate a signal-adaptive procedure. The first step involves the construction of a wavelet filter bank used to decompose the acquired signal in separate modal responses, while the second step lies in the real-time estimation of the instantaneous dynamic parameters (frequencies and amplitudes) for each component.

In particular, the first step involves the preliminary decomposition of the acceleration time histories collected on the structure in different positions and/or directions over a limited time window. The decomposition is performed through a wavelet filter bank, whose properties depend on the parameters selected at the base of the algorithm (i.e., the implemented wavelet function, its order, and the transform level). The signals are therefore decomposed into a series of components, each characterized by a narrow frequency band, which are subsequently grouped into clusters. Then, the signals associated to the same cluster are merged together and only the clusters whose energy (computed as the root mean square of the merged signals) is higher than a user-defined threshold (e.g., the mean value over all the clusters) are selected. Finally, a new filter bank is generated in order to extract by convolution only the selected components. This filter bank is used in the second step of the algorithm, that involves the real-time decomposition of acquired signals and the simultaneous identification of modal parameters.

In the algorithm presented in [12], the clustering procedure is based on the similarity of the operational deflection shapes computed for each component. Since in this application only one sensing node is used, in order to carry out the clustering procedure, the components extracted from two orthogonal channels collected by the same triaxial sensor are analysed, considering a bidirectional element of the operational deflection shape as clustering variable. This method is based on the assumption that the signal window used to build the filter bank is collected under 360° broadband input excitation.

Moreover, in this application, the modal identification is performed by using the Teager Energy Operator (TEO) [13], that allows to compute the instantaneous frequency and amplitude of each component by analysing extremely reduced signal windows. In particular, by implementing the Discrete-Time Energy Separation Algorithm-1 (DESA-1), only five samples per component are required to estimate an instantaneous parameter value, allowing a real-time and relatively simple evaluation of frequencies and amplitudes, easily performed on board low-cost electronic devices.

In this study, the first step is entirely performed on the gateway, while the second step is carried out partly on the node and partly on the gateway, exploiting the computational capacity of both the devices. The algorithm has been converted into a script for the microprocessor and a firmware for the embedded sensing system, the first aimed at the filter bank construction and modal identification, and the latter used to extract the modal components in real time, as illustrated in Fig. 2.

If the filter bank is no longer suitable for decomposing the modal responses due to a variation of modal parameters, it should be updated. For this reason, each identified frequency value is compared to the limits of the bandpass filters. If these limits are exceeded, the first step of the procedure is repeated.

The natural frequencies are temporarily stored on the on-board memory and, after applying a median filter and a downsampling, are logged on an online platform specifically designed for IoT applications. Here, the variation in terms of frequency for each vibration mode is calculated and plotted in real time, in order to allow users to access the identification results from any location at any time.

In addition, a simple script for damage detection has been written within the online platform. In a “training” window of user-defined duration, the median values of all the identified frequencies are determined. Then, the instantaneous variation of frequency for each mode and an average trend over all the identified modes are computed in the same window with respect to the median values. Finally, the maximum term in the averaged variation is multiplied by a user-defined factor and used as a threshold in damage detection (i.e. as the maximum allowed average frequency variation to consider the structure as undamaged).

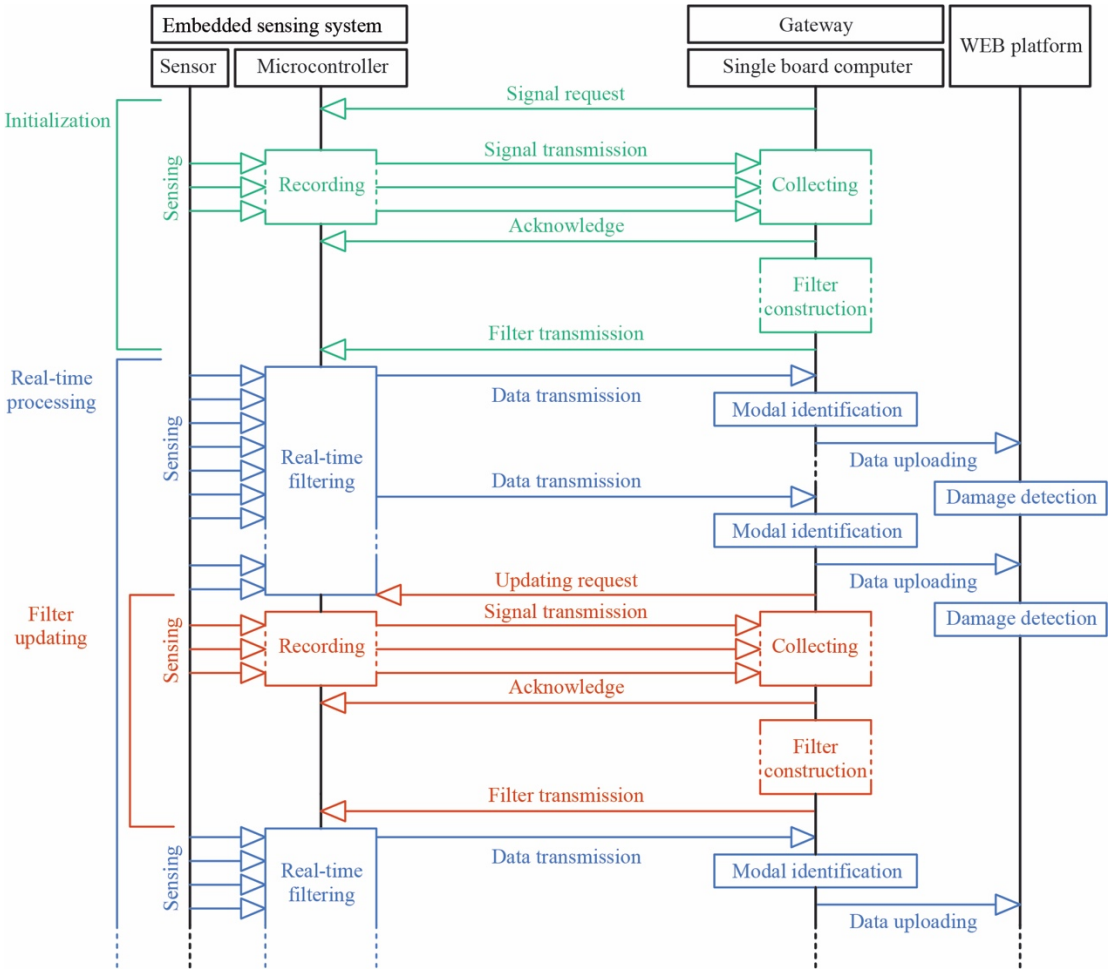

Figure 2: Workflow of the proposed algorithm.

3 APPLICATION

As a first application, the proposed monitoring system has been tested on a scaled steel laboratory model. The experimental tests have been conducted to evaluate the reliability of low-cost electronic devices for structural monitoring purposes and the effectiveness of the algorithm in estimating instantaneous natural frequencies.

This section gives a brief description of the specimen and the discussion of the results obtained during the experimental campaign. First, the accelerations recorded through the MEMS sensor implemented in the embedded system are compared with those obtained through a traditional piezoelectric acquisition system during an impulsive test, in order to evaluate the differences in the recorded signals. Subsequently, the results of real-time identification procedure performed through the proposed monitoring system under ambient vibration are reported.

3.1 Model description and experimental setup

The model is a three-level steel frame structure (Fig. 3) with a total height of 916 mm, whose base is formed by a 16 mm thick rectangular plate with main dimensions of 460x300 mm. Each level consists of a 12 mm thick plate measuring 400x300 mm and is supported by rectangular columns with a section of 40x3 mm. The connections between columns and plates are formed by L30x3 angle profiles and 72x40x3 mm flat plates held together by couples of M4 bolts with washers, as illustrated in Fig. 4. The net distance between each floor plate is 288 mm. The base plate and the top plate are connected to the columns through stud bolts.

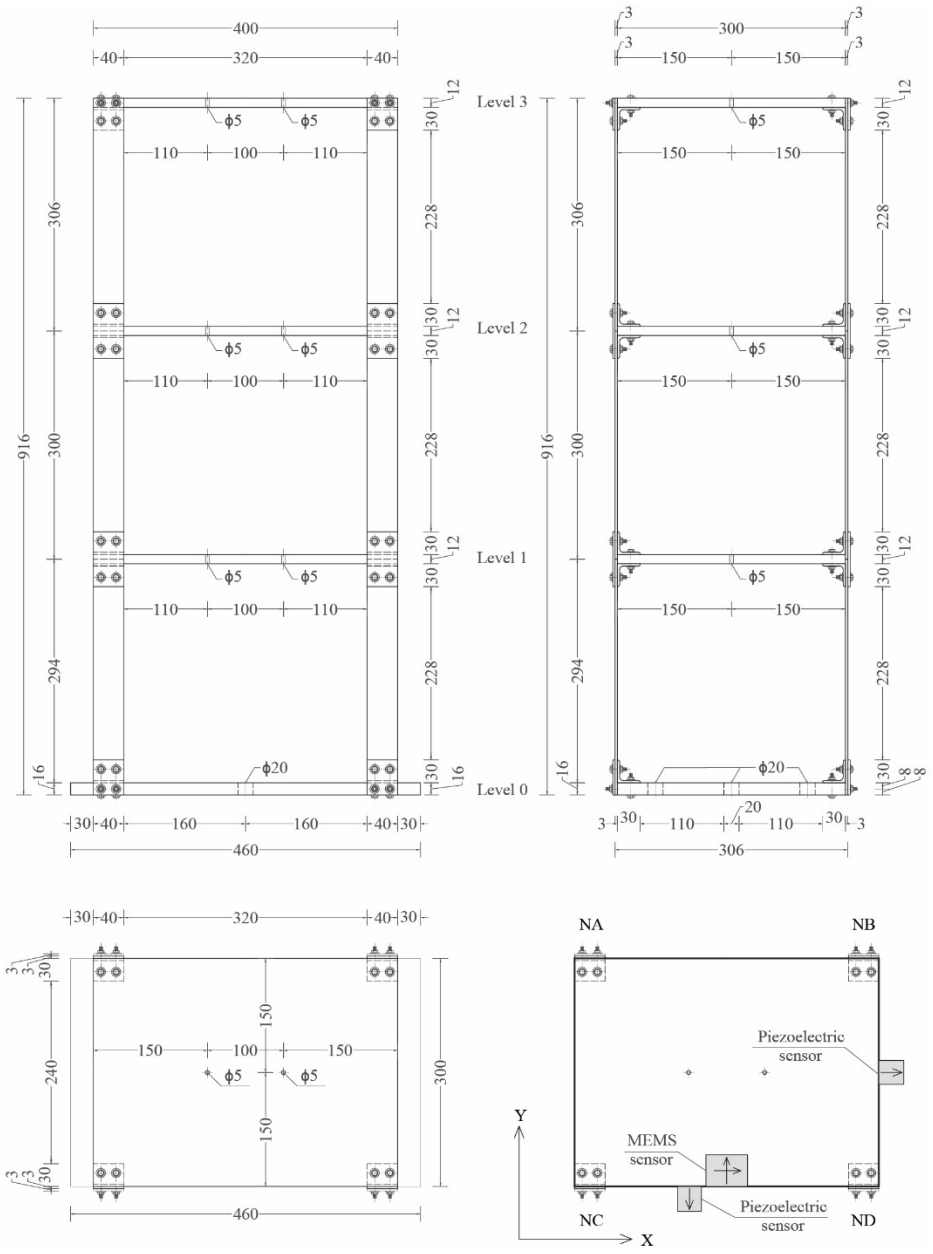

Figure 3: Front, side, and top view of the case study with sensor layout.

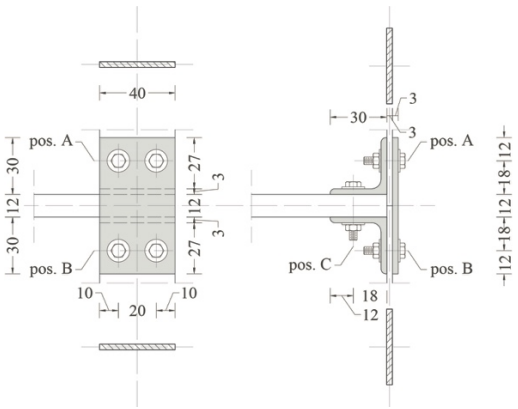

Figure 4: Detail of the connection between columns and plates.

In a preliminary analysis, the proposed monitoring system and two mono-axial piezoelectric sensors have been mounted on the last level of the structure, as shown in Fig. 3 and 5, in order to collect the response of an impulsive excitation along the same two acceleration channels (i.e., X and Y with reference to Fig. 3).

In a second analysis, only the proposed embedded system has been used to monitor the structural conditions under environmental excitation. In this case, several structural configurations (described in Tab. 1) have been reproduced in row, in order to simulate different operative and damaged conditions. After a "training" phase with the reference setup (U, represented in Fig. 3 and 5), four configurations characterized by different mass distributions have been considered. The first three conditions consist of an increase in the floor masses of around 12% (i.e., 1.5 kg steel elements placed on the floor plates), at the first level (MA), at the first and second levels (MB), and at all three levels (MC). Then, in condition MD, an additional mass of 1.5 kg has been introduced at the third level. Subsequently, all the additional masses have been removed in order to bring the structure back to its initial state (R). Then, two damaged configurations have been induced: the first consisted of loosening two bolts in position A for the node NA (with reference to Fig. 3 and 4) at the second level, while in the second configuration two additional bolts in the same position at the first level have been loosened.

Condition	Description	Duration [s]
U	Initial configuration	585
MA	Additional mass of 12% at level 1	605
MB	Additional masses of 12% at levels 1 and 2	610
MC	Additional masses of 12% at levels 1,2 and 3	550
MD	Additional masses of 12% at levels 1 and 2, 24% at level 3	605
R	All additional masses removed	605
DA	Loosened bolts at level 2	590
DB	Loosened bolts at levels 1 and 2	650

Table 1: Summary of the progressively induced structural conditions.

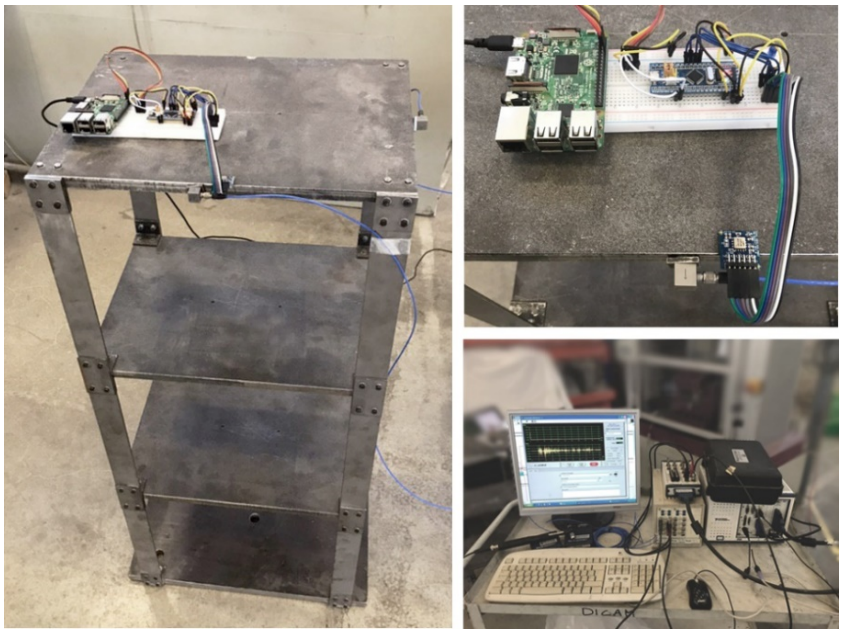

Figure 5: Model equipped with the proposed technology and the traditional sensors (left), detail of the sensor disposition (right-up), and traditional monitoring station used with piezoelectric sensors (right-down).

Acceleration data on all channels have been collected with a sampling rate of 100 Hz through the MEMS sensor and 1000 Hz through the piezoelectric accelerometers. The total duration of the experimental tests of the second analysis is 4800 seconds.

3.2 Considerations on the signal quality

The acceleration data collected by piezoelectric sensors have been first compared to those collected using the MEMS sensor. In Fig. 6, the time histories collected along direction Y (with reference to Fig. 3) after an impulsive excitation in the same direction, over a 30-second time window, are reported. Moreover, in Fig. 7 the intervals 0-50 Hz of the Fourier spectra of these signals are represented.

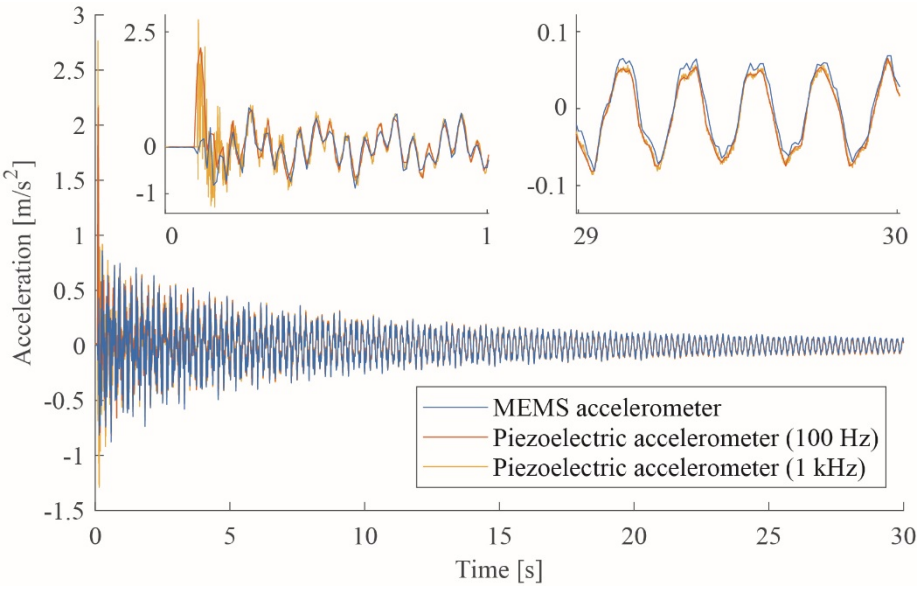

Figure 6: Comparison between the acceleration impulse responses in Y direction collected by the piezoelectric and MEMS accelerometers. In the upper part of the figure, two zoomed windows of 1 second are reported.

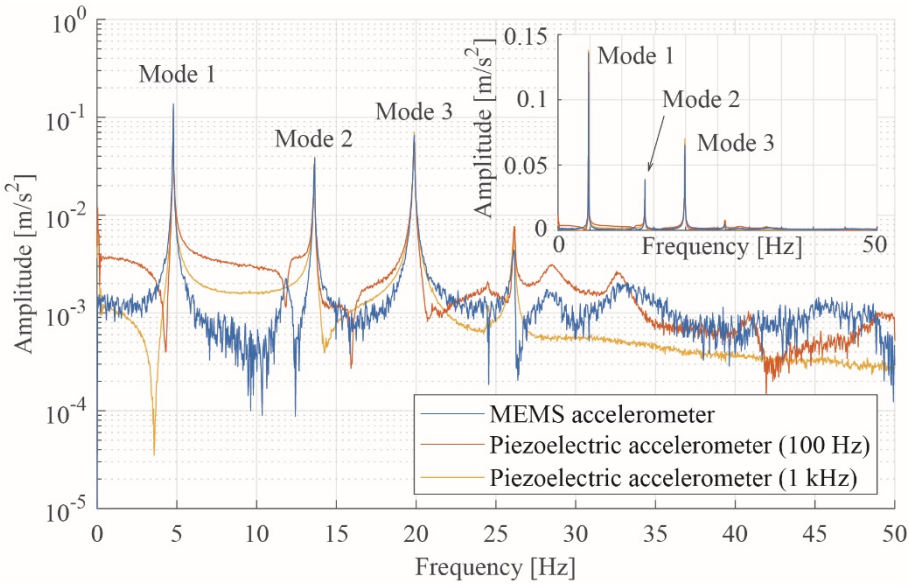

Figure 7: Fourier spectra obtained from the impulse responses. The main figure is represented on logarithmic scale, while the upper graph is on linear scale.

In particular, the first signal is the acceleration collected by the MEMS sensor, which is compared to the second signal obtained through the piezoelectric accelerometer, downsampled by a factor 10 in order to have the same sampling rate as the first. The third signal is the original acceleration recorded by the piezoelectric sensor, reported as a reference.

From Fig. 6 it is possible to observe, especially in the first part of the recording, how the signal obtained by using the piezoelectric sensor is considerably more accurate than the one measured through the MEMS sensor, also for the downsampled version. In fact, the ratio between the root mean square (RMS) of the difference between the two signals (considering the downsampled version for the piezoelectric sensor) and the RMS of the signal obtained through the MEMS sensor is equal to 0.42. However, it is possible to observe how the upper parts of first three peaks in the frequency spectra reported in Fig. 7, are almost coincident. In particular, the main differences are for lower amplitudes, and noticeable only by representing the spectrum on a logarithmic scale. For this reason, even if the MEMS sensor is less accurate, it still allows to correctly identify the first natural frequencies. The three identified peaks also correspond to the natural frequencies associated with the first three translational vibration modes in the Y direction of a finite element model designed to confirm the results obtained from modal analysis.

3.3 Results of the proposed system

Following the analyses performed to evaluate the signal quality, the modal identification algorithm has been applied using only the MEMS sensor under environmental vibration.

The wavelet function Fejér-Korovkin 14 has been chosen to build the filter bank used in the first phase of the identification algorithm. The wavelet transform has been performed up to the fifth order, generating a bank of 32 bandpass filters. Following the clustering procedure, based on the parameters computed over a 10-seconds initialization window, three signal components have been selected, associated with the first three modal responses.

With the application of DESA-1 algorithm, each value of the instantaneous natural frequencies has been computed considering only 5 acceleration samples. In order to lighten the computed parameters, a median value of the frequency has been calculated every 5 seconds. The results obtained for each vibration mode have been then uploaded to the cloud platform. The instantaneous frequency for each identified mode is represented over time in Fig. 8 as a solid line, while the state representing the reference condition, computed as the median value of each natural frequency over a training window of 50 samples obtained during the state U, is reported as dotted line.

During the real-time processing procedure, the estimated frequencies exceeded the limits of bandpass filters in two instants, indicated as vertical violet dashed lines in Fig. 8, where the filter bank has been updated following the scheme of Fig. 2. It can be noted that the proposed algorithm has shown particularly suitable also for detecting sudden changes in modal parameters, since the results reported in Fig. 8 has been calculated continuously, without interrupting the identification procedure during the changes in structural conditions.

Within the cloud platform, a script has been written to evaluate the frequency variation with respect to the baseline, in order to indicate any possible state of damage. The frequency variation has been evaluated with respect to the reference value computed during the training window. The results for the three identified modes and an average trend are reported as functions of time in Fig. 9. In this application, the criterion selected to define a condition as probably damaged consists in evaluating whether the average instantaneous frequency variation exceeds more than twice the maximum average variation value encountered in the training window.

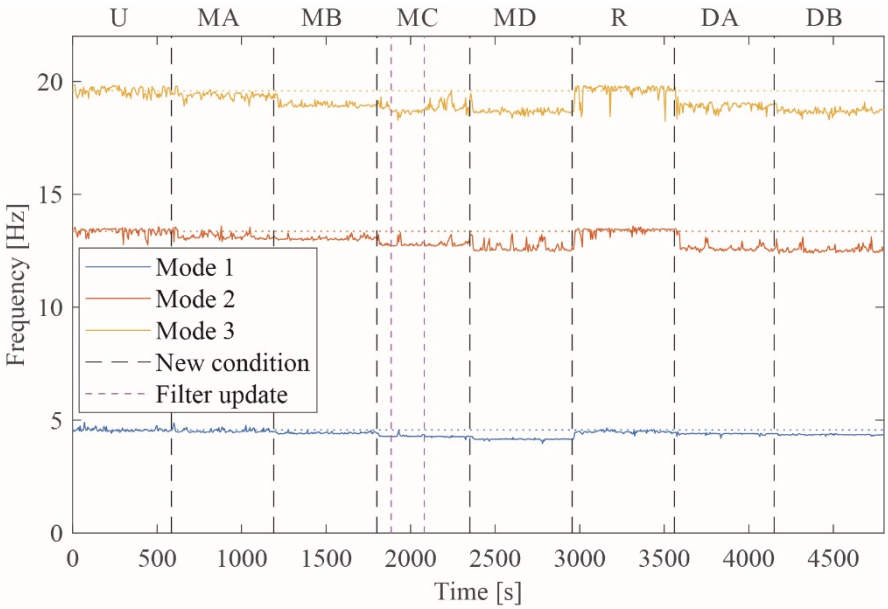

Figure 8: Instantaneous frequencies estimated through the proposed system during the experimental tests.

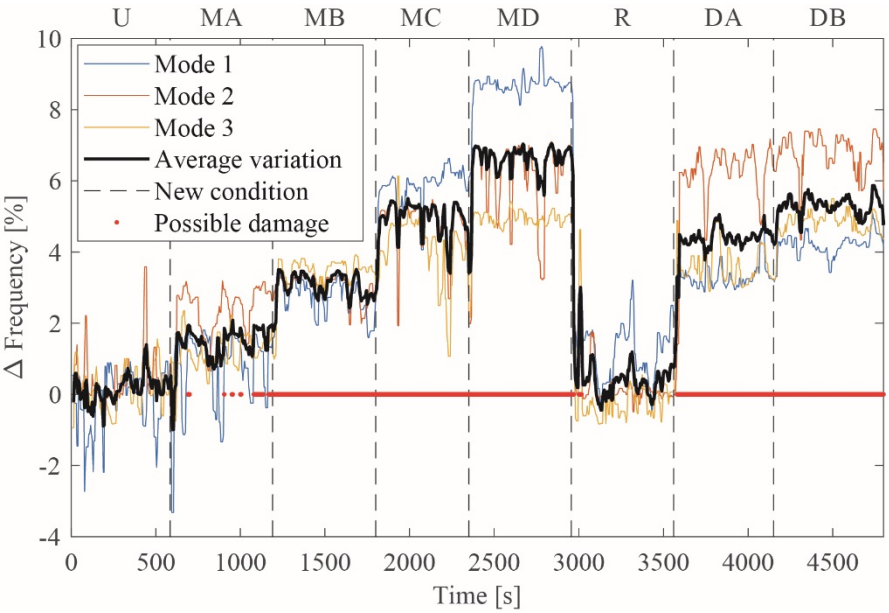

Figure 9: Instantaneous variation of frequency and damage detection performed through the algorithm written within the online platform.

In Fig. 9, the red dots represented on the time axis indicate the instantaneous detection of a "possibly damaged" configuration. Where the red sign appears continuous, a persistent damaged condition is detected, in which the frequency variation does not return within the bounds evaluated during the training interval. It is observable how all the operational and damaged condition have been indicated as "possibly damaged", with some missing alarms for the MA condition, where the frequency variation is in some parts comparable with the values of the training window. However, by applying a median filter with a window of 10 samples to the instantaneous frequency variations, the whole condition MA would be referred to as "possibly damaged" and the detection would become more robust.

4 CONCLUSIONS

In this paper, the implementation of a modal identification and damage detection algorithm on a specifically-designed electronic monitoring system has been presented. The algorithm proved to be particularly effective for the identification of dynamic parameters of a scale laboratory model, even if the quality of the accelerations obtained through the implemented MEMS sensor is lower than the quality of the recordings collected by piezoelectric accelerometers. In fact, also small variations in natural frequencies have been evaluated with sufficient accuracy to allow the distinction between all the considered structural configurations.

On-board processing was made possible by the simplicity and low amount of memory required by the identification algorithm. This allows to apply the proposed method through small, non-invasive and low-cost smart devices.

Abstract

This study aims to establish an evaluation method for bridge pier safety. To achieve this aim, a full-scale bridge pier was constructed, and a series of nondestructive tests were conducted using impact loads. The overburden loaded in the full-scale bridge pier was increased from 0 tonf up to 25 tonf by increments of 2.5 tonf. Impacts were applied to the upper and lower parts of the bridge pier in longitudinal, transverse, and lateral directions to analyze the behaviors of the bridge pier. Accelerometers were used to measure acceleration responses to impacts. Test results were converted to natural vibration frequencies according to impact direction and overburden using a fast Fourier transform algorithm. In addition, phase differences were utilized to analyze the behaviors of the bridge pier from the 1st to 4th modes. The effect of scouring was numerically analyzed. Ultimately, the safety of the bridge pier could be reasonably evaluated through the 2nd and 3rd modes.

1 INTRODUCTION

Special structures, such as railway bridges, and their social and economic impact are receiving more attention than ever. When a structure demands careful maintenance, an appropriate maintenance technology is needed to retain a target performance in accordance with the processes of rational inspection, measurement, evaluation, decision-making, maintenance, and reinforcement. In practice, however, most inspection works depend on manpower. Maintenance works also often lack data about past works, major drawings, and construction records, which are necessary for sufficient examination. Railway bridges do not collapse suddenly; they give signs in advance. The conventional practices of occasional manpower-centered inspection or regular inspection using a vehicle at a considerably long interval have limitations in identifying such signs. Many studies have been performed to develop a technology of detecting the collapse of bridge pier in advance, both at home and abroad. In Schoharie creek, New York, USA, in April, 1987, a bridge was washed away because of scour at the bottom of the footing foundation. This accident caused enormous financial damages and many casualties. After the tragic accident, the research fund for only the scour issue received nearly USD11M. Since then, research projects have been supported at the national level under the remit of National Cooperation Highway Research Program (NCHRP). Additionally, based on the outcomes of active research and assessment programs after 1987, the Federal Highway Administration (FHWA) prepared technical manuals (e.g., Hydraulic Engineering Circular (HEC)-18 (2012), HEC-20 (2001), and HEC-23 (1997)) for bridge scour, channel stabilization, and countermeasures and applied them to the analysis and designs of bridge scour.

However, most studies have focused on bridges built on sandy soils. Therefore, they did not consider the scour characteristics of the ground. The formula proposed by HEC-18 is commonly used for scour analysis. Because this formula is based on experimental data about sand, it is not valid or applicable to different soil conditions. Recently, the scour rate over time and time effects are considered for clay soils [1], and a new approach using erosion index is applied to rock sites [2].

In the Netherlands, the national project called “Dutch Delta Works” has been conducted to systematically and comprehensively investigate scour tendencies since 1953. This research project is led by Delft Hydraulics and the Ministry of Transport, Public Works, and Water Management. Delft Hydraulics performs numerous indoor experiments by considering various parameters about hydraulic characteristics and scour materials. A semi-empirical formula comprising functions of time and locations was derived. A comprehensive technical manual about the scour phenomenon was also proposed. This is the Breusers-equilibrium method and leverages the mean velocity of flow at the maximum scour depth, relative turbulent intensity, and dominant time characteristics [3].

In Japan, a method of evaluating the safety of foundations is being developed, utilizing the variation of natural frequency based on the vibration of the bridge pier caused by water-flow force. A soundness diagnostic index is also being prepared [4]. Keita and Michiko [5] proposed a soundness diagnostic index correlated to natural variation frequency by using the results of model experiments and field measurements. Bridge-collapse accidents are most likely to occur because of the scour, settlement, and cracks of bridge piers. The stability of the bridge substructure is closely related to bridge safety. Unfortunately, most safety inspections and tests in South Korea focus on issues about

bridge materials and superstructures. Thus, no quantitative evaluation method for substructure has been established. This study leverages a full-scale bridge pier where nondestructive impact tests were performed to achieve a method of deriving natural frequencies that could be used to assess the safety of bridge piers. Furthermore, a mode number analysis was conducted to ascertain the tendency of bridge behaviors under impact conditions.

2 NATURAL MODE NUMBER ANALYSIS OF BRIDGE PIER

2.1 Dimensions of full-scale bridge pier

We used a direct foundation type bridge pier to evaluate the characteristics of deteriorated foundations. The slab of the bridge foundation was 5.15-m long, 2.42-m wide, and 0.50-m tall. The pier was constructed to have a height of 4.5 m by repeating the process of placing 1.5-m thick concrete sections and curing three times. The length and width of the pier were 4.15 m and 1.42 m, respectively. Fig. 1 shows the dimensions of the full-scale bridge pier.

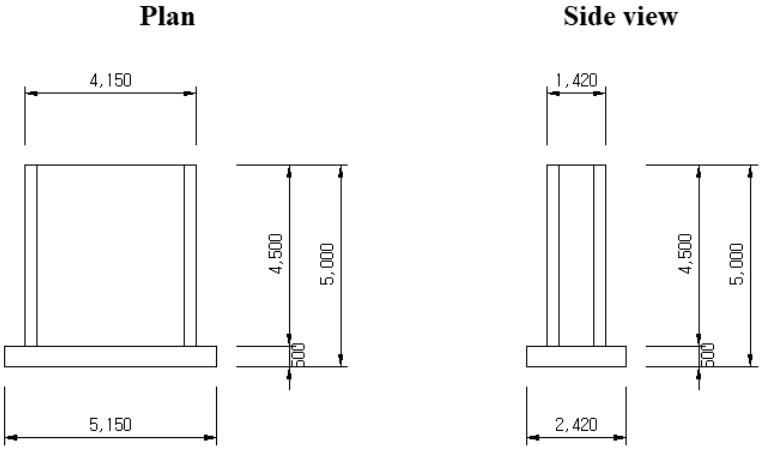

Figure 1: Dimension of full-scale bridge pier.

2.2 Mode number analysis of bridge pier

Before the full-scale bridge-pier test was conducted, the eigenvalues of the bridge pier were derived by using [6], a finite element program, to analyze the behaviors of the pier. The dimensions of the full-scale bridge pier were applied to the analysis. Accordingly, the behaviors of the bridge pier from the 1st to 4th modes could be analyzed according to the eigenvalues. The analysis result is illustrated in Fig. 2. In the 1st mode, the displacement occurred in the longitudinal direction. In the 2nd mode, the displacement occurred in the transverse direction. In the 3rd mode, the bridge pier showed a torsional behavior. In the 4th mode, the middle part of the pier had the largest displacement. The mode number analysis revealed that the transverse impacts caused natural vibration frequencies corresponding to the 2nd mode, whereas the longitudinal impacts generated natural frequencies corresponding to the 1st, 3rd, and 4th modes. Table 1 presents natural frequencies for the 1st, 2nd, 3rd, and 4th modes. Based on the analysis of eigenvalues of the bridge pier, impact directions could be selected to derive the mode numbers of the full-scale bridge pier.

Mode number	**Natural vibration frequency (Hz)**	**Direction of a test impact where a mode number can be driven**
1	**15.28**	**Longitudinal**
2	**25.19**	**Transverse**
3	**37.23**	**Longitudinal (lateral)**
4	**75.12**	**Longitudinal**

Table 1: Natural frequencies and impact directions for the full-scale bridge-pier test through the analysis of eigenvalues.

3 TEST CONDITIONS AND RESULTS

3.1 Test method

Eight accelerometers and an impact hammer were used to evaluate the safety of the bridge pier in a series of nondestructive tests. Fig. 3 illustrates the test cases according to impact directions. The accelerometers were installed at 3 points: 50 cm from the top; 50 cm from the bottom; and at the middle point of the bridge pier. Two accelerometers were attached to each point to measure accelerations in both longitudinal and transverse directions. Apart from the six accelerometers, another two were attached to the external side of the bridge pier in order to measure accelerations in the transverse direction. Impacts were applied in six directions. Table 2 presents the information of the test cases.

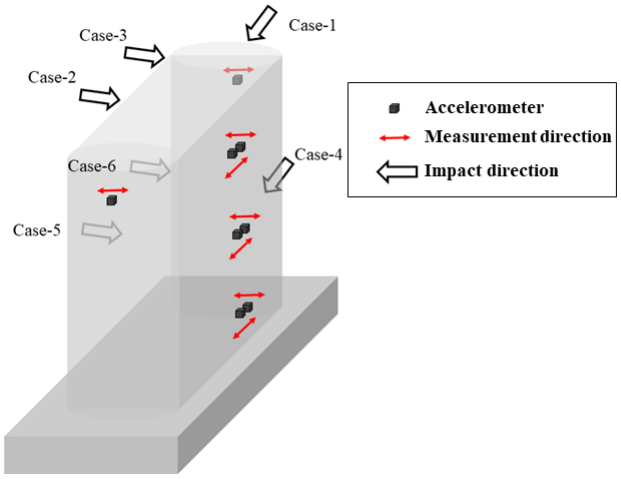

Figure 3: Schematic of accelerometer locations and impact directions.

Test case	**Impact direction**	**Impact location**
Case-1	Transverse	Top
Case-2	Longitudinal	Top
Case-3	Longitudinal (lateral)	Top
Case-4	Transverse	Middle
Case-5	Longitudinal	Middle
Case-6	Longitudinal (lateral)	Middle

Table 2: Natural frequencies through the analysis of eigenvalues and the selection of impact directions for the full-scale bridge-pier test.

3.2 Analysis method of test data

Figure 4(a) shows the accelerations measured in the test. In the case of an impact/vibration test, natural vibration frequencies and modes can be determined by analyzing a spectrum of repeated waveforms obtained from by repeating recorded waveforms multiple times. The fast Fourier transform (FFT) method, which can divide signals at each frequency, is the most appropriate for spectrum analysis. As shown Fig. 4(b), the natural vibration frequencies of the bridge pier in a frequency domain could be derived using FFT. Fig. 4(c) displays the phases of measurement locations. Accordingly, the overall behavior of the bridge pier could be analyzed by obtaining the phase differences among accelerometers.

(b) Natural frequency

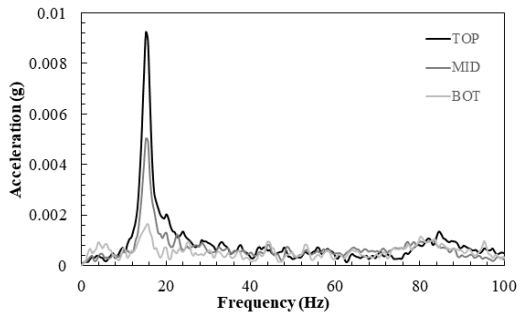
(c) Phase

Figure 4: Results of the analysis using accelerometers.

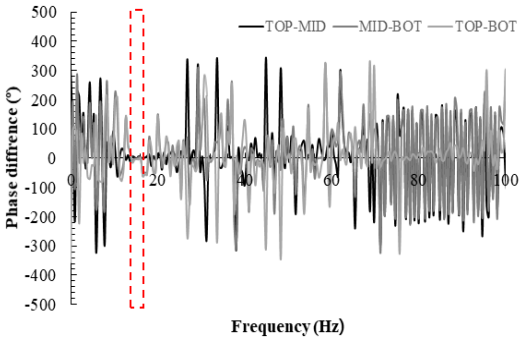
3.3 Derivation of mode numbers in the full-scale bridge pier test

Mode numbers of the bridge pier were analyzed, and the natural vibration frequencies for each mode were derived in a series of tests. Fig. 5(a) shows the natural vibration frequencies of Case 2, where the impacts were applied to the top of the bridge pier in the longitudinal direction. The natural vibration frequencies were around 15.24 Hz. Additionally, phases were calculated from measurements of each height to analyze the behavior of the bridge pier. Fig. 5(b) illustrates the phase differences among the different locations. All phase differences, where a natural frequency occurred, tended to converge on 0°. This indicates that all the accelerometers at each height were displaced in the same direction. Thus, the bridge pier moved in the same direction. This was analyzed to show a similar tendency to the 1st mode of the eigenvalue analysis. Fig. 5(c) shows the result of Case 1, where the natural vibration frequencies were derived at each height by applying a transverse impact to the top of the bridge pier. The natural vibration frequencies were about 22.4 Hz, which was higher than those in the longitudinal direction by about 7 Hz. This difference of natural vibration frequency was analyzed to be attributable to the fact that the bridge pier had a large stiffness in the transverse direction than in the longitudinal direction. Thus, the difference of stiffness was influential on natural vibration frequencies. As shown in Fig. 5(d), the phase difference was analyzed to identify the behavior of the bridge pier in the transverse direction. Like the behavior of the 1st mode, the phase difference was analyzed to converge on 0° when a natural vibration frequency occurred. This was similar to the behavior of the 2nd mode, which was identified by the eigenvalue

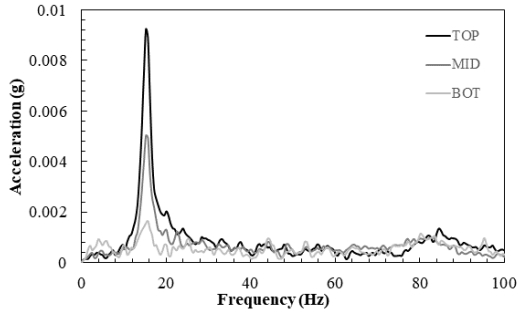
analysis of the bridge pier. Fig. 5(e) presents the natural vibration frequencies of Case 3, where acceleration was measured by applying an impact to the lateral part of the top of the bridge pier. Clearly distinct natural vibration frequencies occurred at two locations. These natural vibration frequencies were 15.14 Hz and 54.19 Hz. Regarding the phase differences of Fig. 5(f), one phase difference at around 15.14 Hz tended to converge on 0°. Because this natural vibration frequency was similar to the behavior of the 1st mode, it was predicted. However, the phase difference at around 54.19 Hz converged on 180°. This result indicates opposite behaviors in the lateral part of the bridge pier: a torsional behavior. This behavior was similar to that of the 3rd mode. Accordingly, when a longitudinal impact was applied to the lateral part of the bridge pier, the 1st mode occurred followed by the 3rd mode: a torsional behavior. Fig. 5(g) magnified the range of 60~100 Hz in the result of Case 2. Whereas there was no clear natural frequency in the range of 60~100 Hz, unlike the other results, the phase difference between the top and the bottom of the bridge pier converged on 0°. Both the phase difference between the middle and the top of the bridge pier and that between the middle and the bottom were 180°, indicating an opposite behavior. This was similar to the behavior of the 4th mode in the eigenvalue analysis. Thus, the 1st mode occurred first. Then, as the impact vibration decreased, the 4th mode appeared.



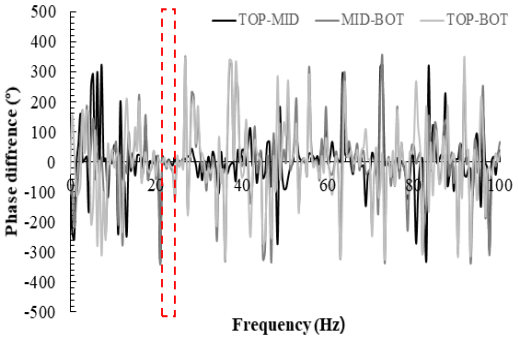
(a) Natural frequency of 1st mode



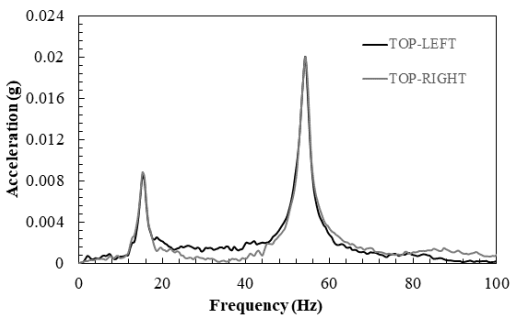
(b) Phase difference of 1st mode



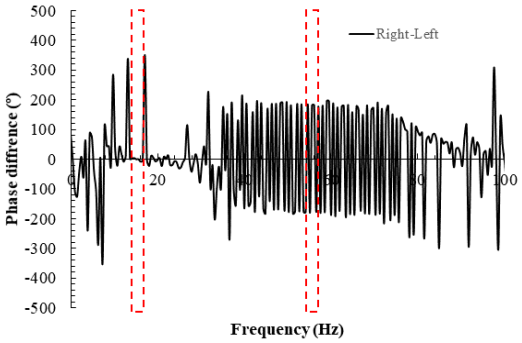
(c) Natural frequency of 2nd mode



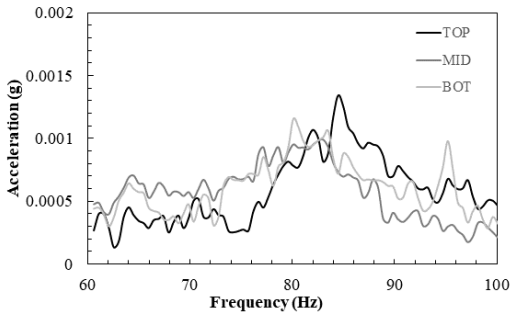
(d) Phase difference of 2nd mode



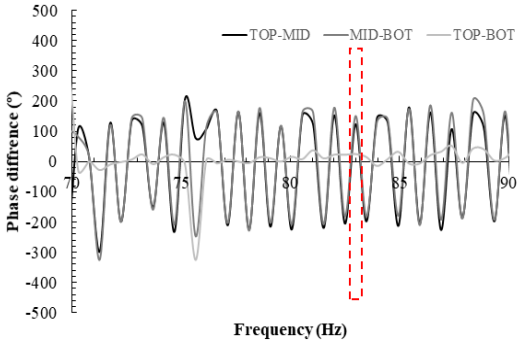
(e) Natural frequency of 3rd mode



(f) Phase difference of 3rd mode



(g) Natural frequency of 4th mode



(h) Phase difference of 4th mode

Figure 5: Natural frequency and phase difference of each mode.

In a series of the full-scale bridge-pier tests, the natural vibration frequencies of the bridge pier were derived using accelerations, and the behaviors from the 1st to 4th modes were analyzed based on phase differences. As presented in Table 3, the natural vibration frequencies of the full-scale bridge-pier test were compared with the results of the numerical eigenvalue analysis. The full-scale bridge-pier test and the eigenvalue analysis showed natural vibration frequencies in a similar range at an error rate of less than 5% in all the modes (1st to 4th).

Classification	**1st mode**	**2nd mode**	**3rd mode**	**4th mode**
Natural frequency of the eigenvalue analysis (Hz)	15.39	23.18	52.04	88.30
Natural frequency of the full-scale test (Hz)	15.14	22.4	54.19	83.94
Error rate (%)	1.62	3.37	-4.13	4.94

Table 3: Comparison of natural frequencies in each mode.

4 ANALYSIS OF PARAMETERS

4.1 Numerical analysis of scour effect

Owing to the limitations of the full-scale bridge pier test, the effect of scour on the na tural vibration frequency was examined by a numerical analysis. Regarding the analysis condition, the scour progress was described by removing one side of the soil under the a butment by increments of 10% until 50% remained. Fig. 6 illustrates the analysis conditi on.

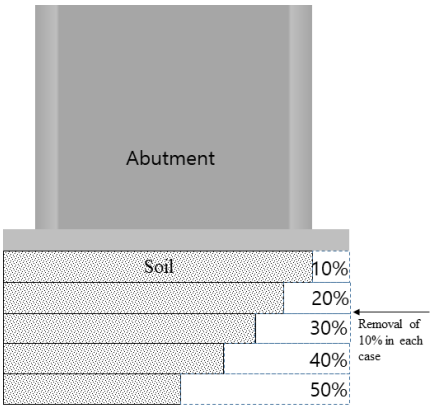


Fig. 6 Numerical analysis condition for the effect of scour progress

The scour effect was analyzed by setting the scour progress to five cases. Figure 7 shows the variation of natural vibration frequencies according to scour progress, which was obtained with the numerical analysis. As the scour proceeded, every natural vibration frequency from the 1st to 4th modes decreased. As presented in Table 4, the natural vibration frequency decreased from 15.39 Hz to 10.24 Hz along with the increase of overburden in the 1st mode. Thus, the maximum decreasing rate of natural vibration frequency was 33% in the 1st mode. The maximum decreasing rates of natural vibration frequency were 57%, 55%, and 23% in the 2nd, 3rd, and 4th modes, respectively. The scour was analyzed to be significantly influential in the 2nd and 3rd modes. Therefore, the test methods of the 2nd and 3rd modes turned out to be reasonable for identifying the effects of soil scour. Moreover, as the 3rd mode indicated a torsional behavior of the bridge pier. It was appropriate to evaluate the scour effect.

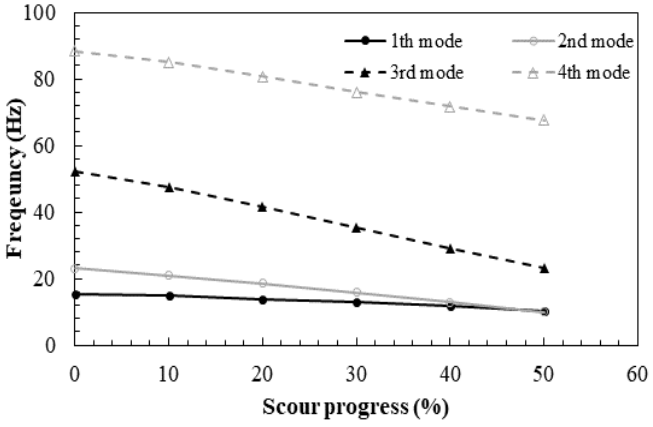

Figure 7: Variation of natural vibration frequency according to scour progress.

Scour progress (%)	1st mode	2nd mode	3rd mode	4th mode
0	15.39 Hz	23.18 Hz	52.04 Hz	88.30 Hz
10	15.14 Hz	22.40 Hz	54.19 Hz	83.94 Hz
20	13.95 Hz	18.53 Hz	41.56 Hz	80.65 Hz
30	12.92 Hz	15.80 Hz	35.23 Hz	76.01 Hz
40	11.69 Hz	12.90 Hz	28.98 Hz	71.65 Hz
50	10.24 Hz	9.95 Hz	23.28 Hz	67.52 Hz

Table 4: Natural vibration frequencies of each mode according to scour progress.

5 CONCLUSIONS

This study leveraged a full-scale bridge pier to conduct an indoor test. The scour effect was also numerically analyzed. Acceleration was measured for the bridge pier under an impact load, and both natural vibration frequencies and phase differences were obtained from the measurements. In this way, a new method of evaluating the safety of bridge piers was established. Moreover, all mode numbers of the bridge pier were analyzed. The results of this study can be summarized as follows.

- (1) Eigenvalues and mode numbers of the bridge pier were derived by conducting a numerical analysis. Thus, based on the full-scale bridge pier test, a method of evaluating the safety of bridge piers was established, which could derive 1^{st}, 2^{nd}, 3^{rd}, and 4^{th} modes.
- (2) The effects of scour on the natural vibration frequency of bridge pier was numerically analyzed. As the scour progress increases, the natural vibration frequency of every mode decreases. The scour effect was largest in the 2^{nd} and 3^{rd} modes. The scour progress at the soil under the bridge-pier foundation can be identified by utilizing the 3^{rd} mode, showing the torsional behavior of the bridge pier.

Abstract

In this study the effects of (SPSI) forces on the seismic response of a hospital in Brig, Switzerland were investigated. The building is an existing reinforced concrete construction with concrete columns. The primary lateral loads are resisted by a reinforced concrete core and a number of shear walls and massive concrete columns. Due to the importance of the building and its potential danger in failure cases of the loadbearing structure, earthquake analysis was first carried out by using a 3D finite element model for the entire structure and FCONE program for the soil under the structure. FCONE program was developed by Smteam for soil modeling based on CONE Model which was proposed by J.P.Wolf from ETH. This program utilizes the equivalent dynamic modeling concept in the analysis of soil dynamics and pile-foundation interaction. The implementation of simulation was conducted in two different conditions: namely fixed-base behavior and soil-structure interaction are considered. In this case, soil-structure interaction is considered by assigning equivalent springs and dashpots located under foundation and the analyses were carried out directly in the time domain for considering the effects of interaction. It is shown that the effects of soil-structure-interaction are demonstrated as increasing the period of vibrations and the displacements. Based on the results obtained by using CONE method, the period of vibration in the case of concentrated piles with the correction factor for pile-group action, exhibiting the value of (1.2 seconds), which is increased up to 42% compared with the case of fixed-based (0.7 seconds). Besides, a comparison was made between the structural responses of the obtained Cone method and 3D finite element simulation in ABAQUS which indicated that these results were in good agreement with direct results. It was concluded that Cone model as a convenient, fast and rather accurate method can be applied for foundation vibration and dynamic soil-structure-interaction analysis in a practical engineering projects whenever possible.

Keywords: Seismic analysis, Soil-Pile-structure Interaction (SPSI), Pilegroup effect, CONE Model, FEM method

1 INTRODUCTION

The soil-pile-structure interaction (SPSI) plays an important role in assessing the dynamic response to seismic ground motions or vibrations internally generated within the structural system. It is very important to note that the SPSI can alter the superstructure's performance by influencing the dynamic properties of structure. A fundamental understanding of this complex phenomenon is essential for improvements of the structural design and construction practices, and, as a result, for reduction of loss of life and monetary damages caused by earthquakes. Extensive field testing and experimental investigations on different aspects of pile behavior have resulted in a number of empirical and approximate analytical methods for the pile-foundation design [1-6]. In addition, other studies have resulted in more rigorous schemes for pile analysis. The results of research from various studies also back up the point that dynamic impedance of foundation is affected by several geometric and material factors such as foundation shape (i.e., disk, rectangular, strip), type of soil profile (i.e., deep uniform or multi-layer deposit, shallow stratum on rock), foundation embedment (i.e., surface foundation, embedded foundation, pile foundation), shear wave velocity and type of loading (static, dynamic) [7-8]. Generally, three direct numerical approaches have so far been evolved for predicting the dynamic pile behavior. The first approach represents soil as an elastic continuum, the second represents the soil-pile system by a set of discrete masses, springs and dashpots, and the third one uses either boundary element or finite element methods based on the actual soil properties [9, 10]. The continuum model was considered to be a generalized Winkler model. The major contribution regarding this approach was carried out by Novak [11], who introduced an approximate method based on the analytical solution of Baranov [12]. The soil was considered to be made of a set of independent infinitesimally thin horizontal layers in this model. Therefore, it automatically considered wave propagation in the horizontal direction. A set of equations for stiffness and damping ratio based on frequency independent parameters were provided for a single pile under vertical vibration. Thereafter, further progress on this model was made by Novak et al. [13] and Dobry and Gazetas [14]. The reduction in soil stiffness and the increase in damping associated with strong shaking are sometimes modelled crudely in these analyses by making arbitrary reductions in shear moduli and arbitrary increases in viscous damping. Moreover, several researchers developed dynamic nonlinear finite element analysis in the time domain using the full 3-dimentional wave equations to investigate the seismic soil structure interaction [15], but is not feasible for engineering practice at present because of the time needed for the computations. A rigorous finite-element analysis of a pile foundation subjected to lateral loading was done by Kaustell et al. [16]. These numerical methods have an advantage in that they can analyze the soil–pile system as a whole. Therefore, no separate analysis is required to calculate the dynamic interaction factors for pile group analysis [17].

The major drawbacks of analytical and numerical models in prior research studies were overcome with the introduction of Cone model which applies only for shallow foundations. Wolf has rearranged and extended the concept of the cone model to cover a complete range of dynamic excitations and physical situations. This model was based on one dimensional wave propagation in cone segments with reflections and refractions at layer interfaces. Due to the simplification of the physical problem, the mathematics of the cone models can be solved rigorously [18-20].

The present study investigates the effectiveness of applying the CONE model to analysis the dynamic response of pile groups in a critical hospital in south of Switzerland. For this purpose, FCONE program were developed for soil modeling. This program utilizes the equiv-

alent dynamic modeling concept in the analysis of soil dynamics and soil-pile-structure interaction.

2 THE CONCEPT OF CONE MODEL

The dynamic response of pile foundations embedded in a horizontally stratified soil profile is determined using the Cone model (Meek and Wolf 1994). Linear behavior of the site is assumed; hence the soil is assumed to remain linearly elastic with hysteretic material damping during dynamic excitation. Figure 1 shows the loaded disk on the surface of a homogeneous half-space, modelled in the one-dimensional strength-of-materials approach as a truncated semi-infinite bar with a vertical axis [20].

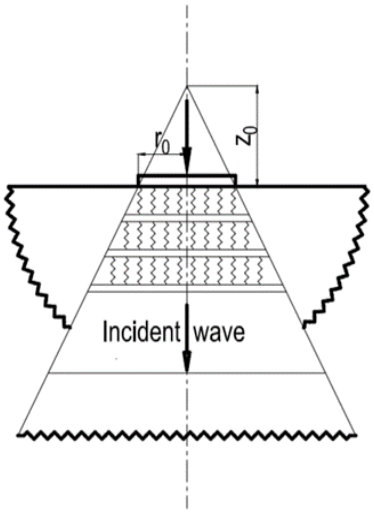

Figure 1: Translational truncated semi-infinite cone model of a loaded disk on a half-space.

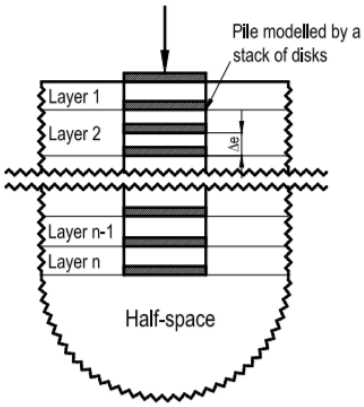

Figure 2: Pile modelled by a stack of disks

The soil region is divided into several segments by massless rigid disks (Figure 2). The disks will coincide with the interfaces of the half-space. In addition, further disks are selected to adequately represent the dynamic behavior. After assemblage, the dynamic stiffness matrices of all the cone frustum segments are then calculated and subsequently assembled together with the underlying half-space to form the dynamic stiffness matrix of the corresponding backbone cone. Applying a unit load at the disk and solving for the displacement amplitudes at all disks leads to a column in the flexibility matrix [$G(w)$] of the free field condition. Thus, the force-displacement relationship is obtained as (Eq.1); where $\{u(w)\}$ is the displacement amplitudes, and $\{P(w)\}$ is the force amplitudes:

$$\{u(w)\} = [G(w)]\{P(w)\} \tag{1}$$

This procedure is repeated for all disks to obtain all columns of the dynamic flexibility matrix [G(w)]. The dynamic stiffness of a single cone $S_1(w)$ modeling an incident wave induced by a disk load of radius r_0 on a half space is given by (Eq.2), where K_s is the static translational stiffness coefficient of the cone modelling the incident wave, c is the relevant wave velocity, w is the load circular frequency and ρ is the soil density. The value of the aspect ratios of a particular cone are shown in (Table 1) for each type of motion.

$$S_1(w) = K_s(1 + i\frac{wz_0}{c}) \qquad K_s = \frac{\rho c^2 \pi r_0^2}{z_0} \tag{2}$$

Table1: Aspect ratios for different types of motion

Motion	Horizontal	Vertical	Rocking	Torsional
Aspect ratio $\frac{z_0}{r_0}$	$\frac{\pi}{8}(2-\upsilon)$	$\frac{\pi}{4}(1-\upsilon)(\frac{c}{c_s})^2$	$\frac{9\pi}{32}(1-\upsilon)(\frac{c}{c_s})^2$	$\frac{9\pi}{32}$
Poisson's ratio υ	all υ	$\upsilon \le \frac{1}{3}$, $\frac{1}{3} < \upsilon \le \frac{1}{2}$	$\upsilon \le \frac{1}{3}$, $\frac{1}{3} < \upsilon \le \frac{1}{2}$	all υ

The dynamic stiffness matrix of the cone frustum segments is obtained by inverting the dynamic flexibility matrix $[S^f(w)]=[G^{-1}(w)]$, and then the forces acting on the top and bottom disks and their corresponding displacements are related as:

$$\{P(w)\}=[S^f(w)]\{u(w)\} \tag{3}$$

It is well known that the behavior of a pile in a compact group is quite different from that of a single pile because of pile-soil-pile interaction. These interaction effects depend mainly on pile spacing. These dynamic interactions incorporated into the analysis by a factor which is defined as the ratio of fractional increase in displacement amplitude at receiver pile to the displacement amplitude at the loaded source pile. The dynamic normal-axial interaction factor $\alpha_\upsilon(w)$ can be obtained from (Eq.4), where C_s = shear-wave velocity; ζ_g = hysteretic damping ratio; w = frequency of excitation; r_0 = radius of the pile; and d = distance between two piles.

$$\alpha_\upsilon(w)=\frac{{u_r}^f(w)}{u_s(w)}=\sqrt{\frac{r_0}{d}}e^{-\zeta_g w\frac{d}{c_s}}e^{-iw\frac{d}{c_s}} \tag{4}$$

$${u_\theta}^f(w)=-Sin\theta.{u_r}^f(90°,w)$$

$${u_{rad}}^f(w)=Cos\theta.{u_r}^f(0°,w)$$

When analyzing soil-structure interaction, two types of damping have to be taken into account, namely the geometric attenuation (radiation attenuation) that results from the distance of the excitation source to the object and the material damping due to the friction between the individual soil particles. The latter can be taken into account by substitution of G and G (1 + 2iζ) and E by E (1 + 2iζ), with ζ as the degree of attenuation of the soil. The material damping is independent of the excitation frequency.

When the distance between the piles is large (greater than about 20 diameters) the piles do not affect each other and the group stiffness and damping are simply the vector sums of the individual pile stiffness and damping. The dynamic stiffness matrix of the pile embedded in the half space can be obtained by replacing the properties of the soil between two consecutive disks with the mechanical properties of the pile section. This can be performed by adding the difference between the dynamic stiffness matrix of the pile and that of the corresponding soil cylinder, $[\Delta S(w)]$ leading to:

$$S(w)=S^f(w)+\Delta S=S^f(w)+[\Delta K]-w^2[\Delta M] \tag{5}$$

$$\{P(w)\}=[S(w)]\{u(w)\} \tag{6}$$

Where *P(w)* is force amplitudes, and ΔK and ΔM is the difference between stiffness matrices and mass matrices of the pile and soil cylinder, respectively. (Eq.6) can be written as

$$\begin{bmatrix} P_z \\ P_x \\ p_y \\ m_z \\ m_x \\ m_y \end{bmatrix} = \begin{bmatrix} K_{vz}(w) & 0 & 0 & 0 & 0 & 0 \\ 0 & K_{hx}(w) & 0 & 0 & 0 & K_{hxry}(w) \\ 0 & 0 & K_{hy}(w) & 0 & K_{hyrx}(w) & 0 \\ 0 & 0 & 0 & K_{tz}(w) & 0 & 0 \\ 0 & 0 & K_{hyrx}(w) & 0 & K_{rx}(w) & 0 \\ 0 & K_{hxry}(w) & 0 & 0 & 0 & K_{ry}(w) \end{bmatrix} \begin{bmatrix} u_z \\ u_x \\ u_y \\ \varphi_z \\ \varphi_x \\ \varphi_y \end{bmatrix} \tag{7}$$

Where *v*, *h*, *r* and *t* denote vertical, horizontal, rocking and torsional motions respectively. It can be noted that coupling occurs between horizontal and rocking motions. Furthermore, the dynamic stiffness coefficient obtained from the analysis is then decomposed into two parts:

$$K_{ij}(w) = K_{st}[k_{ij} + ia_0c_{ij}] \tag{8}$$

In (Eq.7), K_{st} is the static stiffness, i the imaginary unit, k_{ij} and c_{ij}, respectively called stiffness and damping coefficients, are dimensionless coefficients depending on the Poisson's coefficient of the soil and the frequency parameter.

$$a_0 = \frac{w(2r_0)}{C_s} \tag{9}$$

Where $Cs = \sqrt{G/\rho}$ is the shear wave velocity in the soil. Finally, the total displacement of receiver pile(i) due to lateral load of source pile(j) can be written as:

$$u_i(w) = \sum_{j=1}^{i-1} \alpha_v(d_{ij}, w)u_{jj}(w) + u_{ii}(w) + \sum_{j=i+1}^{n} \alpha_v(d_{ij}, w)u_{jj}(w) \qquad ,(i = 1,..,n) \tag{10}$$

or

$$u_i(w) = \frac{1}{S(w)}\left[\sum_{j=1}^{i-1} \alpha_v(d_{ij}, w)P_j(w) + P_i(w) + \sum_{j=i+1}^{n} \alpha_v(d_{ij}, w)P_j(w)\right] \quad , \quad (i = 1,..,n) \tag{11}$$

In order to achieve a sufficient accuracy, the number of disks n has to be selected so that the length L of a pile element does not exceed about one tenth of the shortest wavelength propagating from the pile. Because the shear wave velocity is less than the dilatational wave velocity in the soil, the wavelength of shear waves is lesser than that of longitudinal ones and the number of disks can be chosen as:

$$n \geq 1 + \frac{5}{\pi}\left(\frac{L}{2r_0}\right)a_0 \tag{12}$$

3 CASE STUDY (AN EMERGENCY HOSPITAL IN SOUTH OF SWITZERLAND)

The building is of a general rectangular shape with the overall dimensions of 73 meters in the longitudinal direction, 25 meters in the width direction, and a height of 35.6 meters. The building is a new reinforced concrete construction with concrete columns. The primary lateral load carrying system consists of three reinforced cores and an integrated reinforced concrete exterior frame system. For the earthquake resistance evaluation a special micro zoning map and a response spectrum developed by Resonance Ltd for Brig was used. The building is classified as a category III construction with an importance factor of 1.4. This is the highest class

of building categories in Switzerland. The building was modeled in three dimensions (3D) and calculated for non-ductile behavior according to the SIA Standard 262 (2013 edition). The summary of the building characteristics and modeling assumptions is given below:

3.1 Modeling assumptions:

- Longitudinal direction

The earthquake loads are carried by the three reinforced concrete cores and two shear walls together with the reinforced concrete framework. As the geometry of all floors is similar, continuous transfer of earthquake loads is guaranteed from the roof to the foundation. Additionally, due to the layout and stiffness differences the mass center and the stiffness center of the building do not match resulting in torsional stresses due to lateral earthquake effects.

- Lateral (short) direction

Three reinforced concrete core and two reinforced concrete frames transfer the horizontal equivalent loads corresponding to the earthquake effects from the higher levels through the lobby level to the basements of the building. There is a concern of soft story in the building. As a result, high shear stress concentrations occur in the building due to this irregularity.

3.2 Numerical Investigation:

The earthquake loads are determined according to the Swiss Code SIA 260-262; Merkblatt SIA 2018. The following material characteristics have been used;

Concrete: Ec = 20,000Mpa (Elastic modulus); f ’c= 19.2 Mpa (compressive strength)

For the seismic structural analysis four computer programs were used:

- ETABS which is a well-known structural analysis and design software, CSI, Berkeley, USA

- OpenSees Open System for earthquake engineering Simulation. This is an earthquake simulation software based on the displacement based structural analysis considering material nonlinearities. The program is very suitable for assessing the behavior of buildings in seismic situations. The purpose of modeling with OpenSees is to perform a nonlinear static pushover (NSP) analysis of the reinforced concrete system with concrete cores, shear walls, and the heavy concrete columns. The modeling is based on ASCE 41-13 (2014). Material nonlinearities and hysteretic behavior are considered for the elements under normal forces, bending and shear effects. For the calculations, both force-based and displacement-based methods have been used. For the displacement-based method ASCE 41 procedures have been implemented in the calculation of target displacements.

- FCONE program was developed at Smteam based on the CONE model for soil modeling. This program utilizes the equivalent dynamic modeling concept in the analysis of soil dynamics and pile- foundation interaction [22,23].

-Abaqus/Cae was used to investigate the structure response according to seismic soil-pile-structure interaction effect. The finite element simulation phase of the present study along with a description of boundary conditions, the meshing and analysis techniques and the materials’ constitutive laws is also presented below.

3.2.1 Pile group effect

When piles are used as part of a building foundation system, they are usually configured in groups to support continuous mat foundations or discrete pile caps for individual load-bearing elements. The impedance of a pile group cannot be determined by simple addition of individual pile impedances because grouped piles interact through the soil by "pushing" or "pulling" each other through waves emitted from their periphery. This is called a group effect, and it can significantly affect the impedance of a pile group as well as the distribution of head loads among individual piles in the group. Group effects depend primarily on pile spacing, frequency, and number of piles. They are more pronounced in the elastic range, and dynamic group effects decrease in the presence of material nonlinearity. Numerical analysis methods of soil-pile-structure interaction (SPSI) problems can be classified into two approaches: direct method and substructure method. In the direct method for analysis of SPSI it is necessary to model underlying soil, foundation and structure with best precision and accuracy since they are supposed to be analyzed together. In substructure method, soil-structure system is divided into two parts: first part is structure and the second part is the soil that has common boundary with foundation and each part can be modeled in detail (Wolf 1985) [21]. In order to consider the influence of the piles on the dynamic response of the structure, the substructure method was used in this study. This consists of three consecutive steps:

(1) Calculation of foundation input motion in the absence of superstructure inertia (kinematic interaction) includes translational displacements and rotational components.
(2) Calculation of the dynamic impedances (spring and damping coefficients) for horizontal rotation and the combination of base foundation and pile system.
(3) Calculation of the seismic response of the building supported on the springs and dashpots of step-2 and subjected at its base to the foundation input motion of step-1.

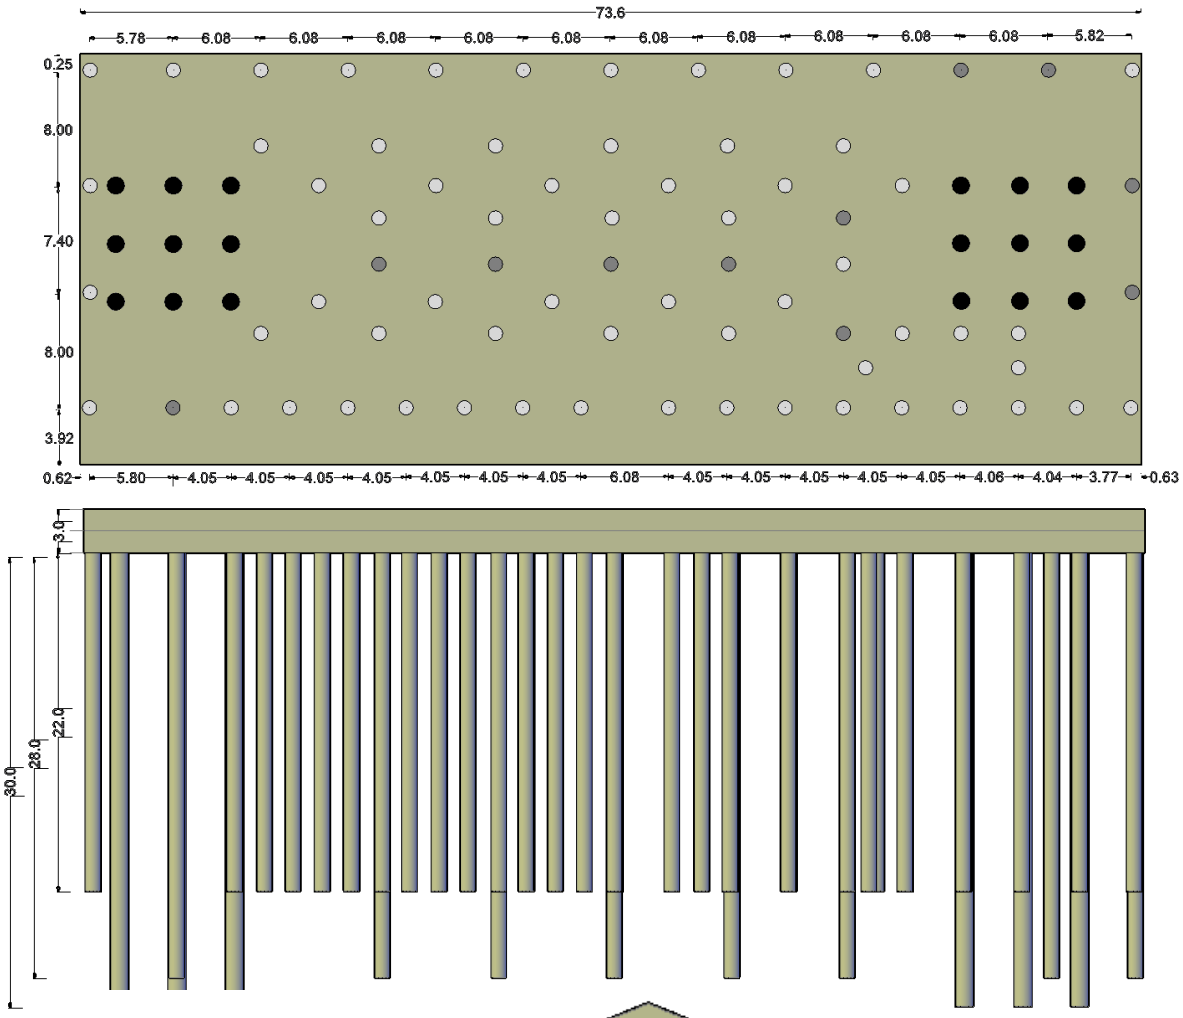
The method of Fan and Gazetas [7], based on the BDWF model (Beam on Dynamic Winkler Foundation) is used to determine the foundation input motion. In this method, the displacement of the pile head (U11) as a function of the free-field motion (Uff) is calculated as follows:

$$U_{11} = \Gamma\, U_{ff} \tag{13}$$

Here Γ is a function of spring and damping constants, frequency, mechanical characteristics of the piles such as Ip, Ap, Mp, Ep.

A detailed study of gazetas shows that the kinematic factor $Iu = U_{11} / U_{ff}$ for small frequencies, like the first frequency of the hospital Brig (0.7 Hz), is equal to 1; This means: no increase in the amplitude of the freefield earthquake motions. Therefore, in the case of the Brig hospital, the kinematic interaction effect was neglected.

The arrangement of pile group in rectangular foundation is shown in Figure 3. In this case, both rigid and flexible foundations are considered. In fixed-base model, the structure is being analyzed without soil and foundation with fixed boundary condition to resist all displacements or rotations at the bottom.



#	Pile Type	Diameter (Cm)	Length (m)
	1	100	22
	2	100	28
	3	120	30

Figure 3: The arrangement of pile group in rectangular foundation

In Cone model the structure is built on a rigid foundation with springs and dashpots in the bottom in place of soil. The response spectrum method was used for determining the displacements and accelerations.

To determine the vertical axial load in the upper part of the piles, a finite element model of the building was created using the ETABS program. In the modeling of the core 3D shell elements were used. The elastic modulus E of concrete has been reduced to 60% of the design value to include the effects of cracking in concrete. The (q) factor (response factor) is set to 2, and the importance factor is assumed 1.4. In 2015, a new earthquake hazard map of Switzerland (Figure 4) was issued with a corresponding design spectrum, which was used for the present study. The modal analysis was performed to determine natural modes of frequencies for the structural model in two different conditions: namely fixed-base behavior and behavior including SPSI (containing embedded piles with pile group effect).

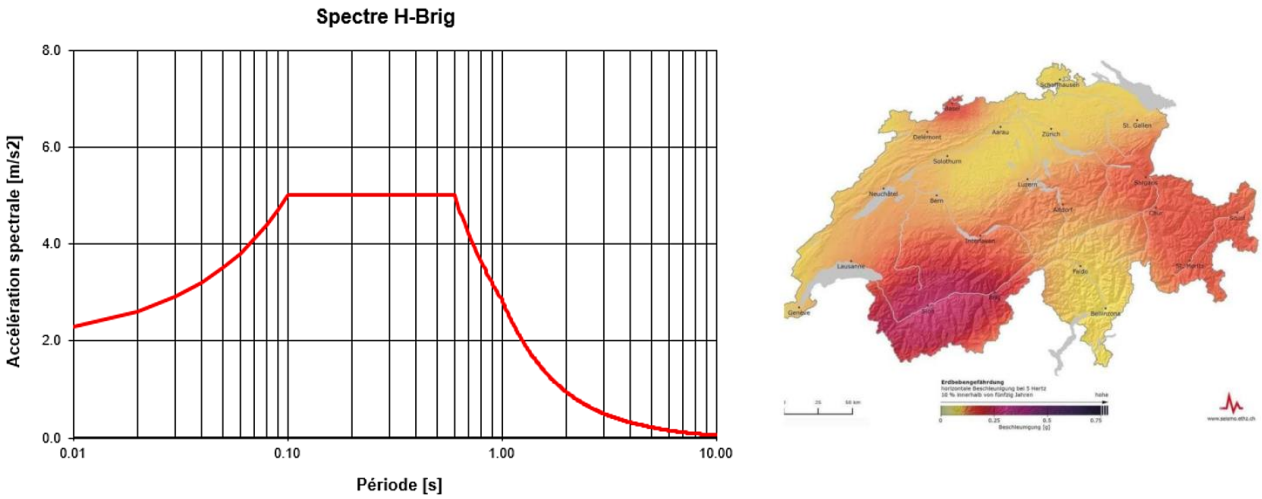


Figure 4: The response spectrum for the Brig ground motion and
The Seismity map of Switzerland

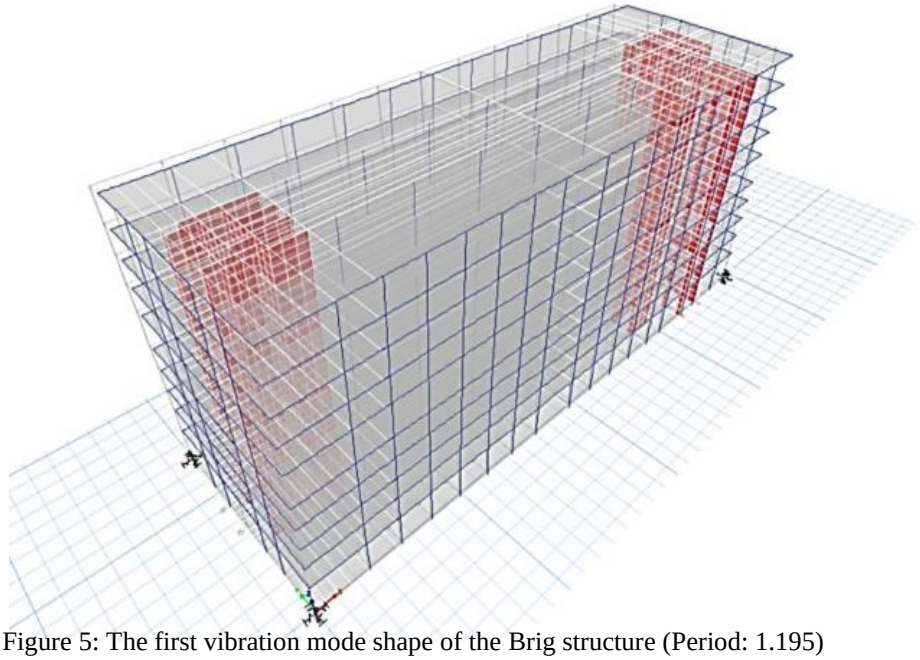

Figure 5: The first vibration mode shape of the Brig structure (Period: 1.195)

The results of ETABS analysis are given in table 2, and the first vibration mode shape of the building with dynamic pile group effect obtained from the ETABS is shown in Figure 5.

Table 2: The results of two analysis obtained from the ETABS model

	Period of vibration (s)	The Roof displacement (cm)
Fixed based foundation (No Piles)	0.7	6.5
Flexible foundation (Including Piles)	1.2	11.5

3.2.2 Target Displacements

The calculated target displacement in long direction and short direction according to the Euronorm 8 and ASCE 41-13, 2014, are found to be 12cm and 15cm, respectively. These values represented the demand on the structure to have a sufficient ductility level under earthquake loads before a collapse of the building can occur.

3.2.3 Nonlinear Pushover Analysis

A pushover analysis involves the application of static lateral loads distributed over the height of the structure, and calculation of the resulting displacements in a model of the SPSI system. A pushover analysis of a structure with a flexible base is schematically illustrated in Figure 6. A non-linear pushover analysis was reported for the reinforced concrete system model of the building with the parameters defined in ASCE 41-13. Behavior of each wall was determined based on the wall thickness, the wall length and the material properties as provided by the ETABS model. At each point on the pushover curve, the deformations of all components in the structural system are related to the reference displacement. The ETABS model has been read into OpenSees for conducting the pushover analysis.

The pushover analysis resulted in displacement capacities of 20 cm in the transverse direction, and 22 cm in the longitudinal direction, as shown in Figure 7. This compared with the target displacements, found from ASCE 41-13, of 12 cm in longitudinal direction and 15 cm in the transverse direction.

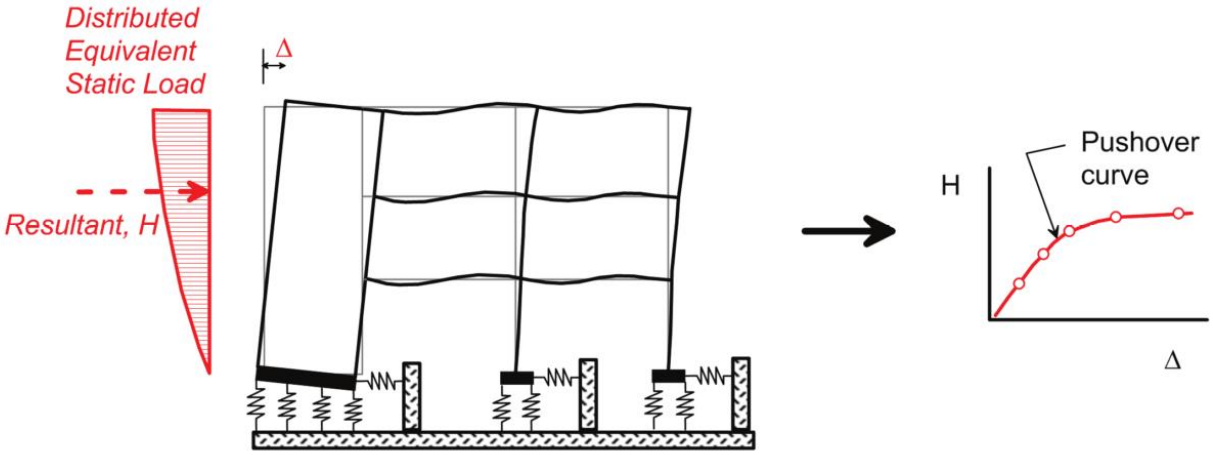

Figure 6: Schematic illustration of a pushover analysis and development of a pushover curve for a structure with a flexible base [24]

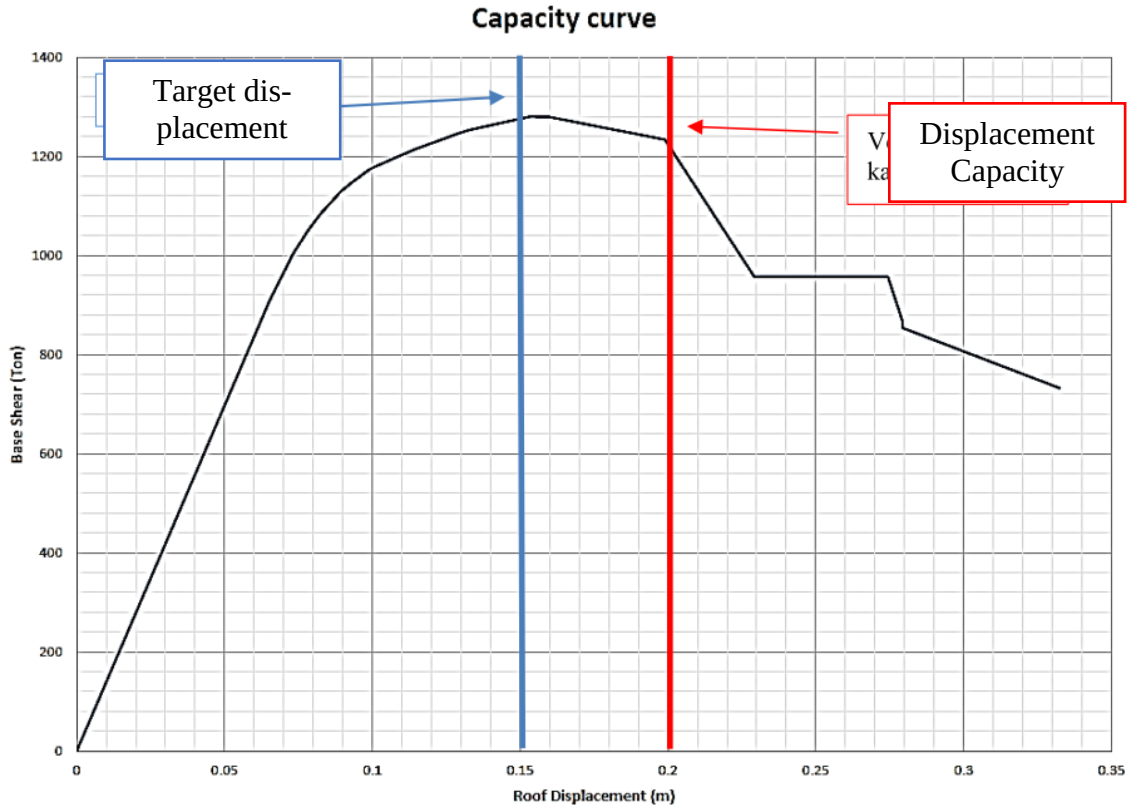

Figure 7: The pushover curve obtained by OpenSees analysis

3.2.4 Dynamic Stiffness of pile groups

Dynamic stiffnesses (spring and damping coefficients) for a pile group are strongly frequency-dependent. Therefore, the dynamic stiffnesses for different blocks (pile groups) as a function of frequency were calculated using the cone method according to John P. Wolf [20]. For the determination of stiffness, a new method of solving dynamic interaction problems was developed at Smteam, which, the seismic behavior of Pile-Soil-Pile structure interaction (SPSI) system is investigated as a whole considering both pile group effect and soil constitutive model according to the CONE theory. Results of the program for one 3×3 block under a core (i.e., spring and damper constants as a function of frequencies) are attached at the end of this report.

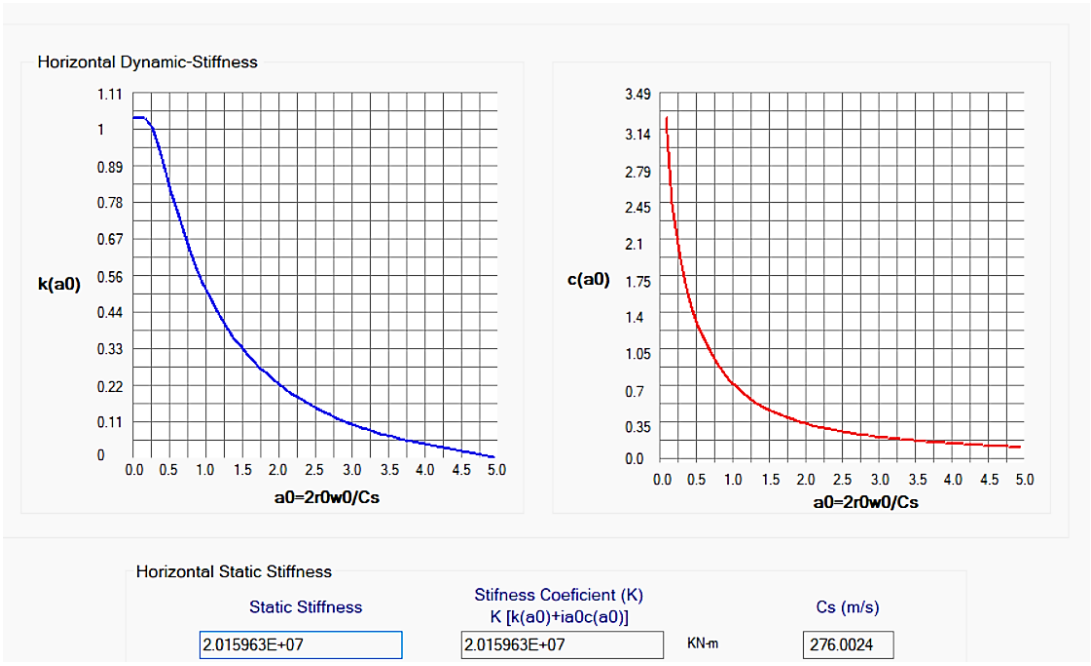
The spectral values have been reduced to take account of the radiation and material damping of the soil. It turns out that in the case of the flexible-base structure, in addition to the added rocking component to the horizontal motion of the structure, a part of the structure vibration energy will transmit to the soil layer and can be dissipated. This results in a reduction of the natural frequency in comparison to the fixed-base model and an increase of the damping (mainly due to radiation damping resulting from the wave propagation and hysteresis damping of the soil materials).

Detaied mechnaical characteristics of the soil has been explained in Table 3 where E is Elastic modulus, G_s is shear modolus, ρ is unit weigth, C_s is shear wave velocity, υ is poisson's ratio and ξ is material damping ratio. The soil region was assumed to be homogeneus with uniform shear modulus and density during analysis. The horizontal, vertical, and rotational dynamic

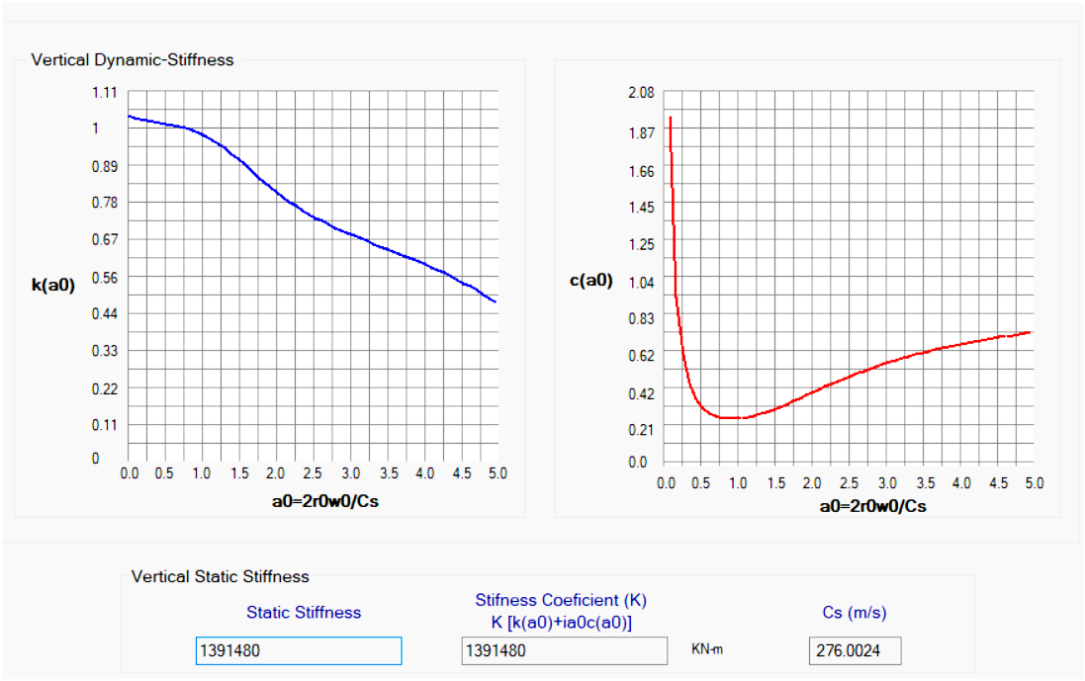
stiffness and damping ratios of a soil layer captured by using FCONE program,which are shown as a function of dimensionless frequency in Figure 8.

Table 3: The mechanical characteristics of the soil

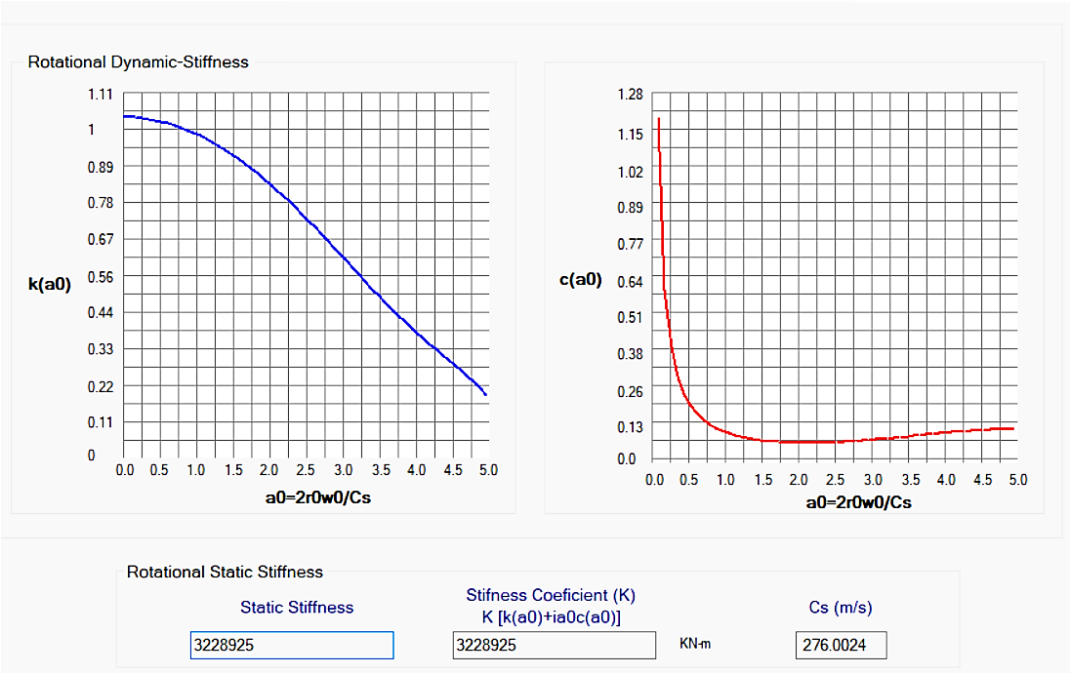
Parameter	E (MPa)	Gs (MPa)	ρ (KN/m3)	Cs (m/s)	υ	ξ (%)
Quantity	350	125	16.45	276.00	0.4	0.05



a) Horizontal Stiffness for a 3×3 Pile group



b) Vertical Stiffness for a 3×3 Pile group



c) Rotational Stiffness for a 3×3 Pile group

3.3 The Finite-Element Simulation:

The finite element code ABAQUS/Cae model as an accurate direct way was used to investigate the seismic behavior of the structure under SPSI effect. For this purpose, the infinite soil medium is reduced to a finite region using infinite element boundaries. In this case, an elastic perfectly plastic model was adopted for modeling the concrete piles with a modulus of elasticity of 30 MPa (C30). In the 3D finite element model developed using Abaqus/Cae, both the pile and the soil were modeled using eight-nodded solid continuum elements (C3D8R) to account for the continuum nature of the soil. This element has quadratic shape function which is well suited to model the medium with bending dominated deformation. A too coarse mesh may deviate from the expected response, whereas a too fine mesh requires very long computational time. Hence, a relatively fine mesh was adopted for the pile and a coarser mesh was adopted for the soil. Overall 11089 elements for the piles and 10205 elements for 10-story SPSI model was used. Soil was modeled using 98400 elements and the soil-pile interaction was modeled by defining the tangential and normal behavior of the contact surfaces in the FE model.

A strain hardening model using Mohr–Coulomb failure criterion was adopted for the soil which uses the five significant soil parameters, such as shear modulus (G), Poisson's ratio (ν′), shearing resistance angle (φ′), effective cohesion (c′), and angle of dilatancy (ψ) as shown in Table 4. An angle of internal friction of 35° was used in the definition of the Mohr–Coulomb failure criterion. The geometrical details adopted for the SPSI analysis is shown in Figure 11.

Table 4: The soil parameters used in the finite element code ABAQUS/Cae model

Elastic Parameters		Plastic Parameters (Mohr–Coulomb failure criterion)	
Mass density, ρ (KN/m3)	16.45	Shearing resistance angle, φ′	34
Modulus of Elasticity, E (MPa)	350	Angle of dilatancy, ψ	0.1
Poisson's ratio, ν′	0.4	Effective Cohesion, c′ (kPa)	22

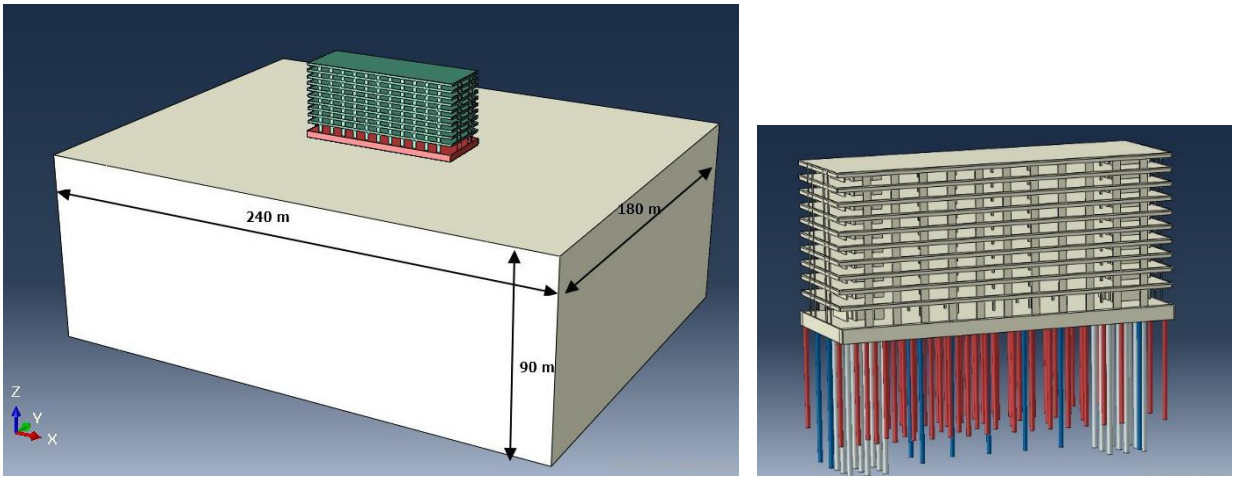

Figure 11: The geometrical details of SPSI model using ABAQUS/Cae

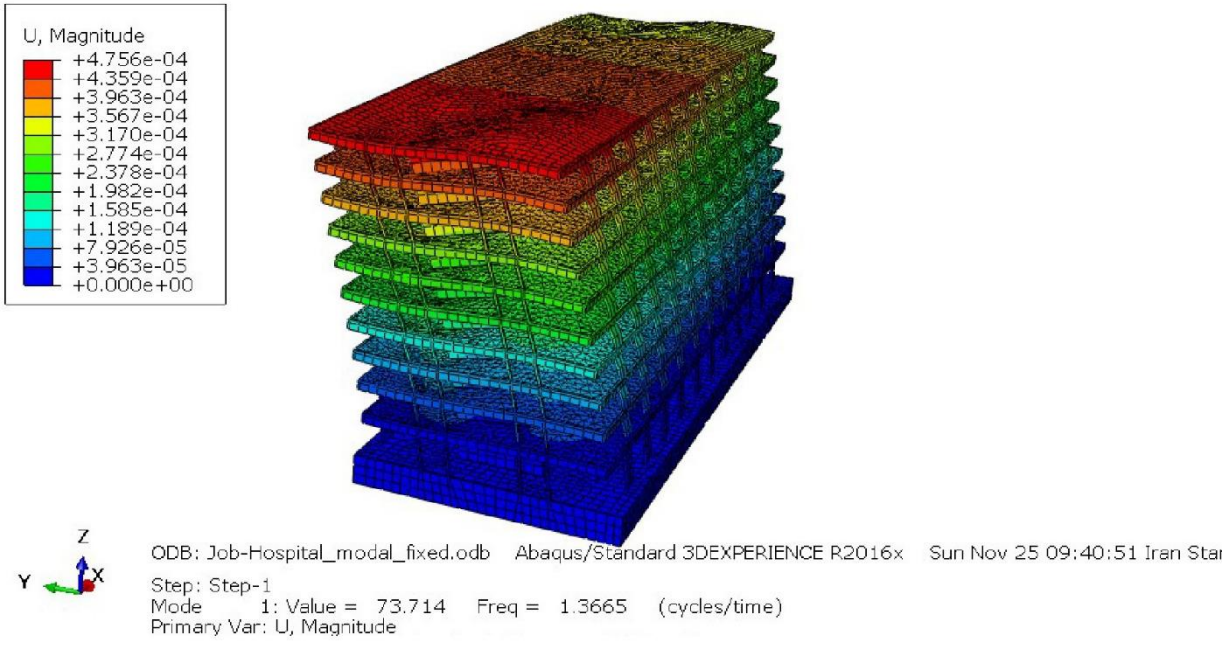
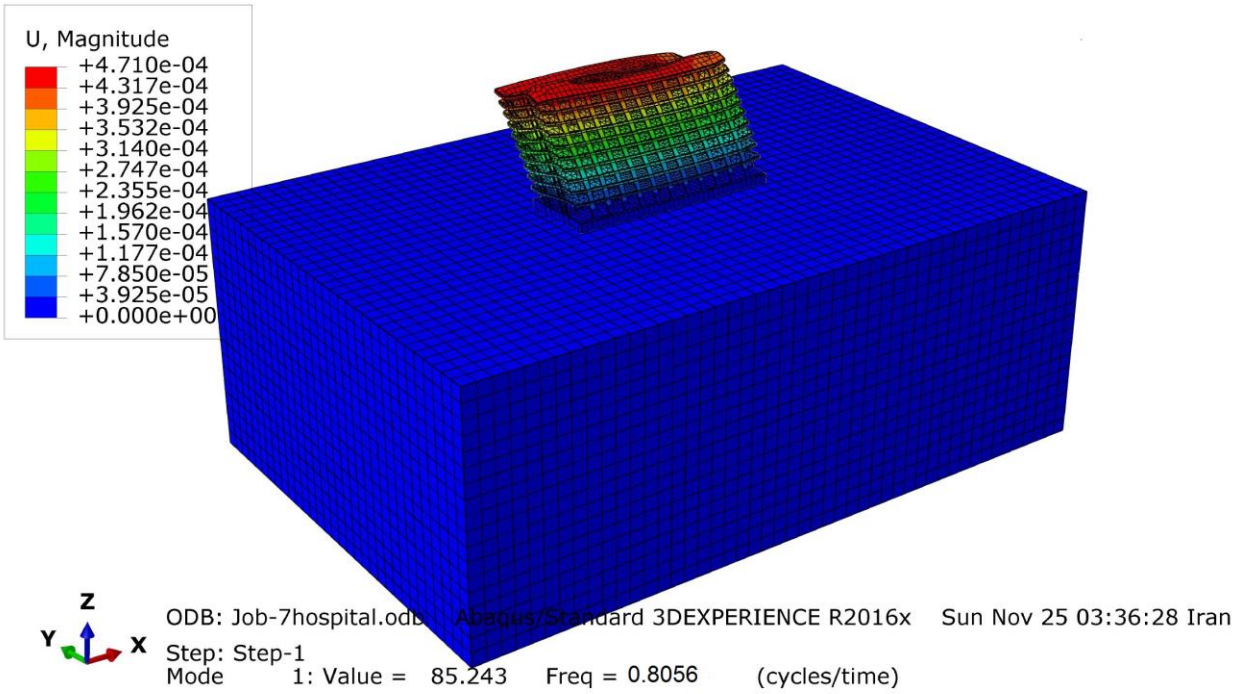
Results of 3D numerical prediction of first mode of vibration in Eigenvalue analysis for both cases (fixed-base and SPSI interaction), and maximum lateral displacements in short direction are shown in Figure 12, 13 respectively.



a) Fixed base behavior (period of vibration: 0.73)



(b) SPSI analysis (period of vibration: 1.24)
Figure 12: The first mode of vibration in Eigenvalue analysis

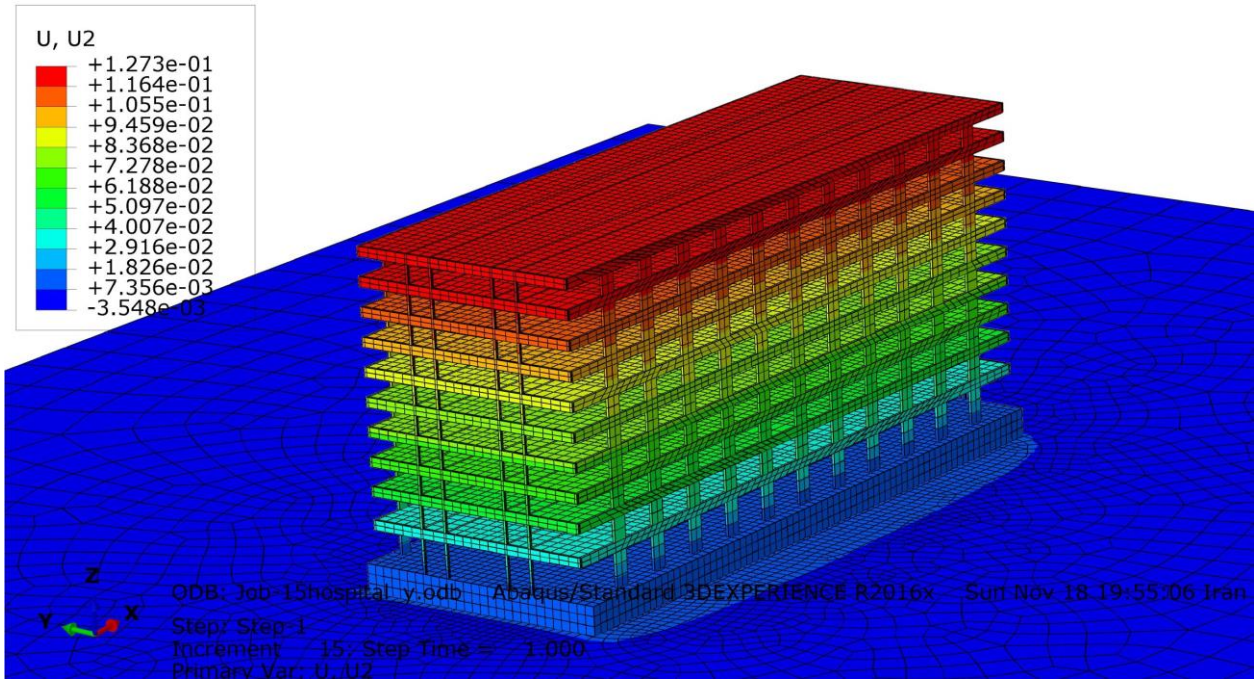


Figure 13: The maximum lateral displacements in short direction

Table 5 provides a good comparison between the results of SPSI analysis obtained by Cone method and FEM solution, which indicate that the results of Cone method are in close agreement with FEM results. As the structural stiffness in comparison with soil or building height increases, the period rate increases as well. For first mode of vibration in modal analysis a

good tendency with negligible difference was observed. Therefore, the Cone model provided reasonable accuracy of modal analysis for the high-rise building responses because the deviation was limited to 3%.

Table 5: Comparison between the results of SPSI analysis obtained by Cone method and FEM solution

	The period of vibration (s) (First-mode)		The lateral displacement in short direction (Cm)	
	Fixed base	SPSI	Foundation	The roof story
CONE Model	0.7	1.20	0.28	11.50
FEM Model	0.73	1.24	0.30	12.73

From the comparison between the maximum lateral displacements, it can be seen that the foundation displacements results obtained from Cone method give good agreement with FEM analysis results with about 6% and the most difference was observed in the roof displacement with around 10%. As expected, nonlinear modeling of soil results in increased lateral displacements of stories. It can be also concluded that the maximum lateral displacement of structures increases with the increasing number of stories, and the upper stories displacements are more affected with SPSI than the lower stories.

4 CUNCLUSION

The FCONE program we designed at Smteam is a new method of solving dynamic interaction problems, in which the seismic behavior of pile-soil-pile structure interaction on a large building is investigated as a whole considering pile group effect and soil constitutive model according to the CONE theory. The capability of the CONE method to predict the dynamic SPSI effects giving it an advantage over other time-consuming rigorous methods. This approach leads to physical insight with conceptual clarity, is simple to use and solve, as the mathematical solution is simplified, and provides sufficient generality (layered site, embedment, all frequencies) and acceptable engineering accuracy. The accuracy of any analysis is limited anyway, because of the many uncertainties, some of which can never be eliminated (for instance the definition of the dynamic loads and the values of the dynamic soil properties in the analysis of a structure). The analysis with cones fits the size and economics of practical engineering projects. Thus, the results presented in this article can contribute to relevant engineers in designing safe and economical structures based on foundation vibration and dynamic SPSI analysis in practical projects whenever possible.

Abstract

A computational method which uses the nonlinear adaptive static (pushover) analysis to evaluate the static force-deformation response of a planar moment resisting frame (MRF) is presented. The MRF considered in this study is a seismic-resisting frame of a prototype five-storey five-bay steel building structure designed based on the Japanese seismic design code.

The frame model is simulated by the finite element software ABAQUS. Failure on members is captured by adopting shell elements for beams and columns combined with a refined meshing. The lateral force distribution is adapted during the pushover analysis according to the first eigenmode of the structure by utilizing a novel inverse optimization algorithm. A new stop analysis criterion is introduced that overcomes the numerical difficulty of the available static-solution algorithms to terminate the analysis in the degrading region of the load-deformation response. The effects of load distribution and first (fundamental) small strain eigenperiod on the force-deformation pushover curve are studied.

The monotonic adaptive pushover procedure is implemented using the programming language MATLAB. The new tool effectively combines the advanced modeling and analysis capabilities of ABAQUS with the programming simplicity of MATLAB, thus leading to a user-friendly environment. The last offers a robust implementation of pushover analysis and superior numerical results can be obtained, especially the descending branch of the pushover curve and collapse mechanism.

Keywords: Pushover, Adaptive, Finite element, Descending branch, Collapse.

1 INTRODUCTION

Static pushover analysis has been widely used in earthquake engineering and design of buildings, such as in the Capacity Spectrum Method (CSM) [1]. In general, pushover analysis is used for seismic evaluation of existing buildings and design verification for new construction in order to identify damage states and their correlation with the amplitude of the seismic ground motion. Among the advantages of the pushover analysis method are that it is simple, fast and provides all the capacity points of a structure until collapse [2,3].

In an attempt to increase the accuracy of the results of the pushover analysis, adaptive force or displacement patterns are considered during the analysis. Adaptivity is realized in a way that ensures that the force or displacement pattern imposed on the building during the pushover analysis is continually updated depending on the instantaneous dynamic characteristics of the structure and/or a site-specific spectrum. Among the first studies that have introduced procedures to utilize fully adaptive patterns for pushover analysis is [4], where the various eigenproperties of the structure and the associated spectral quantities are used primarily to determine the demands to develop a capacity spectrum envelope.

A comprehensive presentation of the importance and various special traits of the pushover curve can be found in [5,6]. It is shown that the slope of the descending branch of any pushover curve depends strongly on the level of modelling sophistication, elastic unloading of the stories not participating in the collapse mechanism, and on the static or dynamic nature of the pushover algorithm. This implies that the reduction of a MDOF system in an equivalent SDOF system or use of simplified plastic hinge formulations may not apply for tracing the descending branch accurately.

An advanced modelling through FEA would be beneficial to accurately capture the descending branch of a pushover curve and finally the collapse mechanism. However, to trace accurately the descending branch in a force-controlled pushover analysis is generally difficult (almost impossible with normal static analysis) since once the maximum capacity is reached the lateral loads cannot increase further. In addition, the use of advanced modelling approaches often generate convergence errors (strain concentration etc.) that terminate the analysis at an early stage. To overcome these problems, FEA softwares have adopted computational techniques, such as the arch-length control static analysis or advanced stabilization algorithms.

In this study, a computational platform that combines ABAQUS [7] and MATLAB [8] is developed and used for the generation of pushover curves of buildings. The key points of this new computational tool are:

a. It uses “active” advanced modelling methods for members and materials instead of “passive” plastic hinge models with fixed material parameters.
b. Failures related to strength and stiffness reduction, such as local buckling, overall buckling etc. are captured accurately through advanced FEA modeling.
c. It utilizes the common static analysis of Abaqus without obscure stabilization algorithms or arc-length methods that may become uncontrollable or give erroneous results under certain circumstances.
d. It is mainly a force-based pushover analysis after the post-peak strength point and captures the collapse mechanism that is not captured in displacement-based pushover analysis.
e. The load distribution is updated based on subsequent modal analysis (adaptive procedure) for accounting the stiffness reduction. The loading pattern is closer to that of a dynamic analysis.

2 NUMERICAL MODELING

2.1 Description of the Analyzed Building

The building under consideration is a five-floor steel structure designed by the Japanese seismic code [9,10] using the A_i force distribution. It has a rectangular floor plan with aspect ratio equal to 1.70. The longitudinal dimension L_X has length 32.0m and five bays, while the transverse dimension L_Y has length 18.6m and three bays. In Fig. 1a, the structural system of a typical floor plan is presented while in Fig. 1b a general view of the building side is shown. The total building's height is 20.50m. The structural system illustrated in Fig. 1a consists of three plane moment resisting frames (MRFs) along the X axis and two MRFs along the Y axis. The building have square tube column sections and H beam sections. The cross-section of the columns and beams are given in Table 1. The seismic design of the building was achieved through a characteristic factor D_s = 0.25 (i.e., behavior factor q = 4.0), while the drift limitation requirement 1 / 200 was satisfied for a base shear coefficient C_0 = 0.20. Table 2 provides the weight of each floor, the Ai load distribution, the strength-based and drift-based seismic forces, the total story strength determined by the cross-sections, and the normalized first mode. The period of the building is 0.94 sec along the X axis and 0.90 sec along the Y axis.

The A_i force distribution is described by the following relation:

$$A_i = 1 + \left(\frac{1}{\sqrt{a_i}} - a_i \right) \frac{2T}{1+3T} \tag{1}$$

where a_i and T is obtained by:

$$a_i = \frac{\sum W_i}{W} \tag{2}$$

and:

$$T = H \cdot (0.02 + 0.01 \cdot \alpha) \tag{3}$$

In the Eq. (2), W is the total weight of structure, ΣW_i is the summation of the weight of all stories above of the story i, H the total building height and α equals 1.0 for steel buildings (along the height). The structural period T was estimated equal to 0.615 sec.

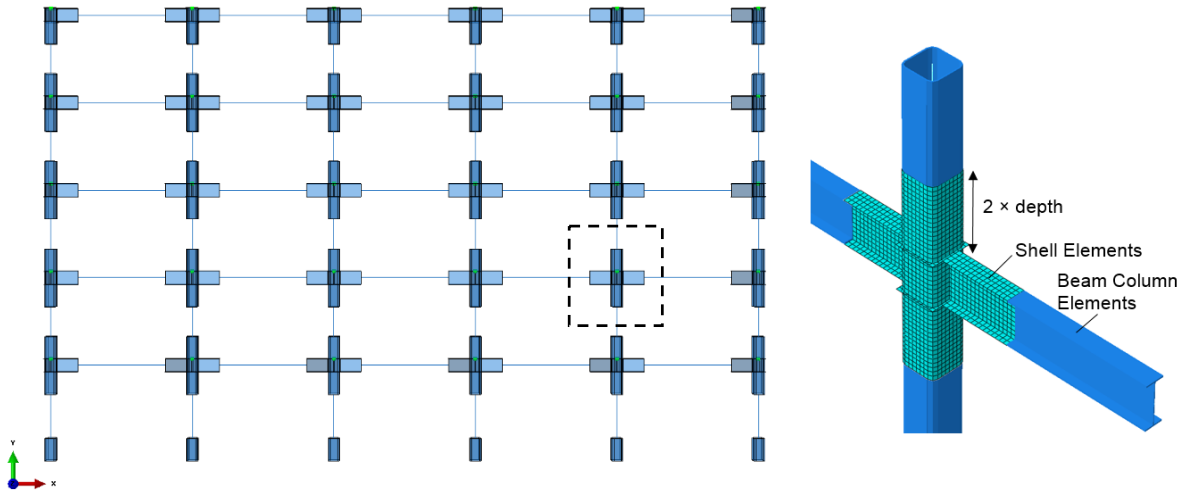
2.2 FEA Model of the Building

One plane frame of the three along the X direction shown in Figure 1 was modelled by the finite element analysis software Abaqus [7]. The overall view of the plane frame (YA) is shown in Figure 2a, while modeling details can be seen in Figure 2b. The model developed is a mixed shell/beam element model that combines the powerful nonlinear S4R shell elements with beam-column elements. Shell elements were used in the critical regions of the building, such as beam-column connections and column at the base, where strong geometrical nonlinearities (e.g., local buckling) are expected to take place. Beam-column elements were used for the rest length of beams and columns which tend to remain mainly in the elastic region. The beam-column connection is fully restrained by diaphragm plates located at the bottom and top of the panel-zone height thus simulating a rigid welded connection. The welding access hole was not modelled. Shell elements were used for a length equal to two times the width of column and depth beam, respectively.



(a) (b)

Figure 2: (a) Overall view of the frame model in Abaqaus; and (b) Modelling details of a beam-column connection.

2.3 Material properties

For sufficiently small straining, steel is modeled as a linear elastic isotropic material with density ρ=7850kg/m^3, modulus of elasticity E=205GPa and Poisson ratio ν=0.3. The constitutive model used for steel includes pressure-independent plasticity with kinematic hardening and is suitable to simulate the inelastic behavior of metals. The evolution of the backstress for the isothermal (temperature independent) material response follows the Ziegler's hardening rule. According to this evolution law, the yield surface is translated in the stress space through the backstress, the rate of which due to plastic straining is in the direction of the current radius vector from the center of the yield surface. The equivalent stress remains constant throughout the analysis, and is equal to its initial value which defines the size of the yield surface at zero plastic strain. The kinematic hardening modulus is linear, and for temperature independent analyses it requires only two stress-strain pairs for its definition: the yield stress at zero plastic strain and a yield stress at a finite plastic strain value. A strain hardening equal to 1.0% of the modulus of elasticity was assigned.

2.4 Analysis

The force distribution that is applied to the structure in each increment of the static adaptive pushover analysis carried out in this study is updated according to the first eigenmode of the structure. This eigenmode is calculated with the use of a shifted block Lanczos algorithm, similar to that developed and described in detail in [11,12]. It is noted that in order to perform an adaptive pushover analysis in Abaqus, none of the analysis types offered by Abaqus can be used since (in the best case) they preserve the load distribution until the analysis is ended. Two types of nonlinear static analysis procedures can be carried out in Abaqus finite element software in order to perform static pushover analysis of any structural model, which are described below, along with their limitations:

- Static analysis with force, displacement and/or force/displacement control. Even in a non-adaptive pushover analysis, it is recognized that this type of Abaqus analysis cannot be used with force-control to trace the descending branch of the material response. Therefore, neither for an adaptive, nor for a non-adaptive constant load pattern pushover analysis can this type of analysis be used.

- Static analysis with arc-length control (Riks). Assuming that the model is loaded with forces of constant pattern, although this analysis can trace the descending branch of the material response, it can trace only a single loading path during the analysis and does not allow the user for control over the force distribution pattern during the pushover analysis. Therefore, for an adaptive load pattern pushover analysis, this type of analysis cannot be used.

Abaqus offers the capability of the restart analysis, which enables the user to stop the analysis at a desired time point and restart at the same or another time point the analysis of an updated version of the model already analyzed. Actually, each increment of the proposed pushover analysis procedure includes a restart analysis, in which the model definitions and all information of the current analysis state is written in a set of restart files. The Abaqus input file is properly updated based on the specified loading definitions in conjunction with the response of the structure calculated so far, and finally the updated input file along with the restart files written at the current increment are read by the restart Abaqus analysis calculating thus the structural response at the next increment.

Since the static Riks analysis with arc-length control cannot distinguish between loading and unloading directions, if the step of the restart analysis is a static Riks step, there is the possibility that the analysis starts from a point different from the last converged equilibrium point, and apply the loading in a direction opposite to the one specified, leading thus the structure to unexpected unloading instead of reloading condition.

For the above reasons, in this study the restart analysis is used only with general static analysis with mixed force and displacement control, as will be shown in a later section. Displacement control is applied by directly specifying the desired displacement at the top of the structure. Force control is applied indirectly through an optimization procedure which ensures that the force pattern is maintained or appropriately updated throughout the pushover analysis. With repeated use of the restart capability, ABAQUS [7] can be consistent with the quasi-static structural loading response.

In each increment of the novel adaptive pushover analysis procedure that is proposed in this study, a static analysis is performed in which both forces and displacements are imposed at the structure. The forces and displacements are imposed in a controlled manner that ensures the linear dependence between the actual force distribution imposed at the structure, $\left\{\tilde{F}_i\right\}$, and the desired force distribution that is based on its fundamental eigenmode, $\left\{\bar{F}_i\right\}$, i.e. that the following relation is satisfied at all storeys of the structure:

$$\tilde{F}_i\left(j\right)=\lambda_i\bar{F}_i\left(j\right),\ j=1,...,5 \tag{4}$$

Since the way of computation of the load proportionality factor λ_i at the i^{th} increment of pushover analysis is not straightforward, it is indirectly calculated through the implementation of an optimization procedure. The optimization problem that is considered at each increment of the

pushover analysis is to find the optimum load proportionality factor λ_i that minimizes the variance of the vector defined by the division of $\{\tilde{F}_i\}$ to $\{\bar{F}_i\}$ in an element-wise manner:

$$R_i(j) = \frac{\tilde{F}_i(j)}{\bar{F}_i(j)},\ j = 1,...,5 \tag{5}$$

If $\mathrm{var}(R_i) = 0$ this means that all the elements of the vector R_i are equal with each other, and equal to λ_i, since it is always $\mathrm{var}(R_i) \geq 0$ by definition. The design variable of the optimization problem is the scalar λ_i and the objective function to be minimized is equal to $F_i^{obj} = \mathrm{var}(R_i)$.

Matlab [8] is employed for carrying out the optimization analysis associated with the mixed force-displacement control static analysis at each increment and operate Abaqus [7] analysis. The optimization algorithm considered in this study for the solution of the optimization problem is the Interior Point Algorithm (IPA). The application Abaqus2Matlab [13] (developed by Papazafeiropoulos et al. [14]) which integrates between Matlab [8] and Abaqus [7] is adopted in this study as a suitable tool for post-processing the analysis results.

3 RESULTS

Figure 3a shows the pushover curves for building model as obtained by utilizing the developed algorithm. The curve is presented in the typical fashion: total lateral force on the building (base shear force) normalized by the total building's weight W on the vertical axis versus roof drift on the horizontal axis. The building is seen to have an over-strength of more than 2 relative to its design base shear of 0.09W. The pushover curve reaches 0.192 W at a roof drift of 0.048 and then descends. The descending branch drops more steeply after reaching a roof drift of 0.10. Gravitational instability is observed at a roof drift of 0.22. Figure 3b shows the normalized by the total weight base shear of each column. External columns reached lower values since they subjected to higher axial loads. The normalized axial loads sustained by each column during the lateral loading are shown in Figure 3c and the bending moment reached is shown in Figure 3d. The building deforms in a collapse mechanism that involves the first two stories. Active plastic hinges are formed in the columns at the building base and just below the second floor level and in the intermediate beams. Figure 4 illustrates the overall view of the collapse mechanism as identified with the proposed method. The failure of local buckling at the columns of second floor level is highlighted.

An additional analysis was also performed utilizing the conventional static algorithm in a single step. Figure 3a compares the conventional pushover curve against the one obtained by utilizing the proposed algorithm scheme. In conventional static pushover analysis, the scaler λ_i is increased over time. However, once the peak of the pushover curve is reached, a converged solution cannot be obtained because the total pushover load being applied is greater than the lateral strength of the structure (assuming there is not a higher peak further out).

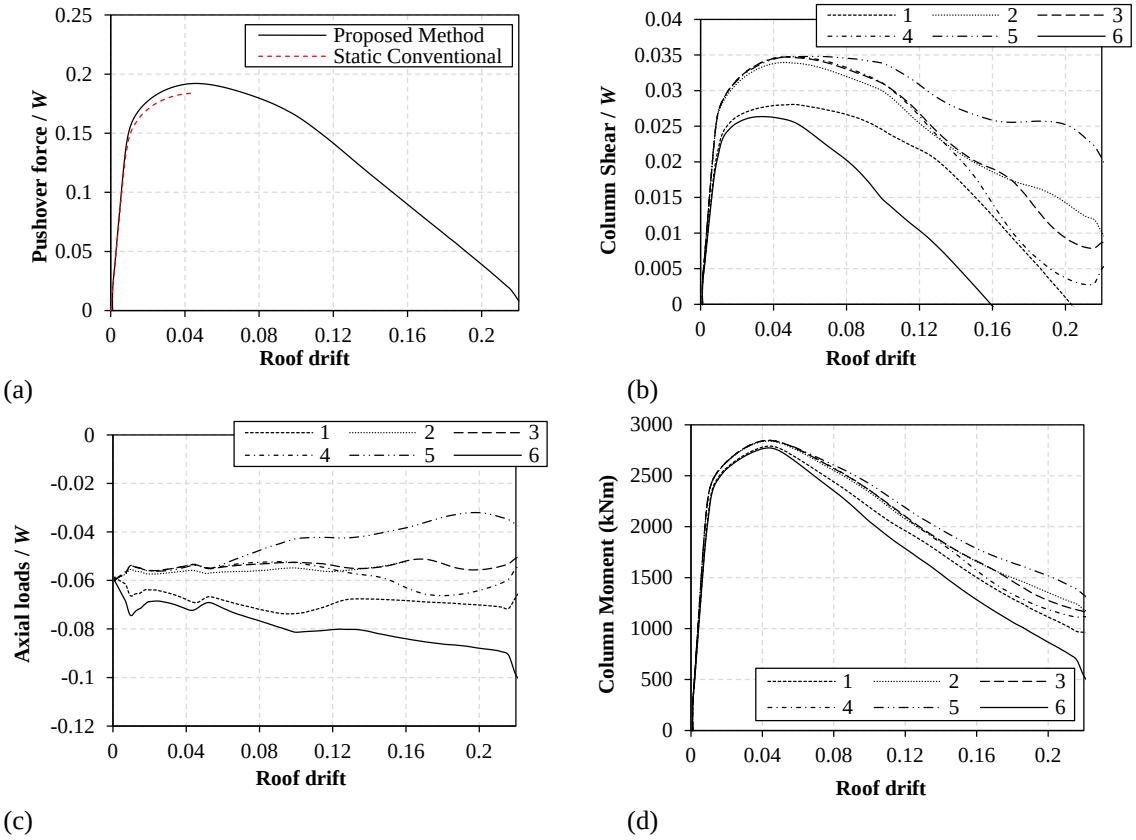


Figure 3: (a) Pushover curve; (b) Base shear at each column; (c) Axial loads; and (d) Bending moment at each column.

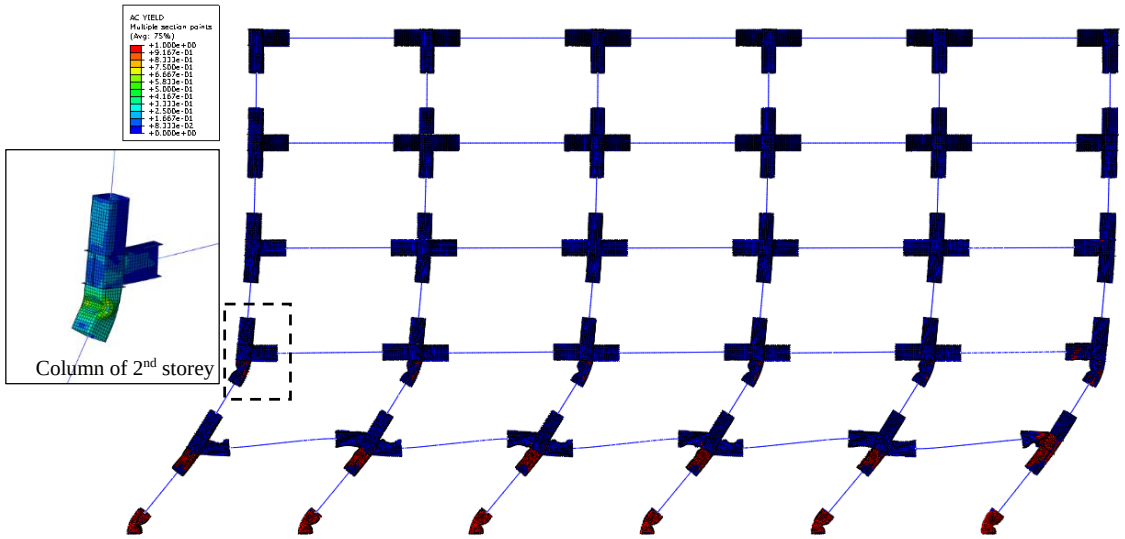

Figure 4: Overall collapse mechanism of the frame model.

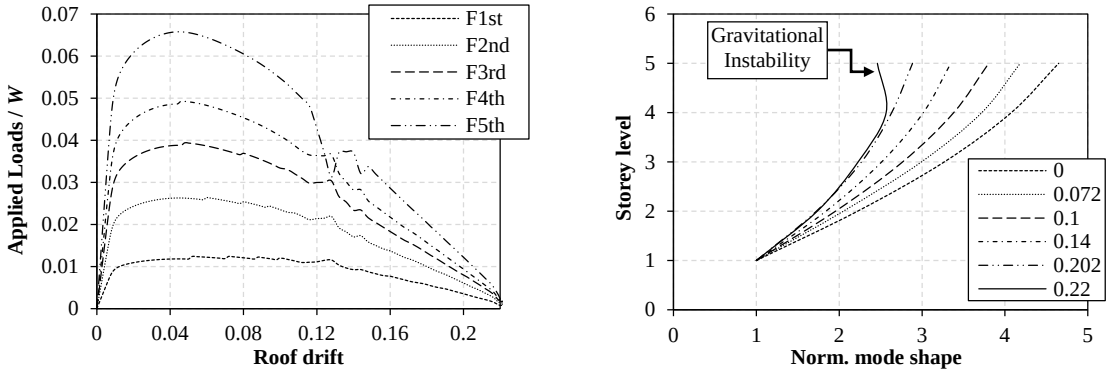
Based on the frequency analysis conducted at the first step of the adaptive pushover analysis, the period T of the frame model is equal to 1.02 sec. The mode shape is [1.00; 2.22; 3.33; 4.17; 4.70] while the load proportion factor (LPF) is [1.00; 2.22; 3.28; 4.11; 5.55]. Figure 5a shows the normalized by the building's weight applied loads per floor level and Figure 5b the normalized mode shapes for roof drifts equal to 0.0, 0.072, 0.10, 0.14, 0.202 and 0.22. The modes are

representative ones from those determined during the proposed adaptive pushover analysis. In the following roof drift at which gravitational instability was observed (i.e., 0.22 roof drift), the roof control displacement obtained a negative value for maintaining the force equilibrium of the reduced stiffness forces and applied loads. At this point the analysis was terminated.



(a) (b)

Figure 5: (a) Applied loads at each storey; and (b) Normalized mode shape for roof drifts 0.0, 0.072, 0.10, 0.14, 0.202 and 0.22.

4 CONCLUSIONS

A computational method which uses the nonlinear adaptive static (pushover) analysis to evaluate the static force-deformation response of structures is presented. The method is validated on a five-storey five-bay steel moment-resisting frame (MRF) designed based on the Japanese seismic design code. Main conclusion of the present study are as follows:

- The computational platform uses finite element modelling methods for members and materials. Failures related to strength and stiffness reduction, such as local buckling, are captured accurately. The load distribution is updated based on subsequent modal analysis (adaptive procedure) accounting for the stiffness reduction.
- The computational platform utilizes the common static analysis of Abaqus without obscure stabilization algorithms or arc-length methods that may become uncontrollable or give erroneous results under certain circumstances. It is mainly a force-based pushover analysis after the post-peak strength point and captures the collapse mechanism.
- The building is seen to have an over-strength of more than 2 relative to its design base shear of 0.09W. The pushover curve reaches 0.192 W at a roof drift of 0.048 and then descends. The descending branch drops more steeply after reaching a roof drift of 0.10. Gravitational instability is observed at a roof drift of 0.22.

Keywords: Early age, pseudo-dynamic, damage, concrete, vulnerabiliy, earthquake.

Abstract. *Reinforced concrete damage over time can cause severe structural problems (e.g. Morandi Bridge in Italy [1]). Many factors contribute to concrete deterioration (Thermal conditions, chemical attacks, shrinkage, creep, carbonatation, corrosion, etc.) [2]. Reinforced concrete deterioration starts at early-age and continues with structure aging. Early-age shrinkage, creep and thermal conditions or initial cracks can have a significant impact on the dynamic behavior of concrete structures. As shown in [3], the natural frequency of a beam subjected to early-age restrained shrinkage is highly affected. In order to quantify the impact of early-age concrete damage on the dynamic behavior of structures, the GEOMAS Lab at INSA Lyon is working on a research project combining both numerical modeling and pseudo-dynamic tests on two groups of reinforced concrete portal frames. The first group is a reference group kept in endogenous conditions during its early age period in a way to limit drying effects leading to cracks while the second group is kept in non-endogenous conditions similar to construction site conditions, which induces damage. The present paper focuses on the enhanced multifiber beam model developed for the portal frames and that allows describing their behavior when subjected to a seismic loading while taking into account their initial damage due to early age effects. Future papers will deal with experimental results obtained using the pseudo-dynamic technique. In the numerical model developed, concrete shrinkage and thermal deformation are calculated independently using a THC 3D model [4] , while creep is described by a series of three Kelving-Voigt models [5] and calculated using strain superposition in series with concrete μ Damage model [3]. Then values are implemented into a multifiber finite element model. Damage evolution of the RC structures over time is followed using the numerical model during 28 days and then their dynamic response when subjected to a seismic event is simulated numerically.*

1 INTRODUCTION

In 2018 the Morandi Bridge collapsed in Italy as well as buildings in France causing many deaths. Such dramatic events remind us that during their aging process reinforced concrete structures get damaged and become more vulnerable. This damage starts at early age and continues during the life time of the structure (Figure 1). It can be caused by creep, shrinkage, corrosion, thermal deformation, carbonatation and so on [2]. As a consequence of this damage, the structure becomes more vulnerable and can collapse either due to its self weight and live loads or due to accidental hazards such as an earthquake or an impact. This paper focuses on the impact of the initial damage that takes place during the early age period (0-28 first days) on the seismic response of reinforced concrete structures. In RC design, early age damage is often neglected and it is roughly assumed that the structure is initially undamaged when put into service. Early age effets on structure dynamic performances need to be quantified.

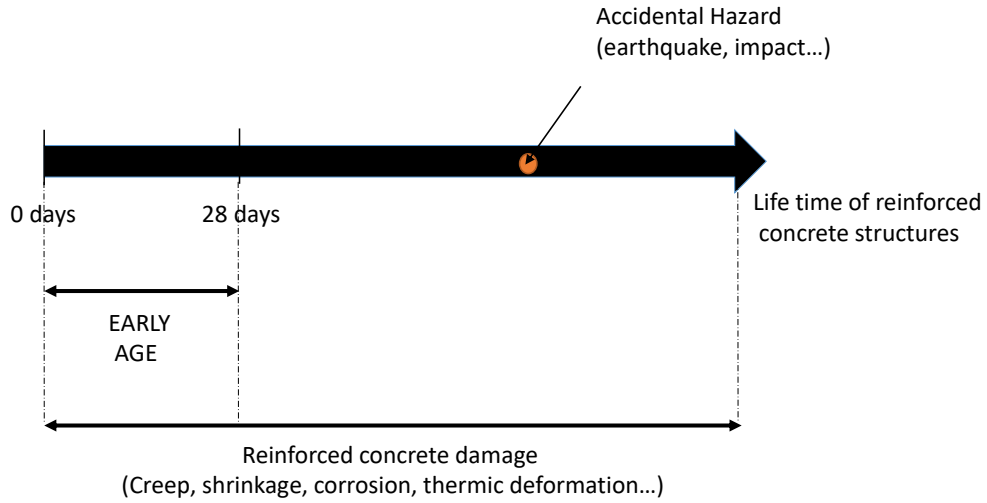

Figure 1: RC deterioration over time

1.1 Methodology

Two types of reinforced concrete portal frames are considered (Figure 2). A first group kept during its early age period in endogenous conditions (by covering it using a plastic sheet) in a way to limit drying effects leading to cracks. It's supposed to be a reference group where almost no damage should happen. The second group will be kept in non-endogenous conditions that are similar to the ones found on construction sites. Consequently, its initial damage will be more important. An enhanced multifiber beam model was developed for each group which allows following their early age damage due to creep, shrinkage, thermal deformation and to evaluate their response under an earthquake. It is based on the THC model of Buffo Lacarrière [4], on the creep model of Briffaut [5] and on the μ damage model [3].The enhanced concrete non-linear constitutive law used will be explained in details. Results obtained with this numerical model will be presented in this paper. In parallel, pseudodynamic tests on the two portal frame groups are still undergoing. Using such technique, which is an interesting alternative to shaking table

tests [6], the same seismic load will be applied on the two types of portal frames after their early age period in order to determine their dynamic response.

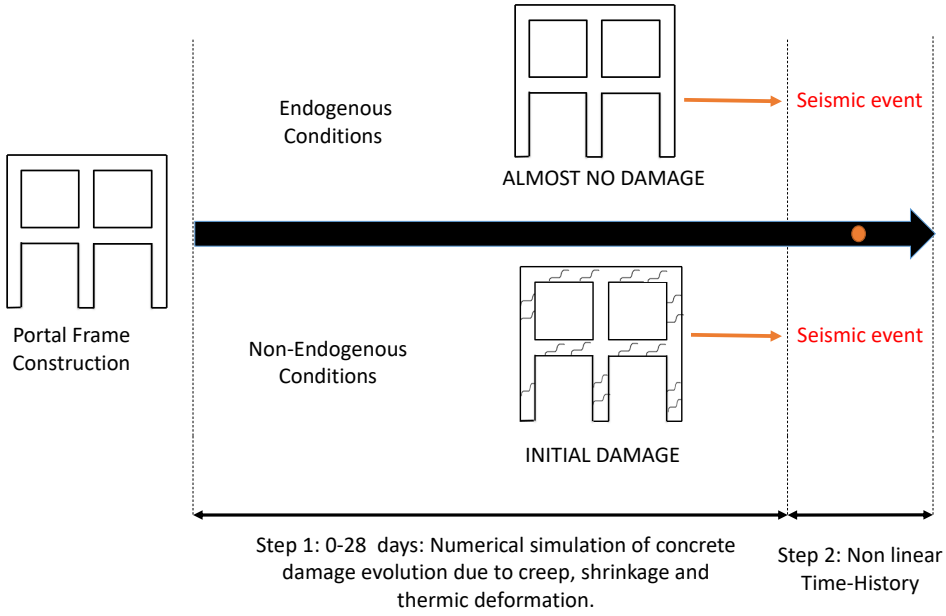

Figure 2: Methodology

Ultimately, the objective of the research project undergoing will be to compare purely numerical results with pseudo-dynamic resuls in order to validate the numerical model and to determine the impact of early age damage on the seismic response of reinforced concrete structures.

2 NUMERICAL MODEL

This section presents in details the numerical model developped for the portal frames.

2.1 Geometry of the structures

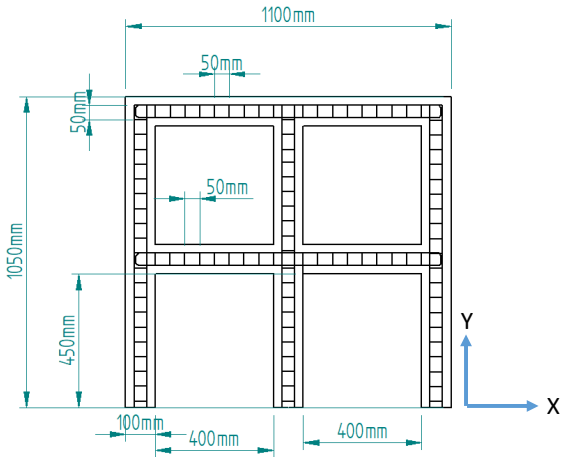
Studied portal frames are 1.05 meter by 1.1 meter structures as shown in Figure 3a. Longitudinal and transverse reinforcements were designed in a way to comply with Eurocodes requirements. Chosen longitudinal and transverse reinforcements have a diameter of 6 mm (Figure 3b). Figure 3c presents the experimental set up that will be used in portal frames pseudo-dynamic tests.

2.2 Material properties

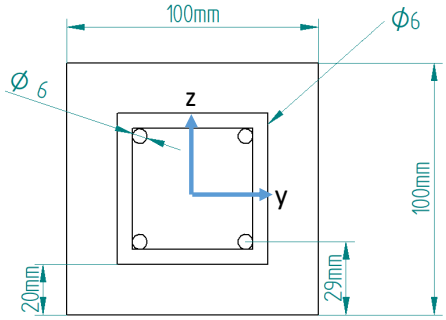
Concrete used in the portal frames has a compressive strength of 30 MPa and a tensile strength of 3.7 MPa. Steel reinforcements have a yield stress of 500 MPa.

2.3 Finite Element discretization

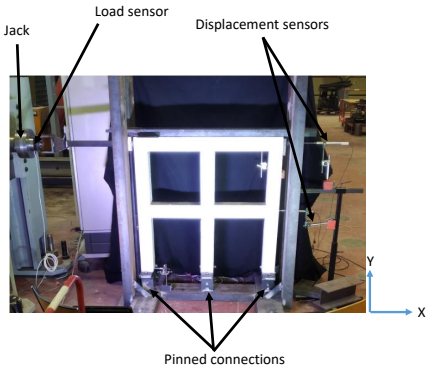
Figure 4b gives node numbers that were used in the finite element model that was developed for the portal frames. The structures are subjected to 3 concentrated masses (M_1, M_2 and M_3)



(a) Front view



(b) Cross-section



(c) Portal frame experimental set up

Figure 3: Geometry of the RC portal frame

(orange circles) representing the contribution of upper floors. $M_1 = M_2 = M_3 = 1148\ kg$. Therefore, $M_{tot} = M_1 + M_2 + M_3 = 3444.4\ kg$. Where M_{tot} is the total mass of the frame (self weight is neglected). The same concentrated masses will be simulated numerically when conducting pseudo-dynamic tests on the portal frames. As seen in figure 4b the structures are pinned at their three ends. It was chosen to use pinned ends rather than fixed ends since such type of connections are more commonly used in constructions (it is very hard to realize fixed connections in practice).

2.4 Multifiber beam model

The portal frame was devided into 3D Timoshenko beam elements, where each beam element is composed of two nodes. At each node there are 6 degrees of freedom: 3 rotations and 3 displacements. Each beam element is composed of 2 Gauss integration points and each integration point represents a cross section made of concrete and steel fibers (for the reinforcements). Concrete fibers are located at the section Gauss points. Using shape functions, displacement value can be calculated at any point of the beam element knowing displacement values at the

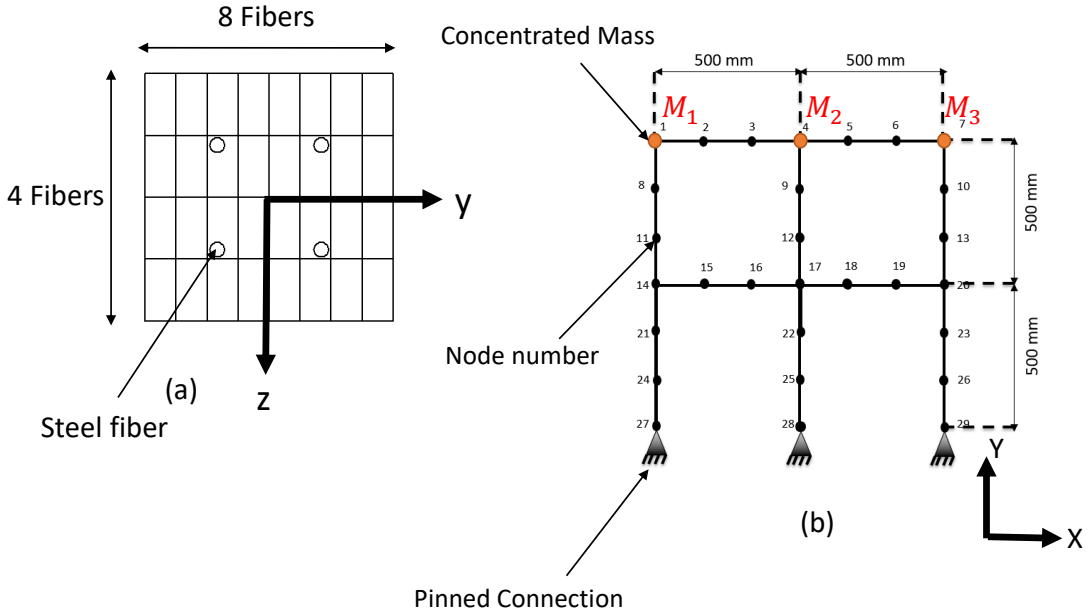


Figure 4: (a) Multifiber cross-section and (b) Finite element mesh and concentrated masses

nodes. Timoshenko kinematic then allows determining strain values at the different fiber elements with displacement values. Then, using a non-linear strain to stress relation stress is determined at the different fibers. Through integration over the cross section, force values at the Gauss points are determined. Figure 5 summarizes the principle of the multifiber beam model used for the portal frames ([10] and [7]). Where: K= Stiffness Matrix; a_s= Section compatibility Matrix; B= Gradient Metric; L= Length of the beam element; U= Nodal displacement; σ = Stress Matrix; P=Load Vector; ϵ= Strain Matrix. Figure 4a gives the multifiber reinforced concrete cross-section used for the concrete portal frames. Its is composed of 32 concrete fibers: 4 fibers in the z direction and 8 fibers in the y direction. 4 additional fibers are used to model steel longitudinal reinforcements (x axis).

2.5 Constitutive Laws

Strain and stress calculation details are given hereafter.

2.5.1 Constitutive laws for concrete

Strain decomposition Deformation at each concrete fiber is calculated in a way to take into account the influence of shrinkage, ceep, thermal deformation, and mechanical deformation. The total deformation at a fiber element is considered to be equal to the sum of all 4 contributions. Hence:

$$\epsilon_{tot} = \epsilon_{shrinkage} + \epsilon_{thermal} + \epsilon_{creep} + \epsilon_{mechanical} \tag{1}$$

Mechanical model Strain to stress relationship for concrete fibers is determined using a non-linear Mazars μ model [8]. This model is based on continuum mechanics. It relates deformation

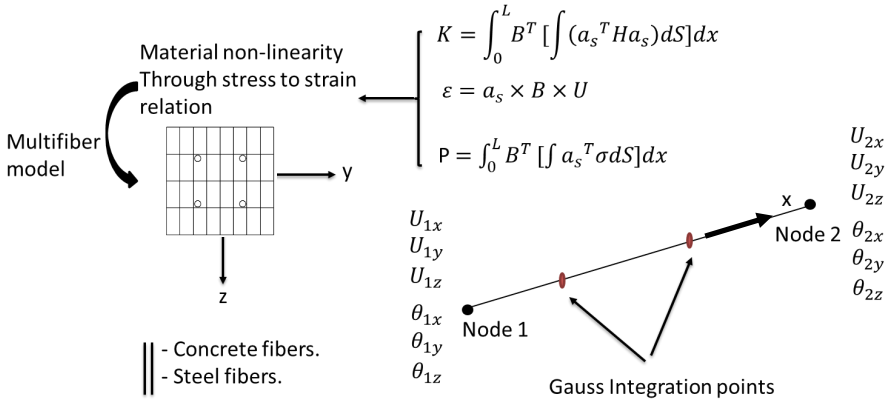

Figure 5: Principle of the multifiber beam model ([7] [10])

to stress using a damage variable D that can be calculated using a thermodynamics framework based on two variables Y_t and Y_c for concrete cracking and crushing.

$$\sigma = \Delta_0(1 - D) : \epsilon \tag{2}$$

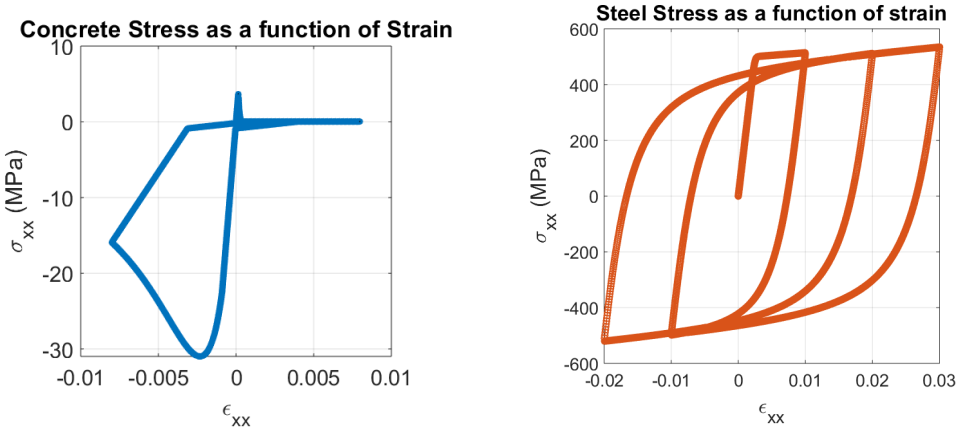
$$Y = rY_t + (1 - r)Y_c \tag{3}$$

$$D = 1 - (1 - A)\frac{Y_0}{Y} - Ae^{-B(Y - Y_0)} \tag{4}$$

Where: Δ_0 = Stiffness Matrix; ϵ = Strain Matrix; σ = Stress Matrix; D = Damage; r = Triaxiality factor; A and B and constant parameters; Y_0 is the initial elastic treshold (takes into account compression and traction contributions). Thus, a 1D cyclic strain to stress relation is used at each concrete fiber as shown in Figure 6a. Where σ_{xx} stands for normal stress along the concrete fiber axis.

Creep model Since strain due to creep and to mechanical deformation are related to each other, an intermediate subsystem as shown in Figure 7 is solved. It is composed of 3 viscoelastic Kelving-Voigt models for creep [5] in series with a non-linear Mazars μ model for concrete [3]. Creep evolution follows a Briffaut model [5] where creep 1 is the primary creep (also known as the transient creep), creep 2 is the secondary creep (also called steady-state creep) and creep 3 is the tertiary creep and has an exponential evolution. Each creep model uses 2 viscoelastic constants τ and k_∞. $\tau_1 = 0.1\ day$; $\tau_2 = 1\ day$; $\tau_3 = 10\ days$ and $k_{1\infty} = 3 \times 10^{11}(\mu m/m)$; $k_{2\infty} = 9 \times 10^{10}(\mu m/m)$; $k_{3\infty} = 2.5 \times 10^{10}(\mu m/m)$. Those values were determined through calibration tests [3] .

Shrinkage and thermal deformations Shrinkage and thermal deformations are calculated independently using a THC (Thermo-hygro-chemo) model with COMSOL Software. The model is based on the work of Buffo-Lacarrière [4] and Mainguy [13]. In such model, the



(a) Concrete Cyclic μ model [8] (b) Steel Cyclic model [9]

Figure 6: Material constitutive laws

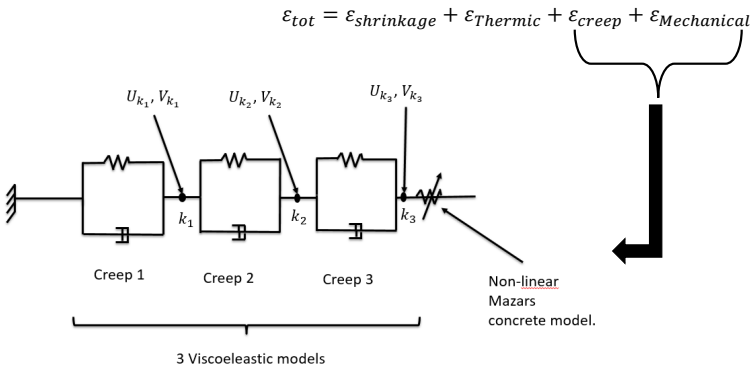


Figure 7: Strain calculation at a fiber element [3] [5]

degree of saturation of the mortar is calculated by solving three sets of differential equations based on conservation laws: liquid water, water vapour and wet air equilibrium equations. The evolution of the total porosity as well as the distribution of pores were taken into account when solving the equilibrium equations to account for early age effects. Using the equivalent pore pressure of cement based materials concept as explained by Coussy [14] shrinkage evolution is then calculated. As for thermal deformation, it was calculated by solving a heat transfer thermal conduction differential equation. All differential equations were solved using COMSOL software and model parameters were calibrated to account for the properties of concrete used in the portal frames.

2.5.2 Constitutive law for steel

For steel reinforcements, a non-linear 1D Menegotto cyclic model with strain hardening [9] is used as presented in Figure 6b. Here, σ_{xx} stands for normal stress along the steel fiber axis.

2.5.3 Material parameters

Table 1 gives concrete and steel parameters used in the numerical model of the portal frames.

Concrete parameters	Steel parameters
$E = 25\ GPa$	$E = 210\ GPa$
$A_t = 0.8$	$F_y = 500\ MPa$
$A_c = 1.62$	
$B_t = 20000$	
$B_c = 500$	
$f_t = 3.67\ MPa$	
$f_c = -10\ MPa$	
$\beta_1 = 0\ MPa$	
$\beta_2 = 0\ MPa$	

Table 1: Concrete and Steel reinforcements model parameters

Where: E= Elastic modulus; ν= Poisson ratio; Y_{01}= Initial damage treshold for traction; Y_{02}= Initial damage teshold for compression; A_t= 1st parameter govering the evolution of damage (traction); A_c = 1st parameter govering the evolution of damage (compression); B_t= 2nd parameter governing the evolution of damge (traction); B_c= 2nd parameter governing the evolution of damage (compression); β_1= anelastic parameter for traction; β_2= anelastic parameter for compression and F_y = Steel yield stress.

2.6 Input Data

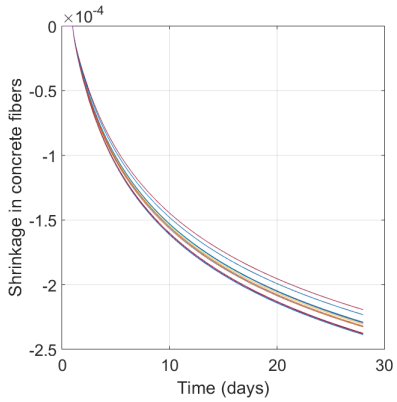
Shrinkage and temperature evolutions calculated using COMSOL were implemented into the multifiber model by interpolation. Figure 8 gives shrinkage and temperature evolutions used as input datas of the numerical model (values at the concrete fibers).

3 Results

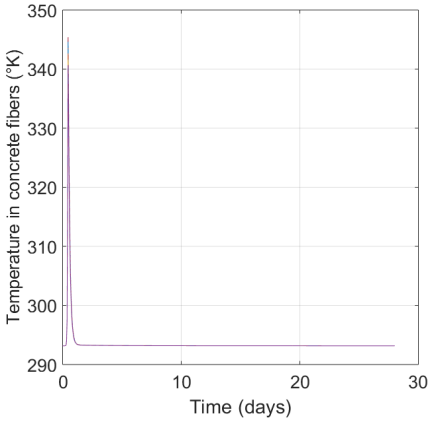
With the enhanced multifiber beam model presented in section 2, concrete damage was followed during the 28 first days of the life time of the two portal frame groups. A modal analysis and spectral analysis were performed in order to quantify the difference in response of both structures after their early age period. A static pushover and a non-linear dynamic analysis were also numerically conducted. Results of those simulations are presented in this section.

3.1 Early Age Damage Evolution

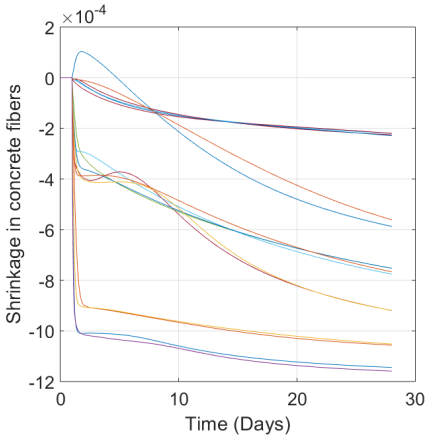
Damage evolution due to shrinkage, creep and thermal deformation was followed for the endogenous and non-endogenous portal frames during their early age period (0-28days). The following results were obtained: During step 1, damage at the different concrete fibers remained



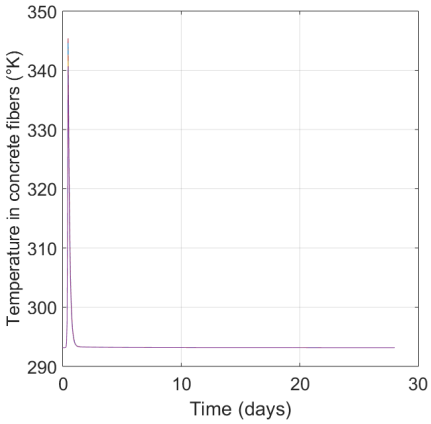
(a) Endogenous case Shrinkage



(b) Endogenous case Temperature



(c) Non-Endogenous case Shrinkage



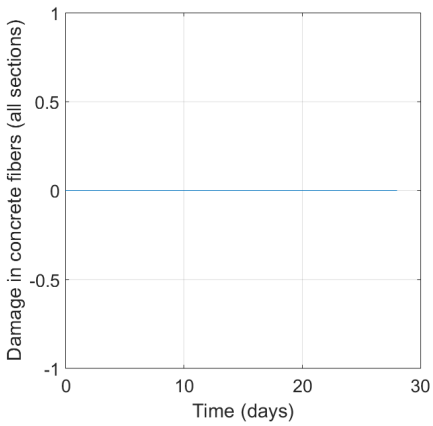
(d) Non-Endogenous case Temperature

Figure 8: Shrinkage and temperature evolutions (at the concrete fibers)

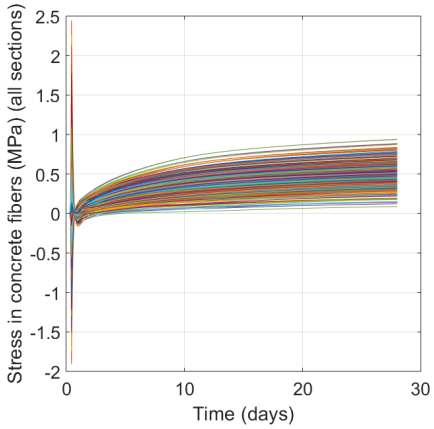
equal to 0 in the portal frame kept in endogenous conditions as shown in Figure 9a since stress value remained below the maximum allowable concrete tensile stress (Figure 9b). In the portal frame kept in non-endogenous conditions, damage increased during the early age period at the different concrete fibers (Figure 9c) since stress reached its maximum allowable value R_t of 3.7 MPa (Figure 9d). Concrete damage during the early age period is thus more important in the non-endogenous case than in the endogenous case because of shrinkage.

3.2 Modal Analysis

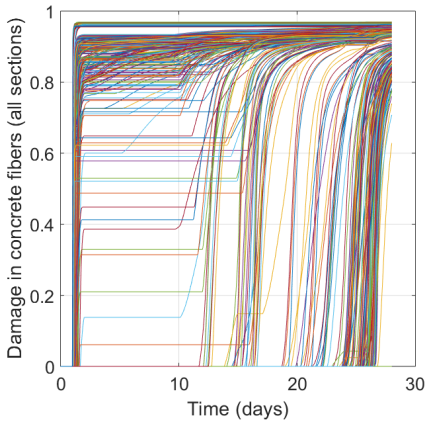
After 28 days (end of step 1 as shown in Figure 2), a modal analysis was performed on both groups. The 3 mode shapes are presented in Table 2. Natural frequencies were calculated after early age for both groups as shown in Table 3. Where f_1= First Natural frequency; f_2= Second Natural frequency and f_3= Third Natural frequency. For the endogenous portal frame, there is no decrease of the natural frequency after the first step since no damage occured. In the non endogenous case, an important damage happened during the first step due to shrinkage, which induced concrete to reach its maximum tensile stress value. A modal analysis performed after that first step showed a decrease (Table 2) of its first natural frequency of about 53% (f_1



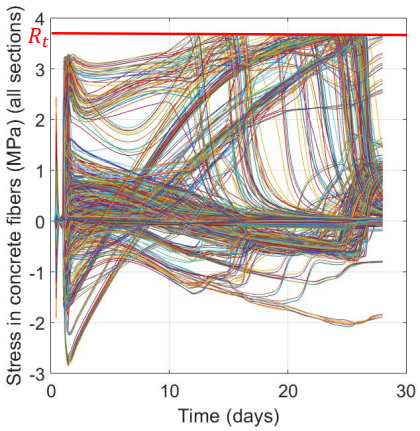
(a) Endogenous portal frame Damage



(b) Endogenous portal frame Stress



(c) Non-Endogenous portal frame Damage



(d) Non-Endogenous portal frame Stress

Figure 9: Damage and normal stress (σ_{xx}) evolutions at early age in all portal frame concrete fibers (many fibers get damaged at early age)

decreased from 6.8 Hz to 3.2 Hz).

It should be noted that the behaviour of the portal frames will be mainly dictated by mode 1. Indeed, concentrated masses on top are very important compared to the self weight of the portal frame. Consequently, effective modal mass participation calculation shows that the total mass M_{tot} of the structure is almost equal to the effective modal mass participation of mode 1. Effective modal mass participation m_{eff_i} of mode i is calculated as follows:

$$m_{eff_i} = \frac{(\phi_i^T M \delta)^2}{\phi_i^T M \phi_i}; \tag{5}$$

Where: ϕ_i is the mode shape value at mode i; M is the structure mass matrix and δ is the projection vector. For instance the endogenous case gives the following results: $M_{tot} = m_{eff_1} + m_{eff_2} + m_{eff_3} \approx m_{eff_1} = 3444.4\ kg$. Thus, the structure behaves as a one degree of freedom system of mass M_{tot}.

Mode1	Mode2	Mode3
		f_1	f_2	f_3

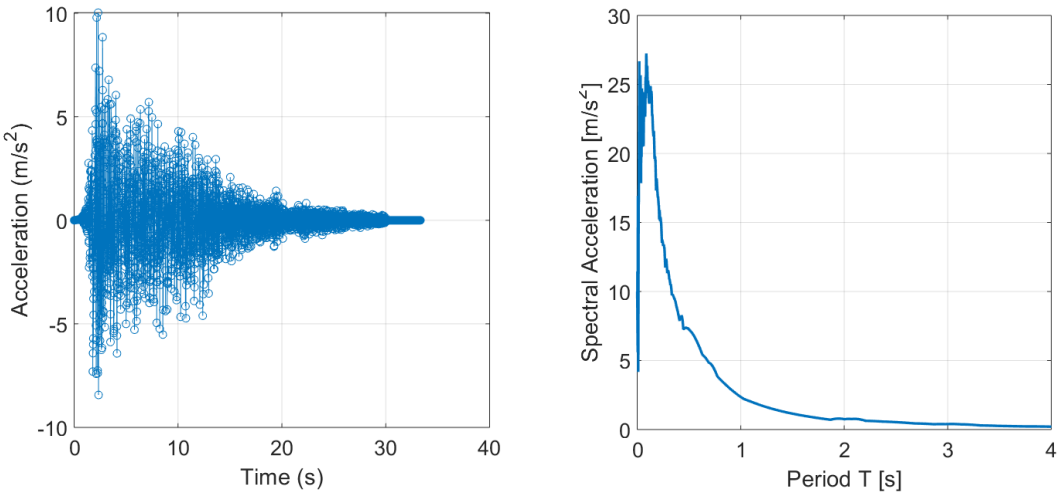
Table 2: Portal frame mode shapes

	Endogenous	Non-Endogenous
f_1 (Hz)	6.8	3.2
f_2 (Hz)	110.7	71.2
f_3 (Hz)	190.8	123.0

Table 3: Natural frequency values at the end of 28 days

3.3 Spectral Analysis

Modal analysis showed that there is a difference in behaviour between the portal frame that was kept in endogenous conditions and the one that was kept in non-endogenous conditions (change in frequency content). In order to further illustrate this difference, a spectral analysis was performed on the portal frames using a Eurocode (French annex) non-linear Time History (Figure 10a). The response spectrum obtained using this non-linear Time History is given in Figure 10b. Spectral Analysis conducted on the two types of portal frames using the Eurocode



(a) Time History [12] (b) Pseudo-acceleration Response Spectrum

Figure 10: Eurocode input data for spectral analysis

accelerogram showed (Figure 11) that the maximum base shear in the endogenous case is equal to 78 kN while it is equal to 42 kN in the non-endogenous case (about 46% decrease). Maximum

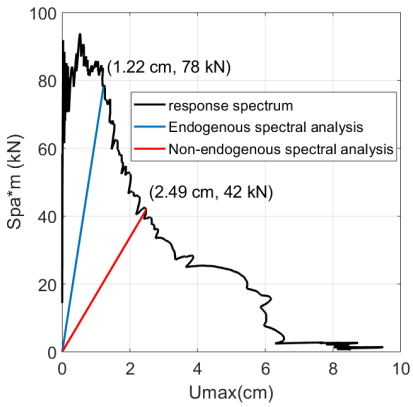


Figure 11: Spectral Analysis results

Base shear is calculated by summing up base shear values F_i^{max} at each mode i.

$$F_i^{max} = \frac{S_{pa} \times \phi_i^T M \delta}{\phi_i^T M \phi_i} M \phi_i; \tag{6}$$

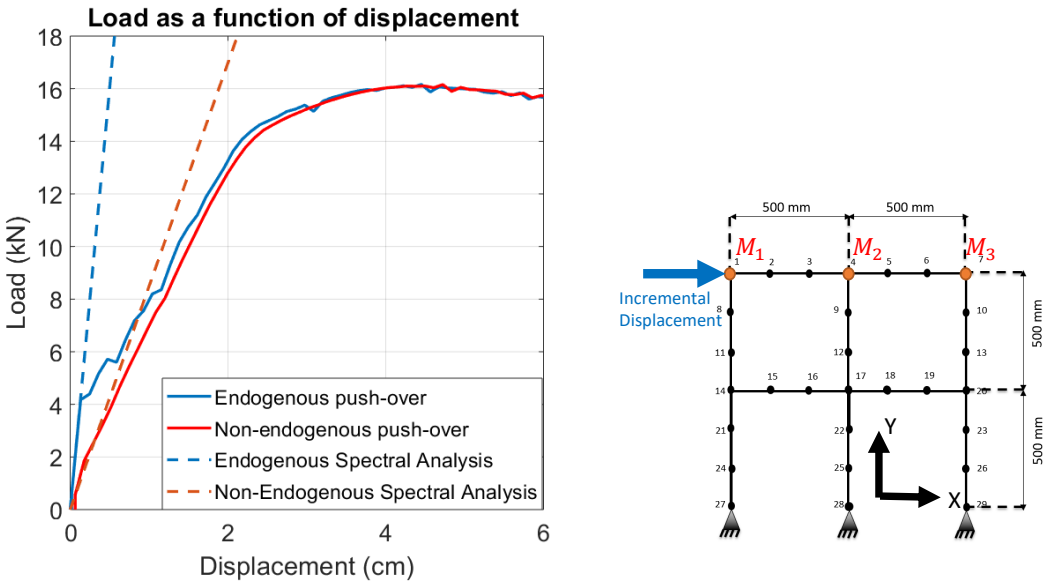
Where: S_{pa} is the spectral acceleration of mode i; ϕ_i is the mode shape value at mode i; M is the structure mass Matrix and δ is the projection vector.

3.4 Static Pushover

A numerical pushover was performed on both groups after their early age period. An incremental displacement was imoposed at node 1 (Figure12b) until reaching the maximum capacity of structures. Load and displacement values at node 1 are calculated in order to plot pushover curves. Results are given in Figure 12a. It can be seen that the initial slope in the endogenous case is 53% higher than the one of the non-endogenous case, while their maximum capacity is similar and equals approximately 16 kN. Pushover results suggest that the behaviour of such structures when subjected to a moderate earthquake will be different while if they are subjected to a very devastating earthquake that cause them to reach their maximum capacity their behavior will be similar.

3.5 Dynamic Analysis

A moderate 0.13 g synthetic accelerogram of the city of Nice (Figure 13a) was applied numerically on the portal frames. Such signal was already used for experimental analysis in [11] and complies with French standards. Load as a function of displacement curves were plot (Figure 13b). Results show that there is a significant difference in behavior between the endogenous and non-endogenous cases. Dynamic curves have the same initial slope as spectral analysis curves, then their slope decreases due to stiffness decrease. Displacement and force evolutions over time are presented in Figures 13c and 13d. It can be seen that the maximum displacement in the non-endogenous case is 30 % higher than the endogenous case while the maximum force is 16 % higher in the non-endogenous case than in the endogenous case. The behaviour of the two portal frames groups is very similar (14) when they are subjected to a



(a) Pushover results

(b) Pushover loading

Figure 12: Static numerical pushover loading (12b) and results (12a)

Eurocode devastating synthetic Time History [12] (French annex) as it causes them to reach their maximum capacity.

4 CONCLUSIONS AND PERSPECTIVES

Hence, numerical multifiber finite element models that allow assissing the behavior of RC structures under a seismic loading while accounting for early age damage were developed. Such models showed that the first natural frequency of a portal frame that was kept during its early age period in non-endogenous conditions, decreases by 53% after its first 28 days while it remains constant for a portal frame kept at early age in endogenous conditions. Under a non-linear moderate intensity accelerogram, portal frames kept in endogenous and non-endogenous conditions during their early age behave differently. It was noticed that the maximum displacement in the non-endogenous case is 30 % higher than the endogenous case whereas the maximum force is 16 % higher in the non-endogenous case than in the endogenous case. Pseudodynamic tests are undergoing on the RC structures. Experimental results will be compared to numerical ones in order to improve and validate the numerical model.

Abstract

Progressive collapse consists in the spreading of local damage from element to element, which results in the collapse of the entire structure or a large part of it. To avoid progressive collapse, the structure should withstand events like fire, explosions, impact or the consequences of human error, without being damaged to an extent disproportionate to the original cause. In this study, nonlinear dynamic response of a reinforced concrete framed structure to multiple column-loss scenarios is investigated by means of fiber-based finite element capacity models and incremental-mass dynamic analysis. The influence of removal of two columns on the behavior of the structure is evaluated. The residual capacity of the structure was assessed under varying location and time of columns' removal. Two different multiple column-loss scenarios were explored, namely simultaneous and sequential removals. Analysis results allow the worst scenarios to be identified, as well as the sensitivity of progressive collapse resistance to be evaluated.

Keywords: Progressive collapse, Robustness, Reinforced concrete buildings, Column loss, Nonlinear dynamic analysis.

1 INTRODUCTION

Extreme events can produce a special type of structural failure that is named progressive collapse and is characterized by damage propagation from a portion of the structure to the whole structural system or a significant part of it. Such a type of systemic failure is referred to as disproportionate collapse when damage propagation produces a disproportion in size between the final and initial amounts of damage. Many structures have suffered progressive collapse, motivating a growing research on this topic in the last twenty years [1]. The Ronan Point apartment building in London, UK, which partially collapsed after a gas explosion, and the Murrah Federal Building in Oklahoma City, Oklahoma, which was destroyed by a bomb explosion, are two symbolic events that have contributed to increase the worldwide interest on progressive collapse. Nonetheless, a few studies have been carried out to assess the influence of multi-column loss on nonlinear dynamics and progressive collapse resistance of reinforced concrete (RC) building structures [2-4]. This work is aimed at investigating the capacity of RC framed buildings subjected to either simultaneous or sequential, sudden loss of couples of columns at the ground floor. The loss of multiple columns can be induced by several actions such as detonation of explosives at different locations and impact of objects dragged by floods or flow-type landslides.

2 METHODOLOGY AND CASE-STUDY STRUCTURE

The building under study is a RC framed structure investigated in previous studies (see e.g. [5]), from which a two-dimensional (2D) capacity model was extracted to carry out progressive collapse simulations. The structure was designed only to gravity loads, according to Eurocode 2 [6], and consists of five floor levels, five primary frames with six bays in the *x*-direction and seven secondary frames with four bays in the *y*-direction. Primary frames provide the main support to one-way slabs and one of those 2D framed systems is considered herein. The case-study structure is characterized by the same span length in both directions ($L_x = L_y = 5$ m) and the interstory height is 3 m at each floor. Column and beam cross sections are 400×400 mm^2 and 300×500 mm^2, respectively. Uniform longitudinal reinforcement consisting of 8 Ø18 was assigned to columns, while 6 Ø18 were used to reinforce beams. Transverse reinforcement is composed of Ø8 stirrups with spacing of 200 mm, both in beams and columns. Concrete and steel properties are listed in Table 1.

Material	Property	Value [MPa]
Concrete	f_{ck}	20
	f_{cd}	11.3
Steel	f_{yk}	450
	f_{yd}	391.3

Table 1: Material properties.

Design strengths of concrete and reinforcing steel were defined as $f_{cd} = 0.85f_{ck}/1.5$ and $f_{yd} = f_{yk}/1.15$, respectively, where f_{ck} and f_{yk} denote the characteristic values of cylinder concrete strength and yielding steel strength.

The structure was modeled through the FE code Seismostruct [7], in which the nonlinear capacity modeling of the structure was based on a spread plasticity approach with force-based fiber formulation. The use of fiber elements allows the flexural, arching and catenary behavioral modes of RC beams to be well simulated [6,8-10]. A force-based formulation was assumed to accurately simulate the deformed shape during progressive collapse analysis. Each

cross section was discretized in 200 fibers. A simple bilinear hysteretic model with isotropic strain hardening was assigned to reinforcing steel. The uniaxial uniform confinement model by Mander et al. [11] was used for concrete, explicitly accounting for tension softening and conservatively omitting strain rate effects in the simulations [12].

Nonlinear time history analysis (NLTHA) was carried out using a tangent stiffness-proportional Rayleigh damping and the Newton-Raphson algorithm with a displacement/rotation based convergence criterion to iteratively equilibrate loads.

The progressive collapse capacity of the structure was assessed through IDA, which is a series of NLTHAs performed with an incremental intensity of gravity loads. According to UFC guidelines [13], the following design load combination was used:

$$Q_{bd} = 1.2DL + 0.5LL \tag{1}$$

in which *DL* and *LL* indicate the dead load and live load, respectively. The former was assumed to be 3 kN/m^2, whereas the latter was set to 2 kN/m^2.

Different scenarios were identified, depending on the position of the removed column and its deactivation time. A special purpose, death element routine (i.e. activation/deactivation time option) was integrated in Seismostruct [7] to operate member removal. Columns were labeled as shown in Figure 1. As gravity loads on the structure were increased, the maximum load capacity, $Q_{b,max,}$ and the corresponding vertical drift, θ_{max}, were monitored in order to identify the worst column-removal scenarios. The vertical drift was defined as follows:

$$\theta = \tan^{-1}(D_v / L_b) \tag{2}$$

where L_b is the beam length and D_v denotes the downward displacement of the residual structure after column removal. That kind of displacement was monitored at the upper joint (control point) of one of the removed columns until system failure was reached.

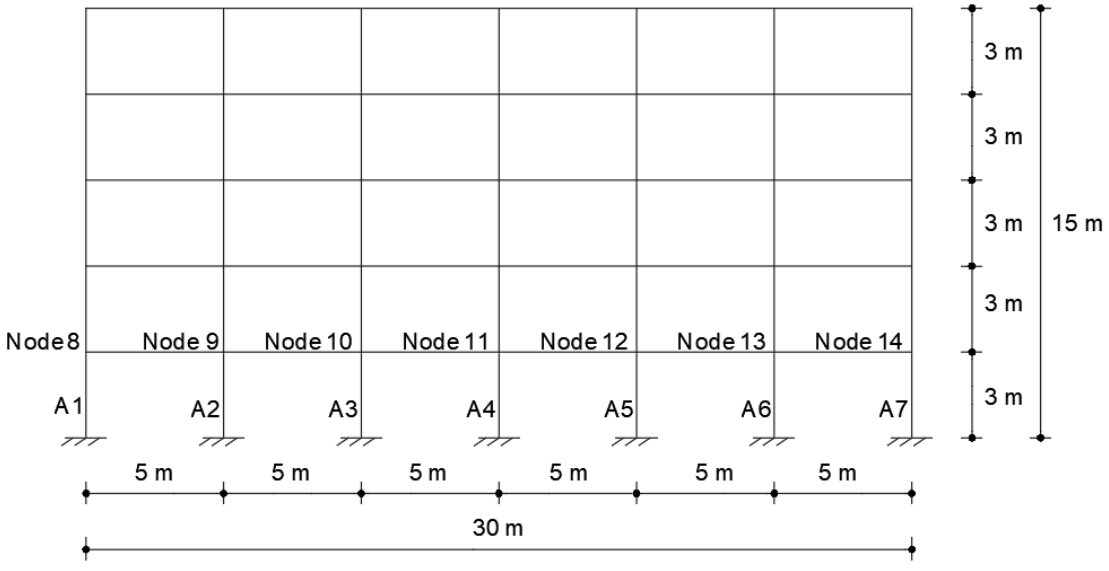

Figure 1: Labeling of columns removed at the ground floor and control points.

The methodology used to generate the multiple column-loss scenarios considered in this research is outlined in Figure 2. Two different strategies were used by varying the deactivation time of columns, which is here denoted as T_d. If two generic columns *i* and *j* are considered, the simultaneous removal was obtained by assigning them the same deactivation time,

i.e. $T_{di} = T_{dj} = 10^{-2}$ s. Conversely, the sequential removal was achieved by removing the generic column *i* (or *j*) at $T_{di} = 10^{-2}$ s and column *j* (or *i*) at either 10^{-1} s or 1 s.

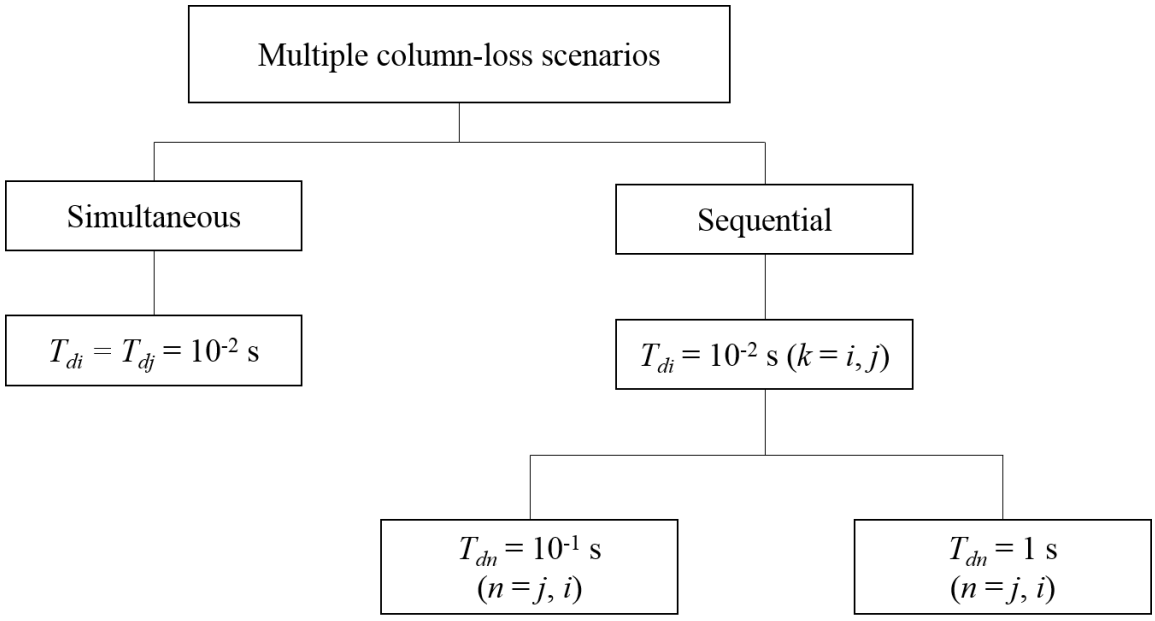

Figure 2: Framework for progressive collapse resistance assessment.

3 DISCUSSION OF RESULTS

3.1 Simultaneous removal of columns

In the first stage of research, the influence of simultaneous removal of columns on the progressive collapse capacity of the structure was evaluated. As previously mentioned, simultaneity was obtained by assigning the same deactivation time to couples of columns *i* and *j*, that is $T_{di} = T_{dj} = 10^{-2}$ s. Twelve multi-column removal scenarios were selected due to the symmetry of the structure and one hundred NLTHAs were carried out. Analysis results in terms of $\alpha_{max} = Q_{b,max}/Q_{bd}$, i.e. the percentage of design load associated with maximum load capacity, and corresponding vertical drift are listed in Table 2. The results show that the structure was able to withstand the highest percentage of design load in case of simultaneous removal of corner columns (scenario A1-A7) and when opposite columns adjacent to corner columns were simultaneously removed (scenario A2-A6). By contrast, when consecutive columns at a frame corner were removed, the capacity of the structure drastically reduced to 30% of design load. Table 2 also shows that, in the case of simultaneous removal of a corner column (A1) and any internal column (A2, A3, A4, A5, A6), the vertical drift is more sensitive to the control point than in the case of other scenarios that do not involve a corner column. To better understand this finding, IDA curves related to scenarios A1-A4 and A2-A4 are plotted in Figures 3a and b. The former scenario involved a corner column, while the latter did not. It is recalled that IDA curve is a dynamic capacity curve that provides the relationship between the gravity load intensity and a response parameter, namely the downward displacement of the control point in this case. Figure 3a shows that IDA curves associated with scenario A1-A4 are quite different in terms of displacement capacity, as the latter structural feature is sensitive to the control point (i.e. node 8 or 11). On the other hand, the curves related to scenario A2-

A4 (Fig. 3b) indicate a negligible variation in displacement capacity between the two control points (i.e. nodes 9 and 11).

Scenario	α_{max} [%]	θ_{max} [%]	
A1-A2	30	Node8	Node9

Figure 4: Collapse mechanisms under multi-column removal: (a) scenario A1-A2; (b) scenario A1-A7.

3.2 Sequential removal of columns

The consequences of column loss scenarios involving the notional (sudden) removal of column A1 were evaluated, because of their greater impact in simultaneous scenarios in terms of maximum load capacity and vertical drift of the structure.

According to the scheme in Figure 2, sequential column-removal scenarios were generated by assigning different deactivation times T_{di} and T_{dj} to each couple of columns i and j, as well as the possible loss sequences with $T_{di} < T_{dj}$ and vice versa. This approach led to 6 scenarios, each of them with 4 combinations of deactivation times (Table 3).

Table 4 outlines the maximum load capacity and maximum drift capacity associated with each scenario and couple of deactivation times, denoting maximum values in bold. It is evident that structural capacity under sequential removal scenarios reduces or does not change when the column is removed at 0.1 s, compared to the case of simultaneous removal. Conversely, the capacity of the structure increases when either a corner or internal column is removed at 1 s.

Scenario A1-A7 remains always the local damage condition that allows the highest load capacity of the structure. Even when central columns were removed at 0.1 s, load capacity reduced by 5%. In almost all scenarios, the removal of the second column at 1 s produced an increase in $Q_{b,max}$, nearly approaching the maximum value (α_{max} = 140%). Indeed, in scenarios A1-A3 and A1-A4, the removal of columns A1 and A4 at 1 s induced the attainment of α_{max} = 139%.

Scenario	Deactivation times
A1-A2	T_{d1} = 0.01 s, T_{d2} = 0.1 s
	T_{d1} = 0.01s, T_{d2} = 1s
	T_{d2} = 0.01s, T_{d1} = 0.1s
	T_{d2} =0.01s, T_{d1} = 1s

	T_{d1} = 0.01s, T_{d6} = 1s
	T_{d6} = 0.01s, T_{d1} = 0.1s
	T_{d6} = 0.01s, T_{d1} = 1s
A1-A7	T_{d1} = 0.01s, T_{d7} = 0.1s
	T_{d1} = 0.01s, T_{d7} = 1s
	T_{d7} = 0.01s, T_{d1} = 0.1s
	T_{d7} = 0.01s, T_{d1} = 1s

Table 3: Sequential column-loss scenarios and deactivation times.

Table 4 also shows the vertical drift capacity of the structure for each sequential loss scenario. The highest value of θ_{max}, which is equal to 11.40%, was attained when considering scenario A1-A2, particularly in the combination where column A2 was removed at 0.01 s and column A1 was removed at 1 s. By contrast, scenario A1-A3 was found to be the worst case in terms of vertical drift capacity. Indeed, the lowest value of θ_{max}, that is 2.54%, was reached when columns A1 and A3 were removed at 0.01 s and 0.1 s, respectively. It is worth noting that such a drift capacity is very low compared to beams drifts observed in several experimental tests, as discussed in [1].

Table 5: Variations in maximum load capacity and drift capacity from simultaneous to sequential scenarios.

If $T_{di} = T_{d1}$ = 0.01 s and T_{dj} = 0.1 s (with j = 2,….,7) are considered, the maximum load capacity reduces with variations ranging from –1.47% (scenario A1-A5) to –12.50% (scenario A1-A3). In scenarios with T_{dj} = 1 s, the maximum load capacity increased, except for scenarios A1-A6 and A1-A7 that produced the same capacity levels and scenario A1-A5 that induced a small capacity drop. The maximum increase, which was equal to 3.33%, was obtained for scenario A1-A2.

Sequential scenarios with T_{dj} = 0.01 s and varying T_{d1} produced the following outcomes:

- the load capacity reduced again in almost all cases when T_{d1} = 0.1 s;

- if T_{d1} = 1 s, the load capacity increased in scenario A1-A2 and A1-A3, while reducing or remaining the same in other scenarios.

The highest increase in maximum load capacity (i.e. +13.33%) was recorded for scenario A1-A2, which was characterized by T_{d2} = 0.01 s and T_{d1} = 1 s. The highest reduction in load capacity (i.e. –12.50%) occurred in scenario A1-A3, namely when the following deactivation times were assumed: T_{d1} = 0.01 s and T_{d3} = 0.1 s.

Scenario A1-A3 is also characterized by the maximum and minimum variations in vertical drift capacity, which were respectively found to be +10.70% and –63.05%. The analysis results outline that in most cases the maximum vertical drift reduced.

IDA curves were derived for each scenario, showing the sensitivity of maximum vertical drift to the percentage of design gravity load and deactivation times of removed columns. Figures 5a–d show the IDA curves related to scenario A1-A3, which turned out to be the most significant. Markers allow a quick identification of the difference between sequential scenarios (red and blue lines) and simultaneous scenarios (black lines).

In addition to IDA curves, displacement time histories associated with consecutive increments of gravity loads were obtained, particularly recording the structural response corresponding to the maximum load capacity. Figures 6a–d show the displacement time histories related to scenario A1-A3 and ultimate conditions (i.e. associated with $Q_{b,max}$).

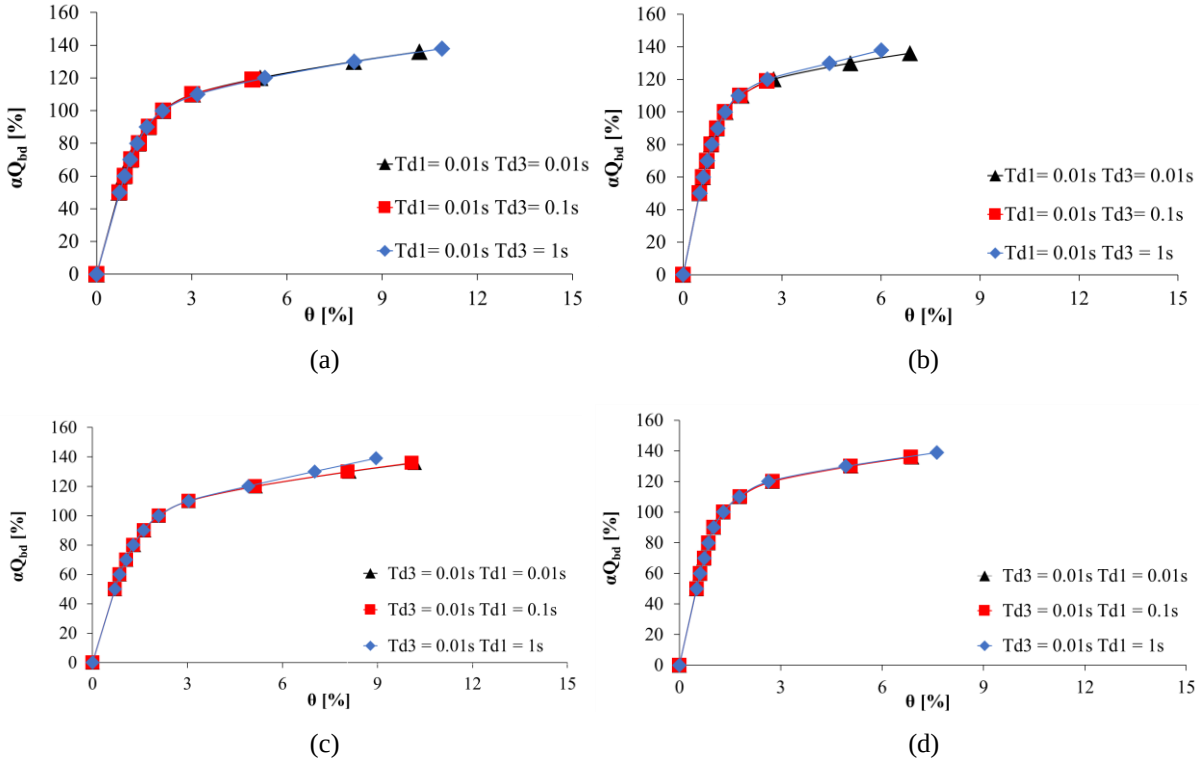

Figure 5: IDA curves related to scenario A1-A3: (a) T_{d1} = 0.01 s and control node 8; (b) T_{d1} = 0.01 s and control node 10; (c) T_{d3} = 0.01 s and control node 8; (d) T_{d3} = 0.01 s and control node 10.

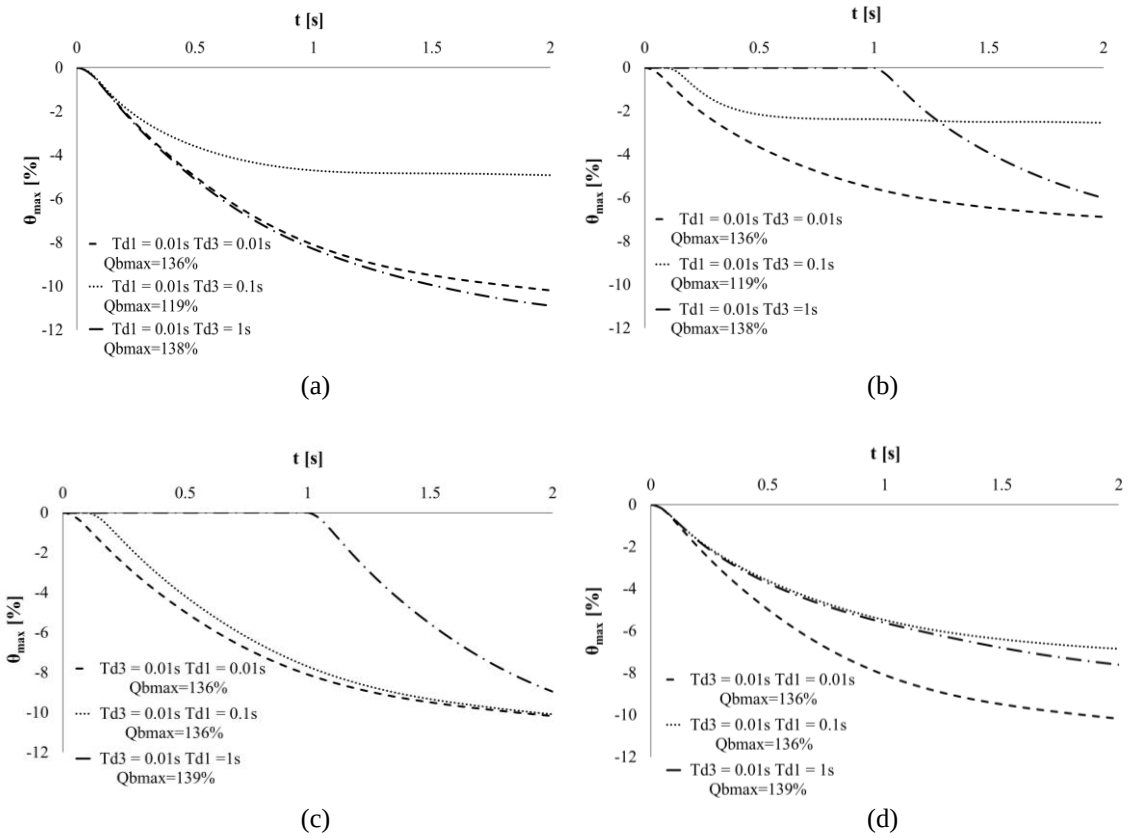

Figure 6: Displacement time histories at ultimate conditions related to scenario A1-A3: (a) T_{d1} = 0.01 s and control node 8; (b) T_{d1} = 0.01 s and control node 10; (c) T_{d3} = 0.01 s and control node 8; (d) T_{d3} = 0.01 s and control node 10.

4 CONCLUSIONS

In this study, two different cases of multiple columns loss, namely simultaneous and sequential scenarios, and their influence on a RC framed building were investigated. Scenarios were differentiated one each other by considering different couples of columns, deactivation times and removal sequences. Analysis results allow the following conclusions to be drawn:

- Simultaneous removal of two columns induced 140% and 30% of design gravity load as maximum and minimum load capacities, respectively.
- After simultaneous removal of columns, the maximum load capacity was reached when two corner columns (scenario A1-A7) and two opposite columns adjacent to corner columns (scenario A2-A6) were removed. Conversely, the minimum load capacity was found when two consecutive columns were removed.
- The maximum load capacity under sequential removal scenarios was lower than or equal to that associated with simultaneous scenarios when the second column was removed at a time instant 10 times higher than that of the first column removal. On the contrary, the load capacity increased again when the second column was removed at a time instant 100 times higher than that of the first column removal.

Further research is required to assess the progressive collapse resistance under simultaneous and sequential scenarios involving the loss of multiple columns located at different floor levels.

Abstract

Driven piles used in the foundations of earthquake resistant structures are typically designed to sustain horizontal shear loads together with excessive axial loads. Moreover, it is frequent to use the equivalent static load analysis in piles design. However, in contrast to vertically loaded piles, laterally loaded piles behavior has different characteristics. Such characteristics include that the soil-pile interaction is more complex, as well as the demand that the soil-pile system must respond elastically.

As a result of that, it can be figured out that the lateral capacity of the pile depends on the soil properties, the geometrical and material properties of piles, such as the pile stiffness, embedded depth, and the horizontal allowable displacement. Furthermore, in-situ static and dynamic pile tests indicate that the lateral capacity of piles results from the comprehensive behavior of various factors described above. Based on such complexity of modeling the problem, it may be beneficial to use field tests results such as PDA tests and CAPWAP analysis to give a close estimate to the actual piles lateral capacity. Such results can act as proof testing, confirming that the expected capacities assumed in design are in fact available in the field.

Thus, based on accumulative results of PDA-CAPWAP tests in different types of soil for different types of piles and by modeling the soil pile-system and asymptotically loading laterally till critical displacements are achieved, a stochastic equation is derived to correlate the piles lateral capacities to available geotechnical information and PDA-CAPWAP tests. This is based on the assumption that the resistance to penetration can be divided into lateral and vertical components.

1 INTRODUCTION

There are many reasons why a geotechnical engineer would recommend a deep foundation over a shallow one, but some of the common reasons are very large design loads, a poor soil at shallow depth, or site constraints like property lines. There are different terms that are used to describe the different types of deep foundations including piles, drilled shafts, and caissons. Piles are generally driven into the ground in situ where other deep foundations or pile are typically put in place using excavation and drilling. The naming conventions may vary between engineering disciplines and firms.

Piles are designed to withstand lateral applied loads without undergoing a structural failure or exceeding deformation limits. The behavior of laterally loaded piles is complicated due to the nature of the pile-soil interaction, where the soil resistance at any point is a function of the pile's deflection at that point, while the pile deflection is a function of the soil's resistance. As such; the engineering parameters of the soil, the pile properties, and geometry are the main parameters determining the response of a laterally loaded free-head single pile. Laterally loaded piles are commonly analyzed using the well-known *P*-*Y*-method, in which the pile-soil stiffness is defined by nonlinear soil resistance (p) vs. lateral deflection (y) curves derived from field tests.[1]

However, the soil profile properties under any structure cannot be neglected in such an assessment since the soil underneath structures is undoubtedly the medium that transfers the seismic excitation to the structures foundations. The process in which the response of the soil influences the motion of the structure and the motion of the structure influences the response of the soil is termed as soil-structure interaction (SSI) [2]. Moreover, studying the soil formation in any region, one can recognize that the geological conditions, topographic characteristics and climatic conditions play a vital role in such soil formation. Thus, the soil is generally considered as a three-phase system (air, water and solid) causing significant changes in the system characteristics due to the interaction of these phases under applied dynamic or static loads [2]. Accordingly, determination of dynamic soil properties is a critical requirement in geotechnical-earthquake engineering problems.

2 PROBLEM DEFINITION

Pile foundations usually find resistance to lateral loads from (a) passive soil resistance on the face of the cap, (b) shear on the base of the cap, and (c) passive soil resistance against the pile shafts. The latter source is usually the only reliable one. Analysis of the problem yields deflections, rotations, moments, shears, and soil reactions as required for the structural design. Beam-on-elastic-foundation theory is adequate for analysis of the problem. Most piles are relatively flexible and may be analyzed as though infinitely long. Only short rigid piles are likely to require consideration of the lower boundary conditions in the analysis. Non-dimensional solutions are available for both constant and linearly increasing modulus-depth relationships. [3].

As Designers usually seek simpler methods for application in their design and assessments, it would be beneficial to obtain estimates of the lateral capacity from available soil properties and CAPWAP field tests results. Such estimates not only can help designers but rather can even help confirm to quality control engineers that the erected driven piles in-situ complies to specifications requirements. For efficiency, the expected behavior of different soil profiles under seismic effect needs to be verified in advance. This application is important as it affects

the design strategy of structures in general but mostly large and strategic ones including piles in their foundation systems.

3 LITERATURE REVIEW

Laterally loaded piles may be classified as active piles or passive piles, with regard to the loading transferring direction between the piles and the surrounding soils (De Beer, 1977). An active pile is principally loaded at its top, with the lateral load being transferred to the soil; such as piles acting as foundations for transmission towers, advertisement posts and offshore structures. A passive pile usually sustains lateral thrusts along its shaft arising from horizontal movement of the surrounding soil; such as piles in a moving slope or landslides. A variety of design and analysis methods have been developed for both active and passive piles. These methods range from relatively simplistic approaches that calculate the ultimate lateral capacity to relatively sophisticated methods involving advanced numerical analyses that estimate the pile deflections. First, the approaches for analyzing active piles are reviewed. They are subdivided into five sections: (1) pile flexibility and critical length; (2) failure modes; (3) limiting force or ultimate soil resistance profiles; (4) ultimate lateral capacity; and (5) load- deflection calculation of laterally loaded piles.

4 CASE STUDY

The lateral load resistance of pile foundations is critically important in the design of structures which may be subjected to earthquakes, high winds, wave action, and ship impacts. Because of the high cost and logistical difficulty of conducting lateral load tests on the pile. Several case studies on 28 driven pre-stressed concrete piles areas in Route 52 Causeway, New Jersey, United States of America (fig. 1)

As part of the site investigation, cone penetration tests were performed to characterize the subsurface conditions. The pile load testing program consisted of dynamic testing by means of the Pile Driving Analyzer (PDA), CAPWAP and full-scale static load tests. The results of the cone penetration tests, dynamic and static load tests, and pile driving records were analyzed to form a database of high quality, well-correlated data to inform the models. The results indicate that cone penetration tests can be used to accurately predict capacity and required embedment lengths for the tapered piles. PDA and CAPWAP testing measures acceleration and strain imparted to a pile during driving. These data are then used in CAPWAP to calculate pile capacity. The CAPWAP program runs a numerical simulation of load testing the pile. It compares calculated capacity to the acquired PDA data, iterating until it converges on the indicated pile capacity.

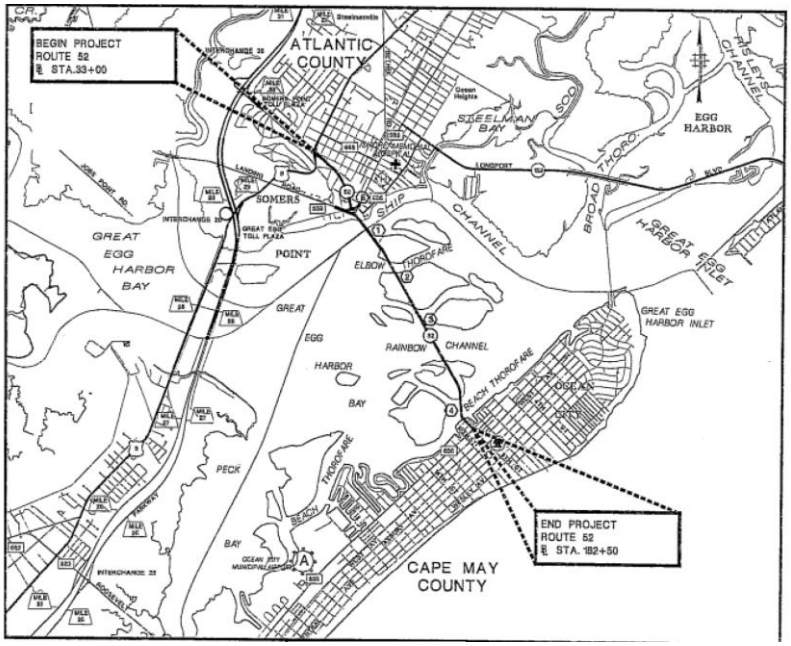

Figure 1

5 DATABASE

Data was collected from 28 PDA tests for the purposes of this study which driven piles were installed for bridge foundations. Typical records of pile driving (pile penetration rate and hammer stroke) were accompanied with dynamic measurements using a Pile Driving Analyzer (PDA) for both end of driving and beginning of restrike conditions. All piles were prestressed concrete piles driven with an impact hammer and is presented in Table 1. In the case of the square piles was calculated the equivalent diameter. According to AASHTO bridge design specifications [4], the resistance factor for driven piles is 0.65.

6 SOIL STRATIFICATION

The subsurface profile was characterized using a variety of methods to provide basic geotechnical data for use in subsequent computer analyses of the test results. Based on the results of the field and laboratory testing, but to simplify reading the soil properties of each layer, the soil profile shown in Table 2 was developed. The soil profile generally consists of two main layers first one was losses sand and the second layer was dense sand.

Table (2) Sample of soil Profile

7 METHODOLOGY

The present study focuses on determining the pile-head deflections. Typically, these values may often govern the design of laterally loaded piles. Therefore, an estimate of these values is of primary importance. In the present study, the LPile program was utilized to determine the pile-head deflections corresponding to the applied lateral load the pile head at the ground surface (i.e., lateral load applied at an eccentricity from the ground surface). The latter program has the capability to generate and take into account nonlinear values of flexural stiffness (EI). These values are generated internally by the program based on cracked/uncracked concrete behavior and user-specified pile dimensions, and material properties for reinforced concrete sections. LPile software can perform pushover analyses and analyze the pile behavior after a plastic hinge (yielding) develops. The soil-layers data structures can be entered conveniently with default values provided. Therefore, LPile may be advantageous over other applications for the subject handled in this research. However, future studies would use other techniques as finite element analysis for soil modeling in the studied problem for comparison.

By using (H. G. Poulos 1980) [5] method, a linear elastic soil response due to lateral pile movements was assumed. A critical length, *L*c, exists for a laterally-load pile, over which any increase in pile length has no influence on the ground line deflection δ. The critical pile length *L*c is a function of the relative stiffness of pile and soil nature (H. G. Poulos 1989). *L*c can be calculated from the following equations:

$$L_c = 4.44 \sqrt[4]{\frac{E_p I_p}{E_s}} \qquad (1)$$

Where: E_pI_p is the bending stiffness of pile, and E_s is the Young's modulus of soil.

8 FAILURE CRITERIA

There are many methods of analyzing the response of a laterally loaded pile. These methods can be categorized into the subgrade reaction approach and elastic continuum approach. Subgrade reaction approach has been initially proposed by Palmer & Thompson and subsequently further developed by Reese and Matlock (1956). Further advancements lead to the development of p-y curves and are commonly used to model the non-linear pile and soil behavior. These have been described by McClelland and Focht [6] and Davisson and Gill (1963), Often nonlinearity typifies the pile load-deflection behavior.

The p - y curve simply relates the unit soil resistance to pile deflection. Theoretically, it is normally assumed that the soil in the back and front of the pile will remain in contact with reference to the pile during lateral displacement. The slope of the *P-Y* curve at any deflection represents the tangent soil stiffness at that deflection. The ratio p/y at any deflection represents the secant soil stiffness corresponding to that deflection [7].

(H. Matlock 1970) developed the empirical expression to represent the p - y curve defined by the power function of deflection normalized by pile deflection at 50% of the ultimate soil reaction. In case of the sand layer (L. C. Reese 1974) [8] proposed the procedure in constructing the *p-y* curves for sand under static and cyclic lateral loadings. The method in developing the *p-y* curves involves the estimation of the initial modulus of subgrade reaction and ultimate soil resistance. Flexible driven piles embedded in a deposit of submerged, dense, fine sand (Cox *et al*., 1974). The characteristic shape of the *p-y* curve is highly nonlinear and can be described by three straight line portions and a parabolic curve as illustrated in Figure 2

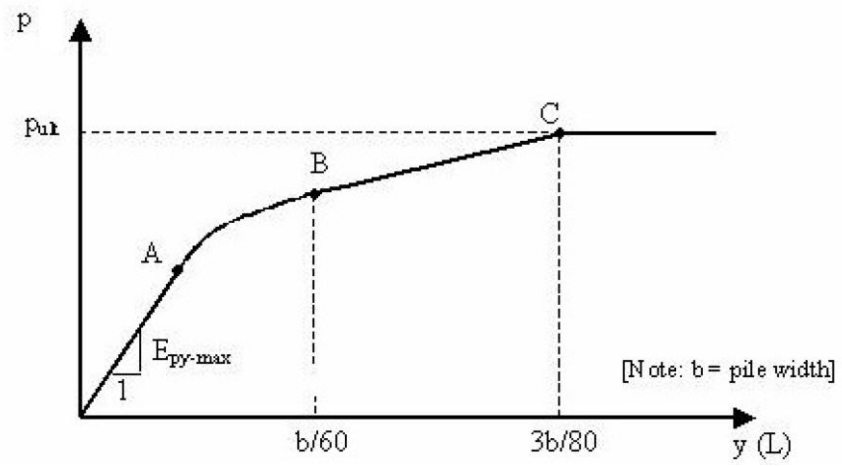

Figure 2

The method in developing the *p-y* curves involves the estimation of the initial modulus of subgrade reaction and ultimate soil resistance. The suggested values of initial modulus of subgrade reaction for different relative densities of sand are given by Reese *et al*. (1974). This initial straight-line portion of the curves (where *Es* is linearly with deflection) governs for only small deflections. Therefore, the initial slope of the *p-y* curve influences analyses for only very small load level, The ultimate soil resistance near the ground surface is developed based on equations for estimating the soil resistance where the ultimate resistance is assumed at pile deflection equal 3/80D where D is a pile diameter. the allowable lateral capacity of a pile is half of the load causing 3/80D of deflection (50% of the ultimate soil resistance)

9 ANALYSIS OF CASE STUDY

Predictive methods of pile behavior under lateral loading are widely ranging in complexity from simple and empirical methods to three-dimensional, non-linear finite element methods, modeling the pile-soil interaction with great detail. (S. L. Paikowsky 2007) [9] Reported that *P-Y* curves were most commonly used by geotechnical engineers in analyzing the behavior of laterally loaded piles in bridge design.

LPile[10] is a widely used computer software which specializes in the analysis of piles and drilled shafts under lateral load. The development for the commercial distribution of LPile by Dr. Lymon C. Reese began in 1985. However, it was preceded by general pile theory a methodology similarly used in the computer program COM624 developed for mainframe computers. The current version used in this work is LPile version 2015.8.03 which will be referred to as LPile throughout the remainder of this thesis. LPile computes deflection, shear, bending moment and soil response as a function of depth. The user interface allows for the consideration of various soil types as well as pile configurations. These features qualify their use in this study

In an LPile model, the soil around the pile is replaced with a series of nonlinear springs representing the soil resistance over a length, p, as a nonlinear function of pile deflection, y Figure (3). The pile is typically divided up into 50 to 100 nodal points, and p-y curves appropriate for the soil type and soil strength are computed at each node. In an iterative process, the lateral resistance at each node is adjusted until it is consistent with the deflection computed at that node based on the p-y curve defined for that node.

The basic differential equation governing the lateral load behavior of a pile in a soil profile is given by the equation[11]

$$EI\frac{d^4y}{dx^4} + Q\frac{d^2y}{dx^2} - p + W = 0$$

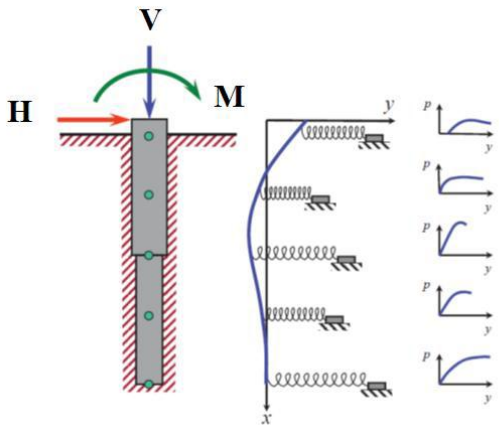

Figure 3

Where:

Q = axial thrust load in the pile

y = lateral deflection of the pile at a point x along the length of the pile,
p = soil reaction per unit length,
EI = flexural rigidity, and
W = distributed load along the length of the pile.

The first term governs the influence of pile flexural resistance; the second term deals with p-delta effects from the axial load on the pile as it deforms laterally, the third term accounts for the soil resistance along the length of the pile, and the last term accounts for the distributed load. The differential equation can only be solved by the application of boundary conditions at the top of the pile which defines applied load or moment, rotation or deflection.

10 RESULTS AND DISCUSSION

For the given pile and the given set of soil conditions, pile-head load versus deflection curves were generated by increasing the lateral load as shown in Figure (4) For the range of pile sizes and soil parameters used in this study, for laterally loaded pile, it was found that the depth below the critical length (L_c) of the pile remains unaffected by the lateral load. Most of the piles achieved complete bending with zero deflection at the pile tip.

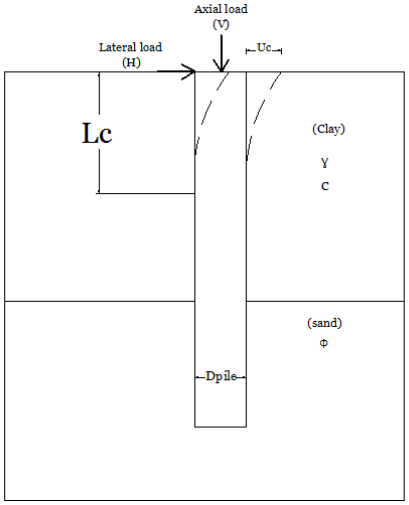

Figure 4

Calculation of lateral load capacity of pile using LPile

Lpile is capable of determining the flexural response of pile and load increased automatically. The passive resistance of soil is considered by the software and is indicated by it whenever it is exceeded. This principle has been considered taking into account the generated *P-Y* curves. In the present paper, the load acting at the pile head and the number of increments have been provided to reach the load. In Lpile software, an automatic load increment feature is available which is used to estimate
the lateral load capacity of the pile as shown in table 3

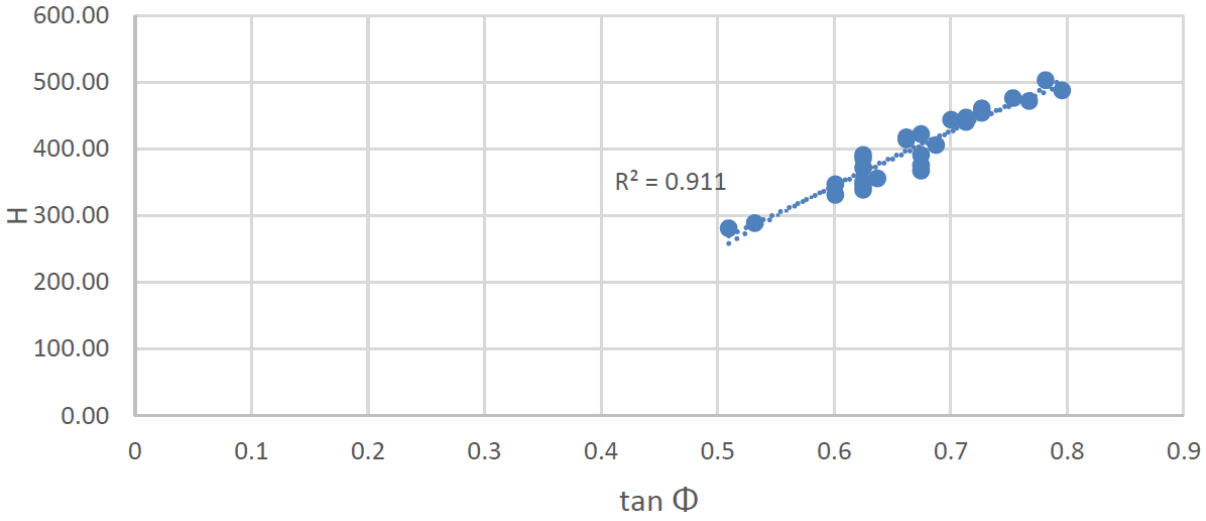
ESTIMATION OF LATERAL LOAD CAPACITY OF PILE

After the analysis of these results for 28 concrete pile in soil profile a trial was done to find a relation between the lateral load (H) versus the internal friction angle (Φ), as well as the relation with the unit weight (ɣ) of the soil where the pile-soil system is assumed to deflect along the critical length. Nearly linear relations were found in both cases, as shown in Figure (5), (6). In addition, the relationship between the lateral load capacity and axial load, therefore, it was tried to find a between the ratio (H/V) versus the axial vertical load (V) was investigated and found that (H/V) is inversely proportional to (V). The relationship is non-linear between (V), and (H/V) as shown in figure (7). Moreover, it is shown in Figure (7). That the lateral to vertical capacities ratio ranges from 4% to 11% of the axial capacity.

Figure 5 The relation between *H* in *kN* vs. the internal friction angle tan (*Φ*)



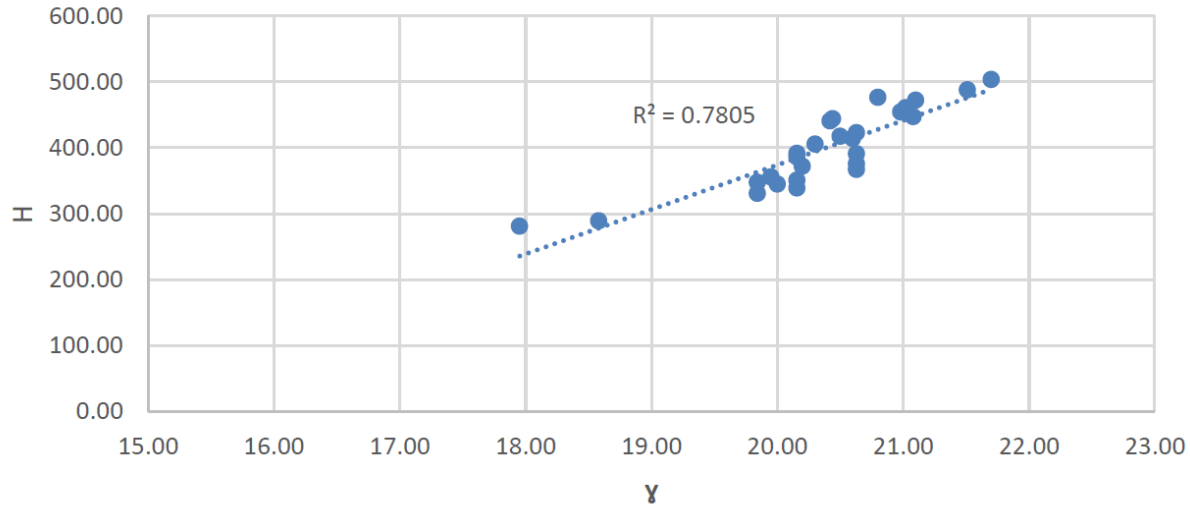


Figure 6 The relation between *H* in *kN* vs. the unit weight *ɣ* in *kN/m*³

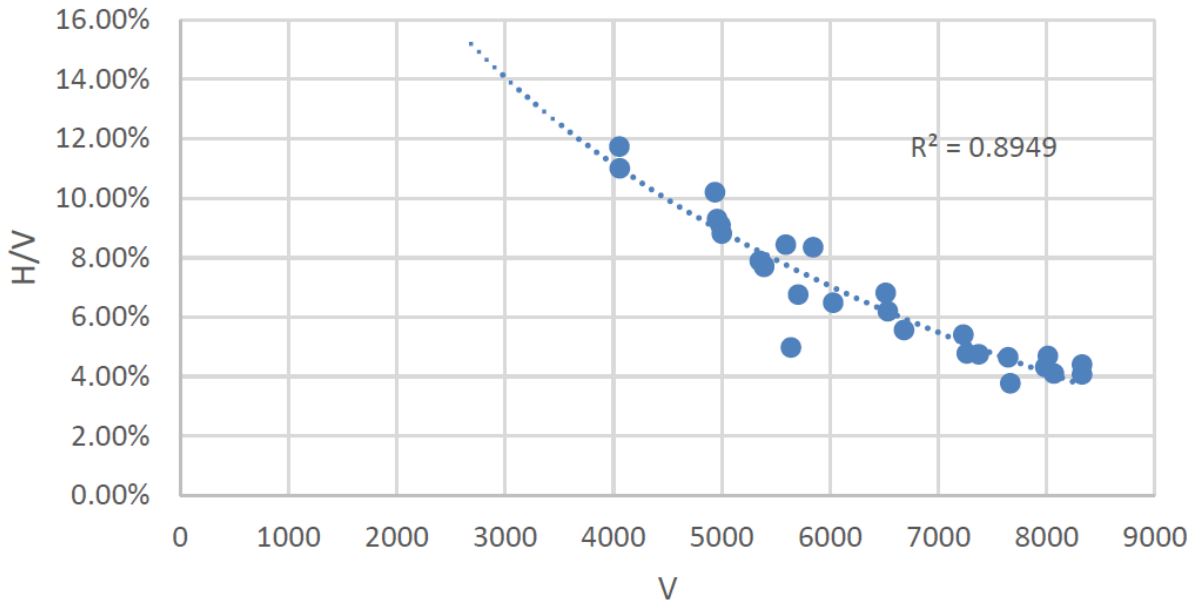

Figure 7 The relation between the ratio (*H/V*) vs. the axial load (*V*)

Based on the observed relations from Figures (5),(6),(7) one can distinguish that there are multiple parameters that affect the estimate of the lateral capacity such as the friction angle **(Φ)**, the unit weight, *ɣ*, and the vertical capacity, *V*. Moreover, studying the results as shown in Figure (7), one can realize that there is not one parameter that is solely sufficient to identify the lateral capacity. Thus, a multiple non-linear regression analysis by using SPSS program is applied to relate the cor-related parameters to the lateral capacity of piles. where founded that H = fn. (V, *Φ* ɣ). The latter analysis between the friction angle **(Φ)**, the soil unit weight (ɣ) and the axial load (V), is used to obtain a four-dimensional relationship between the above-mentioned parameters versus the lateral load capacity.

After finding correlated parameters to the lateral capacity of piles, we can draw a relation in two-dimensional between the H vs. V and H vs. Φ with constant values for other parameters in Figures (8),(9).

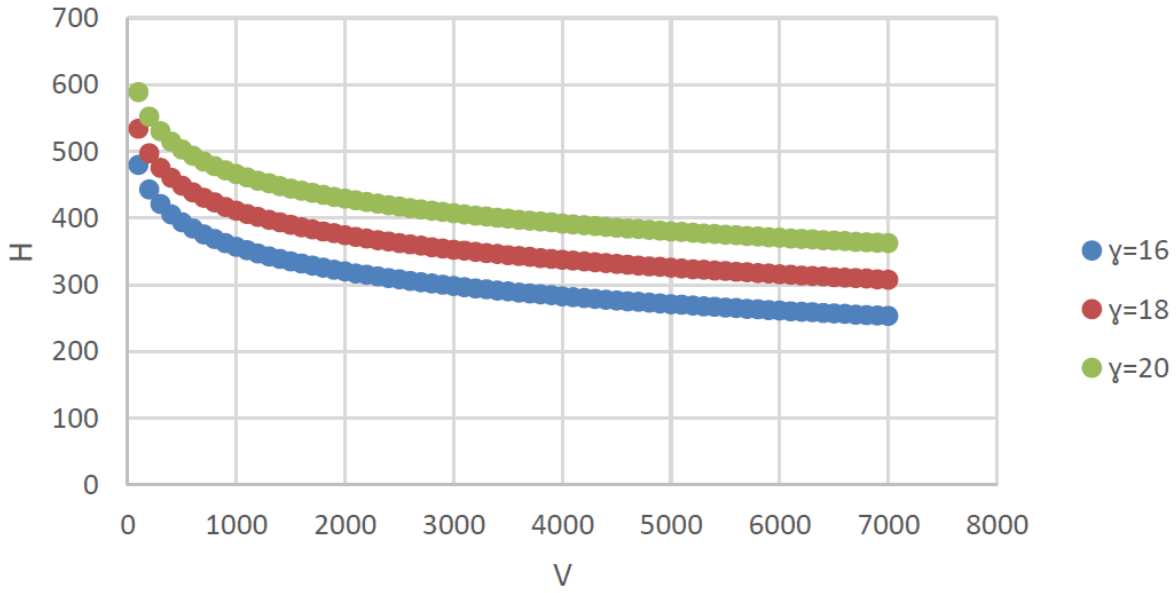

Figure 8 The relation between *H* in *kN* vs. *V* in *kN* at *(ϕ) =32*

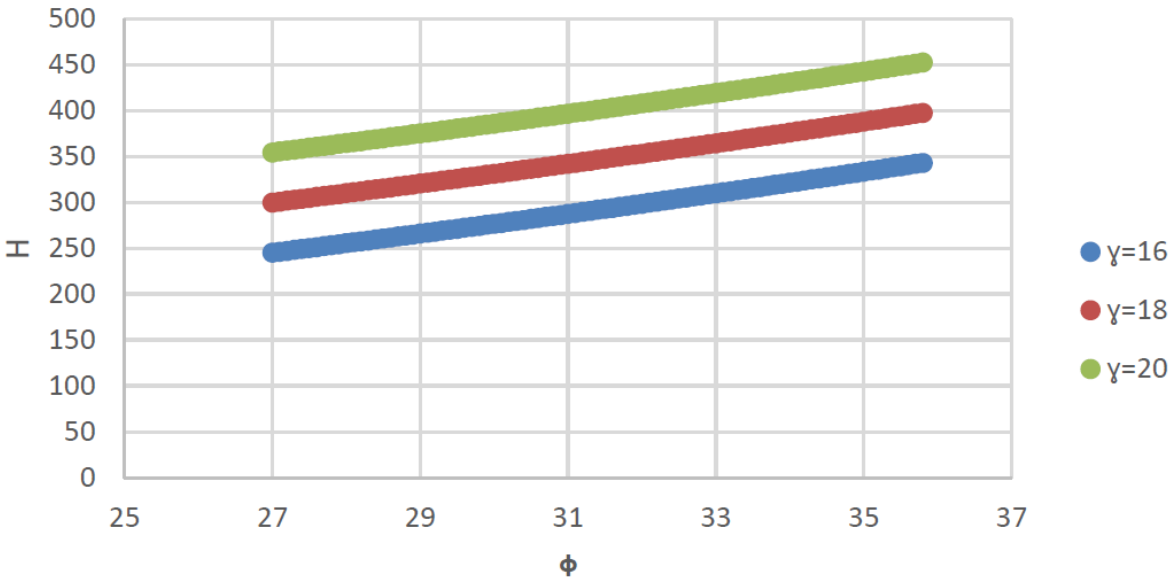

Figure 9 the relation between *H* in *kN* vs. *Φ* at *v* =3000 *kN*

Moreover, from the defined nonlinear multi parametric equation, by setting the unit weights to be in the range between 16 to 20 *kN*/*m*3, the space schematic is shown in Figure (10) is obtained. The latter schematic incorporates the full results from the CAPWAP tests and the available soil profiles properties for all piles to allow users to estimate a lateral capacity for any driven prestressed pile.

Furthermore, Figure (11) shows a three-dimensional surface that relates the soil properties and the CAPWAP results for the case of having a unit weight of 17 kN/m3 for the soil layers within the critical depth of the piles. Similarly, other three dimensional surfaces can be obtained for other unit weights of the soil within the critical depth of the pile along which the pile deflects. The lateral capacity for the driven piles can be obtained easily from such relations.

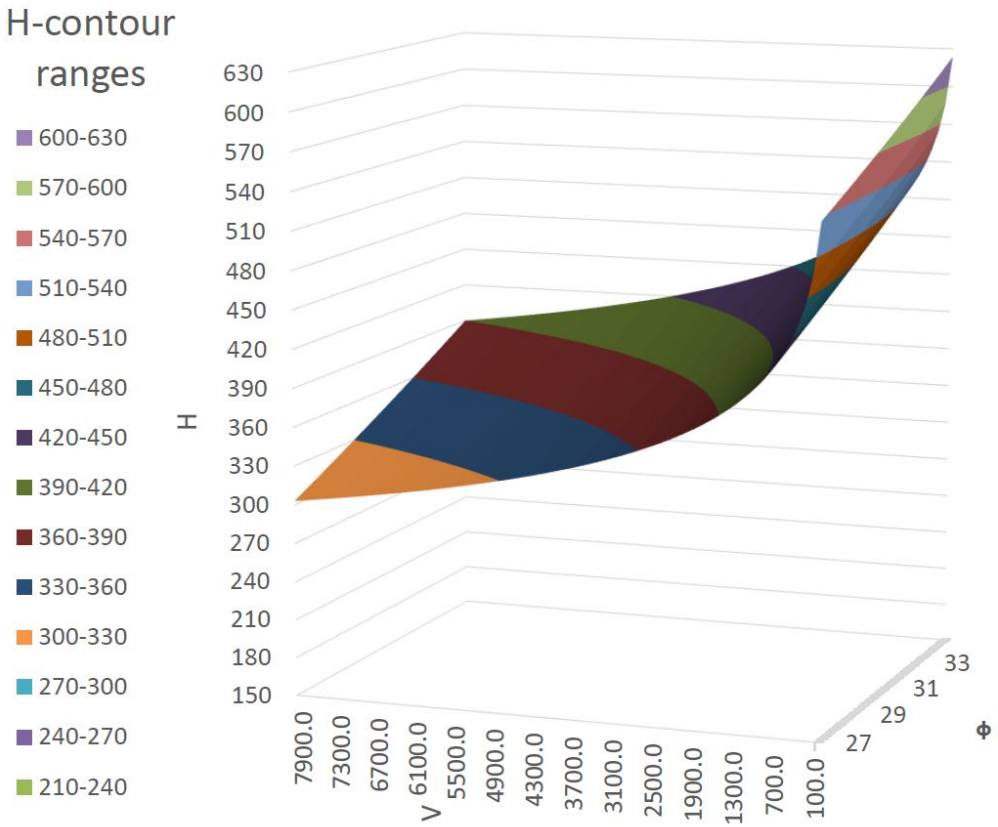

Figure 11 The relation between lateral load (H) & axial load (V) & and friction angle (ϕ) and a unit weight (ɣ)=17kN/m^3

11 CONCLUSIONS

As Designers usually seek simpler methods for applications in their design and assessments, it would be beneficial to help designers to obtain estimates of the piles lateral capacity from available soil properties and axial load. This study focused on piles behavior in soil profiles that are composed of soft stratum right below the surface, followed by stiff stratum underneath. The lateral capacity of the pile was found to depend mainly on three major parameters. These parameters include the angle of internal friction *(Φ)*, unit weight *(ɣ)* for the soil layers within the critical depth of the pile from the surface in which the pile is allowed to deflect, in addition to the vertical axial load capacity of piles *(V)*.

Based on the results of the present study, it was observed that:

- The lateral load capacity of the pile *(H)* is strongly affected by the properties of soil layers surrounding the critical length (L_c) in which the pile deflects laterally.

- The pile's lateral capacity *(H)* increases in a nearly linear relation to the soil cohesion *(c)* or tan *(Φ)* the angle of internal friction and unit weight *(ɣ)*.

- The relationship between the pile vertical axial load capacity *(V)* and the ratio *(H/V)* is a non-linear relation.

- For the studied case, the ratio *(H/V)* is ranging from 3.00% to 11.00%.

Abstract

This work examines experimentally and numerically the influence of steel fibre reinforcement on lightweight aggregate concrete (LWAC). The replacement of conventional aggregates with recycled lightweight ones has several benefits such as reducing the mass of the structure leading to more economical designs (also beneficial under earthquake loading). The experimental project showed that it was possible to produce higher strength to weight ratio of LWAC compared to normal weight aggregate concrete (NWAC) as dry densities were approximately 700 Kg/m3 lower for identical characteristic compressive strengths between 40MPa and 30MPa. This could lead to savings in materials, construction and transportation costs making it especially useful and economical for long-span and seismic-resistant structures. Conversely, LWAC is noted for its highly brittle nature due to its associated weak aggregate interlock mechanism which can be typically compensated for by increasing shear reinforcement and dowel action by means of adding higher reinforcement ratios. Nonetheless, this creates several challenges in construction such as congestion of reinforcement in critical regions as well as increased dead loads which render LWAC use counterproductive. Thus, steel fibre reinforcement emerges as a promising solution where partial or total substitution of conventional transverse reinforcement could become a possibility. This project carries out examination of the effectiveness of hooked-end steel fibre reinforcement with fibre volume fractions of Vf = 1% and Vf = 2%. The experimental investigation includes the study of direct uniaxial compression and tension (unique pullout test) and indirect splitting and flexural tensile tests. Moreover, a nonlinear finite element study has been carried out using ABAQUS to model the experiments using CDP. Currently, there is no international standards or design guidelines for steel fibre reinforced lightweight concrete (SFRLC). This project will help address that and lead to sustainable and innovative seismic design solutions in the future.

Keywords: Recycled lightweight concrete, Hooked-end steel fibres, ABAQUS, Ductility, Flexural beam test, Pullout.

1 INTRODUCTION

Today, the use of structural lightweight aggregate concrete has become attractive especially as a precast material due to advantages which mainly involve the reduction in structural weight as compared to normal weight aggregate concrete. This in turn results in a decrease in the amount of reinforcement required, material transport costs and in the cross section of structural members especially columns, beams, walls and foundations which leads to reduced inertial and gravity loads and the catering for the growing need for taller and longer span structures. This is especially beneficial for seismic structures. In this sense, LWAC can grow to be competitive against NWC (Libre et al., 2011; Campione, 2014; Dias-Da-Costa, 2014; Mo et al., 2017). Although the price for lightweight concrete per m^3 can be higher than that of normal weight concrete, the overall cost of the structure due to the aforementioned savings can be substantially reduced with increased structural performance for an equivalent normal concrete structure. Kang and Kim (2010) report overall savings of 10% to 20%. Other advantages of lightweight concrete include reduction in carbon emissions and providing solutions to the lack of sufficient gravel and quarry resources foreseen in the imminent future (Gerritse, 1981).

Concrete in general and lightweight in particular is a brittle material which lacks material toughening mechanisms such as aggregate interlock. This makes LWAC susceptible to cracking and sudden brittle failure. To address the latter and enhance ductility, steel-bar reinforcement is usually incorporated in structural elements. However, due to the brittle nature of lightweight concrete this may become impractical and inherently counterproductive as a large number of reinforcement bars coupled with stirrups may increase the total weight of the structure and lead to difficulties in placing them within critical zones in concrete section during construction. Therefore, fibre reinforcement which has long proven its effectiveness in controlling and bridging tensile and shear cracks in the past for both lightweight and normal weight concretes can become an adequate solution (Gao et al., 1997; Balendran et al., 2002; Campione and La Mendola, 2004; Abbas et al., 2014a; Di Prisco, Colombo and Dozio, 2013; Grabois et al., 2016).

Steel fibre reinforced concrete is a composite material defined mainly by improved post cracking tensile behaviour due to the capability of fibres to bridge the crack faces preventing their propagation and widening into bigger cracks. This crack control mechanism leads to improved toughness, ductility and flexural and shear load carrying capacity (Swamy, Jones and Chiam, 1993; Kang and Kim, 2010; Di Prisco, Colombo and Dozio, 2013; Iqbal et al., 2015; Grabois et al., 2016). Unlike plain concrete, fibrous concrete can display tension softening or tension hardening depending on fibre dosage which leads to enhanced energy dissipation and ductility. Also, since cracking due to shrinkage is present naturally in concrete even prior to loading, fibres can be used to control cracking due to all types of shrinkage (Libre et al., 2011). The mechanical properties of SFRC are governed essentially by the bond strength between matrix and steel fibres, their dispersion, location, orientation, volume fraction and type (geometry and aspect ratio) (Concrete Society, 2007; Di Prisco, Colombo and Dozio, 2013).

Even though the advantages of the usage of fibrous concrete has been reported for over 40 years (Ritchie and Kayali, 1975), comprehensive studies on SFRLC (especially with modern fibres) is still largely scarce with most of the current work being merely theoretical and SFRC-based. It should also be noted that currently, there is no international standards or design guidelines for steel fibre reinforced lightweight concrete (SFRLC). This work will help pave the path for the latter.

This project suggests a comprehensive methodology to test lightweight fibrous concrete both on the meso- and micro-scale levels experimentally and numerically.

2 EXPERIMENTAL LABORATORY WORK

2.1 Experimental Programme

The experimental programme comprises tensile and compressive tests on lightweight and fibrous concretes. The aim is to study the influence of the incorporation of fibres into the lightweight mix on the mesoscale level (compression tests, direct fibre pullout tests) and macroscale level (flexural beam tests). The philosophy behind the experimental testing and its parameters can be seen in the table 1 below. As mentioned previously, the experimental programme will include a variety of specimen types. For uniaxial compression tests, both cylinders and cubes (3 per mix) are used and compared besides prisms to evaluate Modulus of Elasticity, Poisson's ratio, compressive ductility and to study the effect of fibres on short columns. For tensile tests, direct pullout cubes (2 per mix) will be tested to evaluate the direct tensile behaviour of plain and fibrous lightweight concrete while indirect tensile tests on splitting cylinders (3 per mix) and unnotched and notched beams will be carried out to study the material and flexural and shear behaviour of LWAC and SFRLC.

Mix	**Parameters**					**Aims**
	V_f (%)	**Fibre type**	**f_{ck} /$f_{ck,cube}$**	**Reinforcement layout**	**Stirrups spacing**	
1.1	0	N/A	LC30/33	2T12 @ Bot; 2T6 @ Top	R6 @120mm & 240mm	Study the behaviour of plain concrete
1.2	1	3D				Study the effect of increasing fibre dosage and potential replacement of stirrups with fibres in beams
1.3	2					
1.4	1	5D				Study the effect of the modern 5D fibres on the behaviour of concrete
1.5	0	3D	LC35/38			Study the effect of fibres on a different concrete strength
1.6	1					

Table 1: Summary of parameters used in experimental testing

The testing programme encompasses the study of 3 types of concrete strengths, 2 different steel fibres, 2 different fibre dosage V_f and 2 different steel cages. Steel fibres were either 3D or 5D. This was the case because hooked-end 3D fibres are currently the most commonly used in industry (Abdallah et al., 2018) and will be used as the base of experiments while modern hooked-end 5D fibres with more extensive hooks than the typical hooked-end 3D fibres are considered to be the strongest. Moreover, DRAMIX claim that this type of fibre is capable of replacing primary reinforcement in beams. Fibre dosages of 1% and 2% are chosen for testing. This is the case since most common structures such as tunnels and pavements require at least a dosage of V_f=1% for efficient crack control and thickness reduction (The concrete Society, 2007). Also, 2 different stirrups spacing was used. A spacing of 120mm is valid to EC2 shear design and the beam should thus fail in flexure while a spacing of 240mm is inadequate according to EC2 and the beam should thus fail in shear. The cross sections for the beams are shown in figure 1. Also, a relatively low reinforcement ratio in tension (ρ=0.0018)

was used to study the flexural effect of fibres on concrete beams. This was similar to the reinforcement ratio used by Kodur et al. (2019).

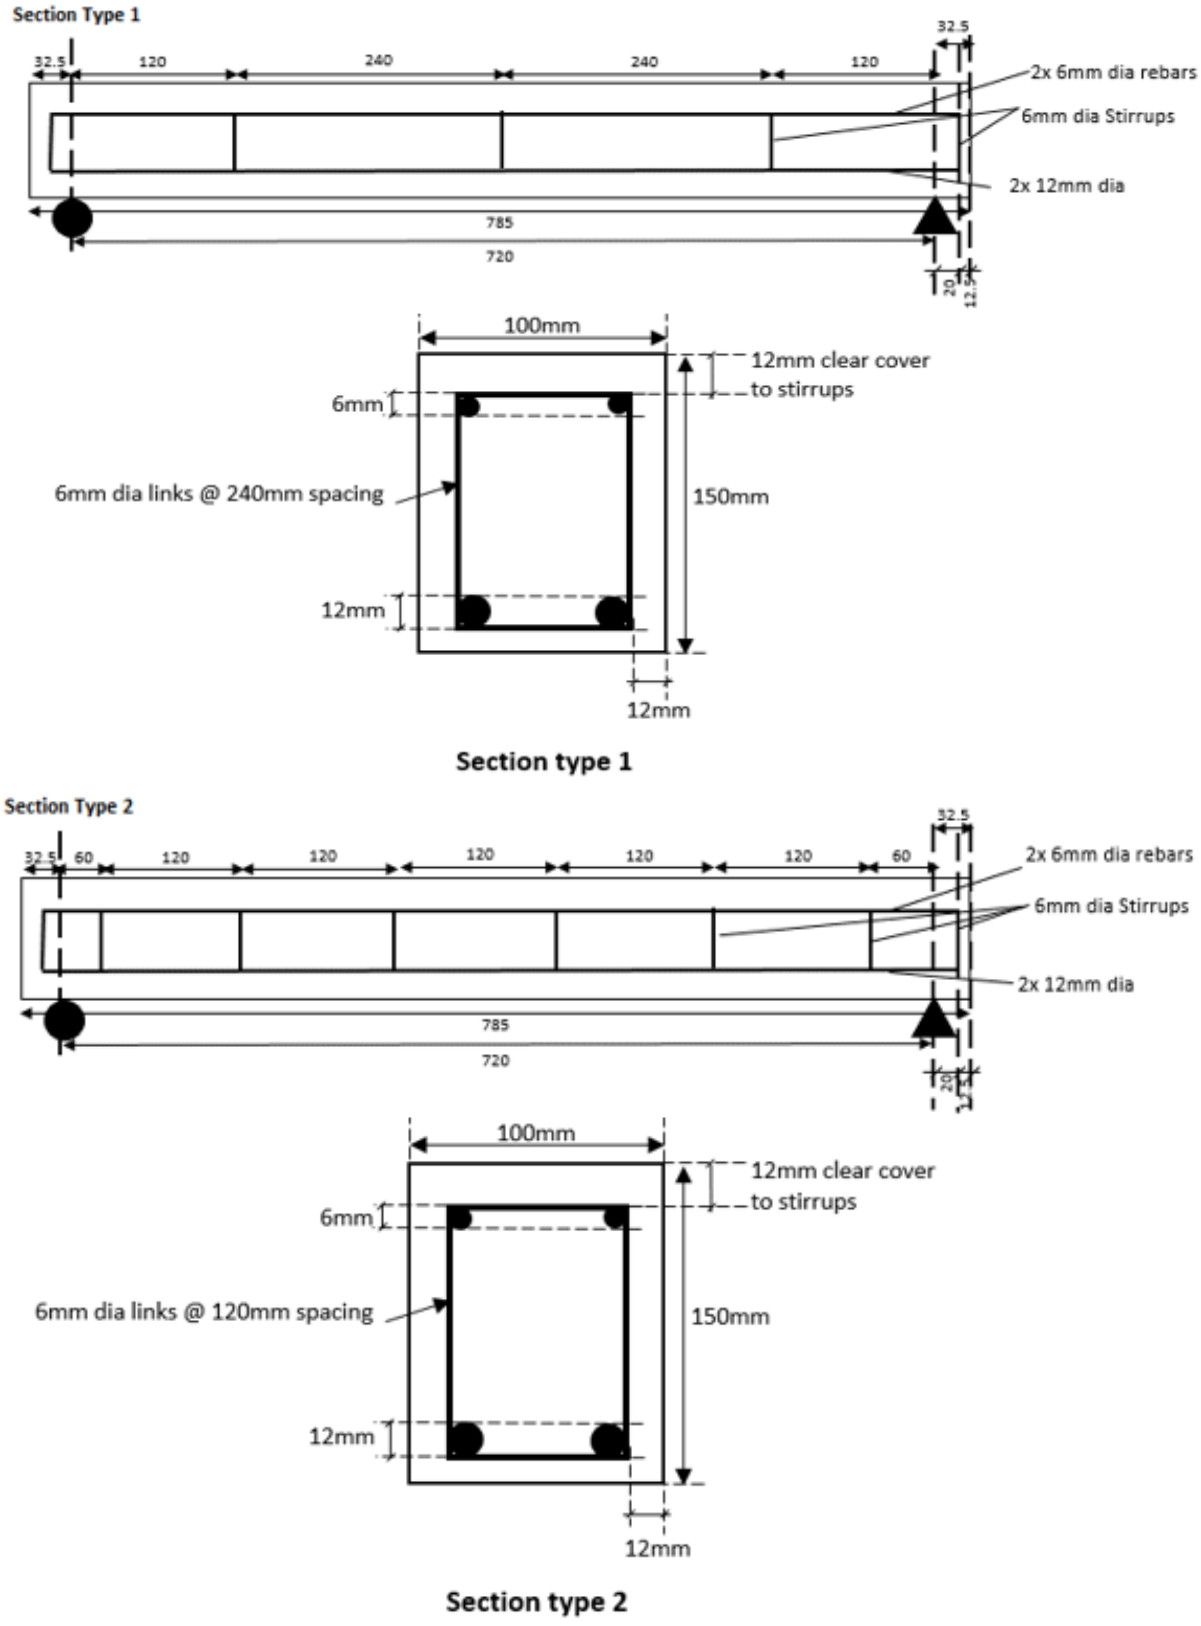

Figure 1: Longitudinal and cross-sectional sections for the beams tested

2.2 Experimental tests

The experiments include splitting tensile, the pullout test, compression cylinder and flexural beam tests. The Splitting tensile tests on cylinder specimens will be performed according to BS EN 12390-6. A direct uniaxial tensile fibre pull-out test was designed to study the effect of the embedded fibre onto the direct tensile stress-crack width of the concrete. Unlike Robins et al (2002) pullout test, the test is designed to have the fibre completely embedded in Lytag concrete. To ensure breakage of the specimen in tension at the monitored middle section, this section of the concrete was reduced to a diameter corresponding to the area a single DRAMIX fibre is predicted to occupy in the concrete. This area was determined using numerical and statistical models which depend mainly on fibre geometry and fibre volume fraction and take random distribution and dispersion of fibres into account (Krenchel et al., 1975; Romualdi and Mendel, 1964; Soroushian and Lee, 1990). Hence, this test can be regarded as a truer and more realistic pullout test than the classical pullout test with the fibre embedded on 1 side while the other end of the fibre is clamped by the machine (Abdallah et al., 2018). The pullout specimen is carefully placed in a tensile testing machine equipped with an in-built calibrated displacement transducer which will be used to measure the deformation histories of the effective section of the pullout specimens with a load cell where the two steel bars from each end are securely gripped in a way to disallow any superfluous slip. While one end is fixed, the other will be gradually pulled in tension at a displacement-controlled loading.
Due to their uniform stress distribution and adequate confinement, cylinders are the chosen specimens to test for compression and thus generate the complete compressive stress-strain behaviour for lightweight plain and fibrous concrete. A calibrated compressometer-extensometer steel ring designed according to ASTM C 469 and fitted with LVDT's is clamped onto the concrete cylinders. For the flexural beam tests the LVDTs were glued using high strength epoxy after the concrete surface in touch with the LVDT was ground in the mid-section at the front of the beam to enable the LVDTs to fully adhere onto the concrete. The LVDT's are connected to a computer software. For the purpose of estimating the vertical deflection accurately, a steel bar inspired by a technique similar to JSCE-SF4 recommendations was made. The beams are placed onto two frictionless steel supports. This was deemed adequate as the loading was symmetrical. A displacement controlled constant loading of 0.2mm/min was adopted using the hydraulic machine which has a load capacity of 500kN. It should be noted that the machine is also supplied with a calibrated displacement transducer.

3 NUMERICAL PROGRAMME

3.1 FEM approach

The 3D NLFEM analyses (Zienkiewicz and Taylor, 2005) will be carried out using the finite element package ABAQUS (Habbit et al., 2000). This software has proven its successful prediction of the behaviour of SFRC specimens and other composites in the past by using material relationships adopting a discrete crack approach (σ-ω) (Ngo and Scordelis, 1967) or smeared crack approach (σ-ε) (Rashid, 1968) to predict the tension stiffening behaviour post-crack and was used by a number of researchers (Tlemat, Pilakoutas and Neocleous, 2006; Mirza, 2008; Syed Mohsin, 2012; Abbas et al, 2014a, b). ABAQUS can address the tensile, compressive and shear behaviour of fibrous concrete to a great level of accuracy as well as determining the cracking patterns and failure mechanism in the presence of steel fibres and reinforcement. The methodology used in this work will not model fibres discretely. Instead, fibres will be modelled as part of the concrete matrix. This approach was opted for as modelling fibres discretely can be time consuming and will produce a purely FE based model, diffi-

cult to practically use by designers. In addition, fibrous concrete as a composite material involves the randomness of fibres inherently. This means that modelling fibres discreetly as realistic as it might be is also likely to completely miss the actual distribution and location of the fibres in a particular beam test especially for lower V_f and longer fibres. On the other hand, modelling fibres as part of the concrete matrix can offer an easier and simpler way to derive the behaviour of the material while also taking into consideration the random distribution and dispersion of fibres by introducing factors on the composite fibrous concrete stress-strain. The latter is derived from the uniaxial tensile pullout tests. However, the main disadvantage of the homogenous composite concrete modelling method is that local failures on the mesoscale level (such as fibre pullout) are not explicitly detected unlike in the discrete fibre 3D continuum modelling method (Zhang et al., 2018).

Concrete damaged plasticity (CDP) was calibrated and chosen to model the concrete specimens of the experiments. Previous papers (Syed Mohsin, 2012; Behinaein et al, 2018) claim that both brittle cracking (CBC) and damaged plasticity produced good results for their models. While this remains somewhat true, for the work carried out in this project CDP was deemed the more accurate and suitable tool to model reinforced and non-reinforced plain and fibrous concrete beams. This was the case as the experimental results for both tension as well as compressions tests can be used which makes CDP more realistic as compared to the crude CBC which assumes the behaviour of concrete to be completely elastic in compression. The other issue with CBC is that the performance of concrete is highly sensitive to the material shear behaviour which has to be calibrated. No material pure shear tests were carried out in this research. It should also be noted that convergence problems were very common for CBC and there was a need to use the Brittle failure criterion which might significantly affect the accuracy of the results.

The explicit dynamic solver in a quasi-static analysis is also adopted. The explicit dynamic analysis was found to be a more computationally efficient tool at solving the problems used in this project as compared with implicit solver which had a tendency to terminate.The experimental results from this thesis will be input into ABAQUS to model SFRLC structural beams. This project models the uniaxial pullout cubes and compression cylinders on ABAQUS first to calibrate both the behaviour of fibrous Lytag concrete in tension and compression. Then, these were used to model the flexural beam tests.

3.2 Calibration of material models

For concrete model using CDP a few important parameters need to be defined namely; Eccentricity, fb0/fc0 which is the ratio of initial equibiaxial compressive yield stress to initial uniaxial compressive yield stress, K is the viscosity parameter and the dilation angle. The latter was found to be the single most influencing parameter on the behaviour of concrete beams for explicit CDP analysis. The dilation angle was calibrated using uniaxial compression tests on cylinders where volumetric strains for both experimental and numerical results were compared in a manner inspired by Kupfer (1974) (Szczecina and Winnicki, 2016). Other factors were determined to have little to no influence on the behaviour of plain and lightweight fibrous concrete based on the calibration work from this research and previous work (Szczecina and Winnicki, 2016; Rodriguez et al., 2013; Jankowiak and Lodygowski, 2005; Hafezolghorani et al., 2017). The behaviour of concrete in uniaxial compression and tension was taken directly from the experiments. With regards to the behaviour of plain concrete in uniaxial tension, lightweight concrete would fail abruptly once the peak is reached. However, ABAQUS requires a tension softening curve to avoid computational errors and convergence problems. For this reason, a small displacement based on a calibrated fracture energy method calculated using fib model code 2010 was used.

With Regards to steel material model, a simple elastic-plastic stress-strain curve based on experiments is input.

4 RESULTS AND DISCUSSION

4.1 Experimental Results

Slump tests according to BS EN 12350-2 are carried out immediately after mixing the concrete to evaluate the consistency of the concrete and compare it to the consistency values recommended by Lytag. Table 2 below summarises the values of slump. Although consistent amongst each other, it can be seen that the values of slump highly exceed those recommended by Lytag (70 mm). This was also observed elsewhere (Lambert, 1982). In the latter, it was also explained that in a practical situation such as mixing on site, longer period of time lapses between mixing and placing allowing more of the free water to either evaporate or be absorbed by the lightweight aggregates.

It can be seen that the addition of fibres drastically reduces workability. At fibre dosage of V_f=2%, it was observed that the finishing process becomes challenging, the possibility for balling of fibres high and inhomogeneity of concrete likely. This further emphasizes that the design of mixes for fibre dosage should not exceed V_f=2% provided that no superplasticizers or water reducing agents are used.

Overall the wet density of concrete fell in the recommended range 1910-2000Kg/m^3. Theoretically the addition of steel fibres should increase the density of the concrete. However, it is clear from the table below that the higher the steel fibre dosage the less the density of the concrete. This was the case as hooked end fibres tend to create air voids within the concrete lattice. This finding is also consistent with Mo et al. (2017) observations for fibres with similar geometrical properties.

	Properties of mix		Slump (mm)			Wet Density Kg/m3
	W/C ratio	Fibre Type	Plain	V_f =1%	V_f = 2%	
Mix 1.1	0.49		169			2145
Mix 1.2	0.49	3D	168	60		2000
Mix 1.3	0.49	3D	147	55	26	1860
Mix 1.4	0.49	5D	150	50		1934
Mix 1.5	0.43	3D	170			2081
Mix 1.6	0.43		150	45		2002

Table 2: Slumps and Wet densities

Figure 2 depicts the average normal compressive stress-strain behaviour for the cylinders. The compressive strength values for the cylinders lied within the acceptable design values for both LC30 and LC35. Young's Modulus of Elasticity was measured to be 17.8, 17.3, 18.6 and 17.6 GPa for mix 1.1, 1.2, 1.3 and 1.4 respectively. These values are lower than Eurocode 2 table 3.1.11 recommendations, which suggest 22.1 and 22.8 GPa for both LC30 and LC35 respectively. Nonetheless, this is consistent with Lambert (1982) experiments on Lytag, which measured the modulus of Elasticity to be between 17.5 and 18 GPa for similar strengths de-

pending on curing conditions. The measured Poisson's ratio values ranged between 0.16 and 0.19 for all the specimens. These were consistent with Lambert (1982).
The behaviour of cylinders can be split into 3 stages. During stage A, both fibrous and plain Lytag lightweight concrete mixes experience a progressive load increase before macro cracking starts to take place in the middle section of the cylinder. This gradually reduces the tangent modulus of Elasticity and marks the start of stage B. As soon as a larger crack is formed, the cylinder specimens for plain Lytag concrete mixes 1.1 and 1.5 collapse in diagonal shear through the middle section. This is attributed to the absence of crack arresting and lateral confining mechanisms such as aggregate interlock. For fibrous lightweight concrete however, stage B illustrates a plateau-like behaviour. The macro cracking at the end of stage. At stage C, as extensive lateral cracking dominates the post peak behaviour of the cylinders, the compressive load finally begins to decline in a ductile manner for both lightweight fibrous mixes 1.3 and 1.6. The post-peak compressive ductility is measured by $(\varepsilon_{ult} - \varepsilon_{peak})/ \varepsilon_{peak}$ with ε_{ult} as the strain at 50% of the peak compressive strength. Cylinders with V_f=2% added a post peak ductility of about 7.7 whereas those with V_f=1% added a post peak ductility of about 3.5. Hence, as V_f dosage is doubled, the ductility provided doubles as well
It can be seen that fibre reinforcement has no effect on the elastic behaviour of the cylinders and merely gradually manifest as post peak softening depending on type and dosage of fibres. Therefore, compressive strength, modulus of Elasticity and Poisson's ratio remained unaffected with the addition of fibres to the lightweight concrete mix whereas post-peak ductility substantially increased. This finding is consistent with Li et al. (2018) which found that random SFRC has little to no effect on the modulus of Elasticity and slight favourable or unfavourable effect on compressive strength depending on the mixing process and the geometry of fibres.

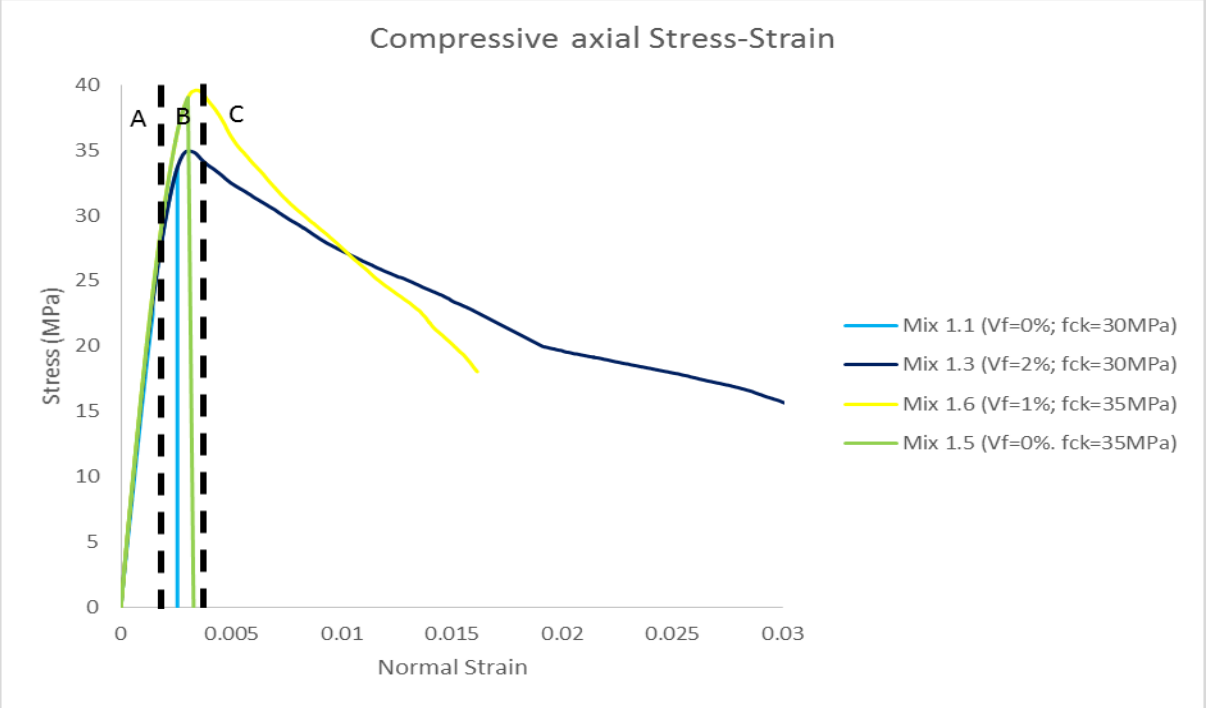

Figure 2: Compressive stress-strain behaviour for cylinders

Table 3 summarises the mean values of splitting tensile strength measured by crushing 3 cylinders per mix. It can be seen that plain lightweight concrete cylinders which included mix 1.1 and 1.5 produced splitting tensile strengths within 10% of Eurocode 2 table 11.3.1 recom-

mendations. LC30/33 cylinders reinforced with V_f=1% produced splitting tensile strengths equivalent to those of C40/44 while those reinforced with V_f=2% produced tensile strengths equivalent to those of C70/77. Also, LC35/38 cylinders reinforced with V_f=1% generated an equivalent strength of LC100. This shows that steel fibres are highly effective at upgrading the tensile resistance of lightweight concrete. Nonetheless, fibres may or may not be concentrated at the vicinity of the main crack to provide bridging reinforcement. Hence, it can be understood from the table below that some cylinders reinforced with V_f=1% (mix 1.2) showed a lower upgraded splitting tensile strength at 20% as compared to those reinforced with V_f=1% (mix 1.6) which was estimated to be at 47%. This can also be blamed for by the possibility of developing stronger bond between 3D fibres and LC35 which has lower W/C ratio than that between 3D and LC30. The latter and the random distribution and dispersion of fibres remain the two most important factors governing the behaviour of fibrous lightweight concrete. This will be investigated in the pullout test.

Mix	**$f_{lctm,\ Exp}$ (MPa)**	**$f_{lctm,\ EC2}$ (MPa)**	**Upgraded Strength due to fibres (%)**	**Equivalent EC2 Class**	**Std**
Mix 1.1 (LC30/33, Vf=0%)	2.67	2.64		LC30	0.12
Mix 1.2 (LC30/33, Vf=1%)	3.21	2.64	20.1	LC40	0.10
Mix 1.3 (LC30/33, Vf=2%)	4.20	2.64	57.3	LC70	0.12
Mix 1.4 (LC30/33, Vf=1%)	3.03	2.64	13.5	LC35	0.49
Mix 1.5 (LC35/38, Vf=0%)	3.19	2.91		LC40	0.47
Mix 1.6 (LC35/38, Vf=1%)	4.70	2.91	47.3	LC100	0.02

Table 3: Splitting tensile strength

The figure below depicts the uniaxial tensile pullout behaviour of plain and fibrous lightweight concrete with V_f=1%. Using the curve above the peak uniaxial tensile stress of plain lightweight concrete was calculated to be 2.16MPa based on the cylindrical volume of concrete through which the fibre is embedded. After reaching peak, the concrete stress drops immediately to 0 at 0.8mm slip which is expected for lightweight concrete due to the absence of strong aggregate interlock and any tension stiffening mechanism. The peak uniaxial tensile stress of lightweight concrete reinforced with a single 3D fibre equivalent to V_f=1% was calculated to be 2.35MPa and 2.88MPa at approximately 1.2mm and 1.8mm slips for both LC30 and LC35, respectively based on the cylindrical volume of concrete through which the fibres are embedded. As compared to mix 1.1, mix 1.2 saw an upgrade of 9% in maximum uniaxial tensile strength due to the presence of steel fibre. After reaching peak, fibre hook straightening followed by eventual frictional pullout which took place at approximately 19mm and 14mm slips for mix 1.2 and 1.6, respectively. For 5D fibres, the concrete again cracks at a load of 280N, however due to the extensive number of mechanical hooks and higher fibre tensile strength the load peaks at a higher load of 662N. This is equivalent to a uniaxial tensile stress of 5.86MPa which is 2.6 times greater than that of plain Lytag fibrous concrete. After that, hook straightening, and frictional pullout finally took place at a slip of around 26mm.

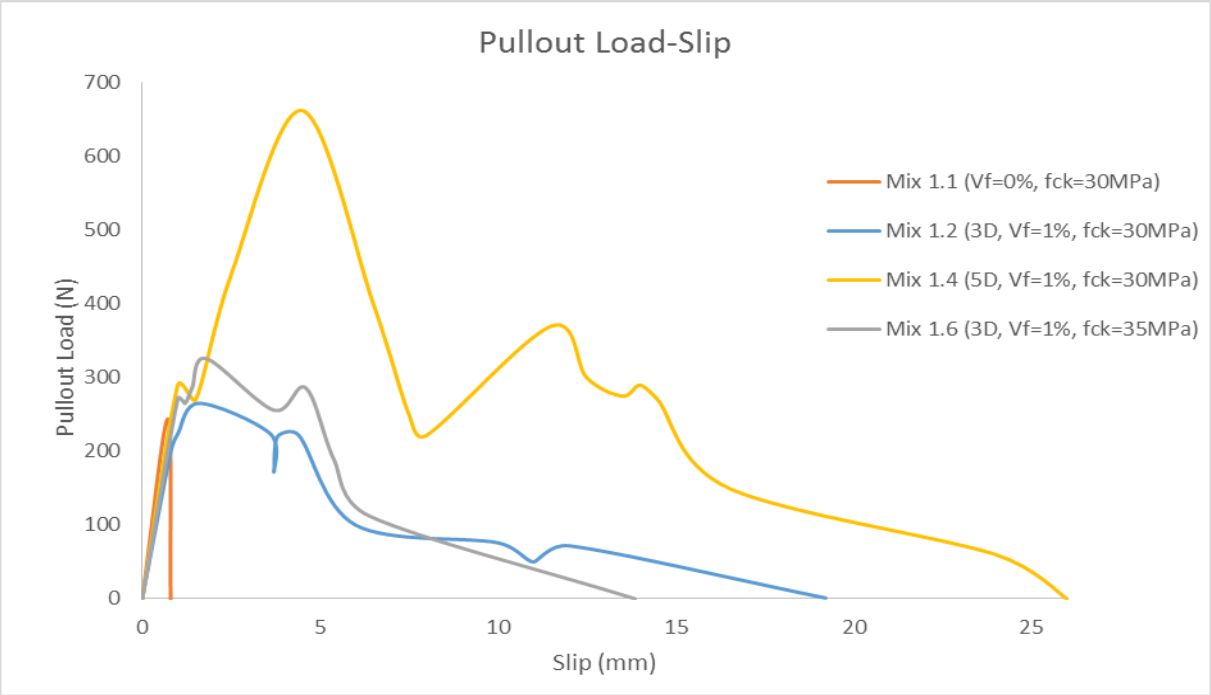

Figure 3: Pullout load-slip

Figure 4 below depicts the load-deflection curves for the 6 beams tested with different stirrup spacing and fibre dosages. All beams showed ductile behaviour as expected aside from mix 1.1 beam with inadequate spacing S=240mm and V_f=0% which failed in a brittle shear manner as predicted by Eurocode 2 shear design calculations. Hence, steel fibres are capable of altering the failure mode from shear to flexure. Using uniaxial tensile test results in combination with TR63 and Model Code 2010 flexural and shear design calculations for SFRC, it was possible to theoretically estimate the failure mode and the maximum load possible for the structural beams which agreed with the flexural beam tests results. It is observed that the ductility of the beams increases as spacing of stirrups and dosage of fibres increase. Ductility is calculated by dividing ultimate deflection at load 85% of the peak by the yield deflection at the load-deflection curve gradient before reaching peak. The ductility of fibrous beams are summarised in the table below. Relative ductility is the ductility of the beam being evaluated divided by the beam with the lowest ductility (failed in shear).

It can be seen from the table that the relative ductility for the beams with V_f=0%, S=120mm and that of V_f=1%, S=240mm are approximately identical with the latter having slightly higher ductility. A similar trend is seen for beams with V_f=1%, S=120mm and that of Vf=2%, S=240mm. This means that adding 1% of fibres is equivalent to halving the spacing of stirrups from S=240mm to S=120mm. The behaviour of beams with 2% fibre volume fraction is of an elastic plastic nature.

Beam	Ductility	Relative ductility
V_f=0%; S=240mm	1.57	1
V_f=0%; S=120mm	1.91	1.21
V_f=1%; S=240mm	1.99	1.26
V_f=1%; S=120mm	2.69	1.71
V_f=2%; S=240mm	2.83	1.80
V_f=2%; S=120mm	9.22	5.87

Table 4: Ductility and Relative Ductility of the beams

4.2 Numerical Results

Figure 5 below depicts the pullout stress-displacement of plain concrete from ABAQUS in comparison with experimental fib model code derived curve. It is noticed that ABAQUS is capable of predicting with a reasonable approximation the uniaxial tensile stress-cracking displacement until the load drops to about 5% where an asymptote is seen to avoid numerical convergence errors.

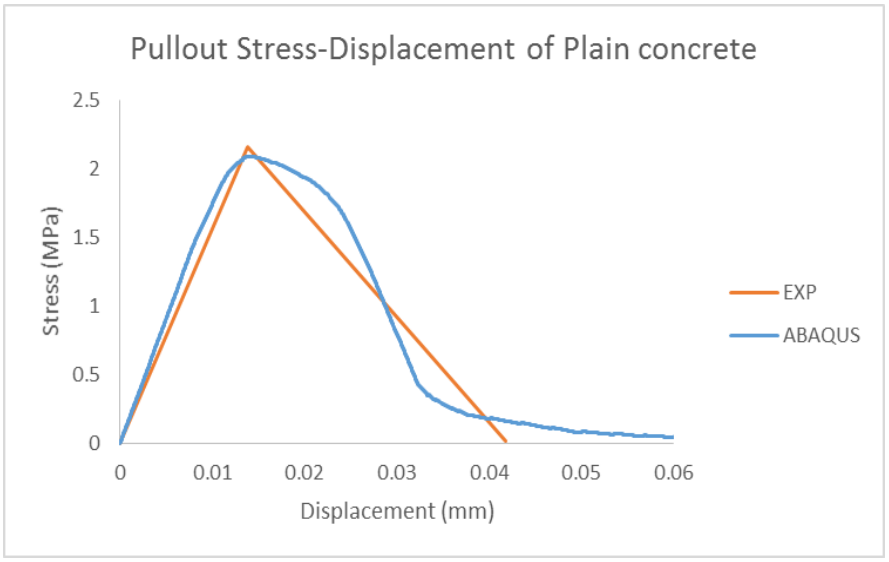

Figure 5: Derived Stress-Displacement using ABAQUS

For the compression cylinders, the ABAQUS and Experimental stress-strain behaviour is almost perfectly identical aside from 5% difference at the peak strength where the ABAQUS prediction is more conservative than the experimental solution. Figure 6 illustrates the latter relationship for plain lightweight concrete.

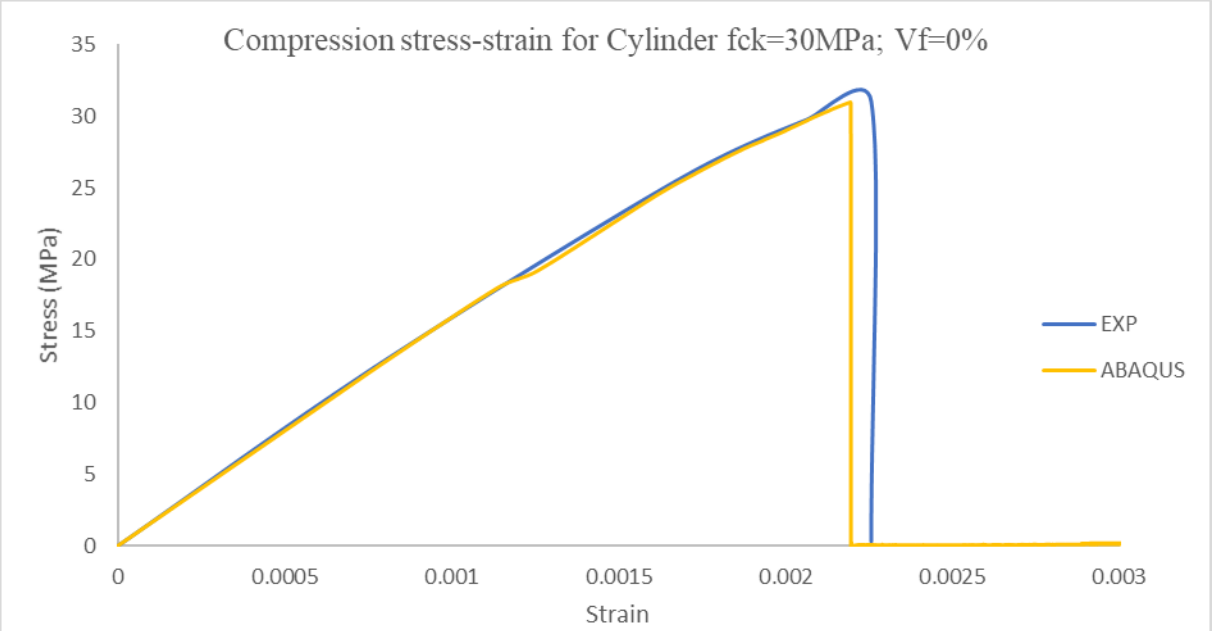

Figure 6: Compression stress-strain for ABQUS vs EXP

Figure 7 below show the cracking pattern for the reinforced beam with stirrup spacing S=120mm. The patterns are similar to experiments

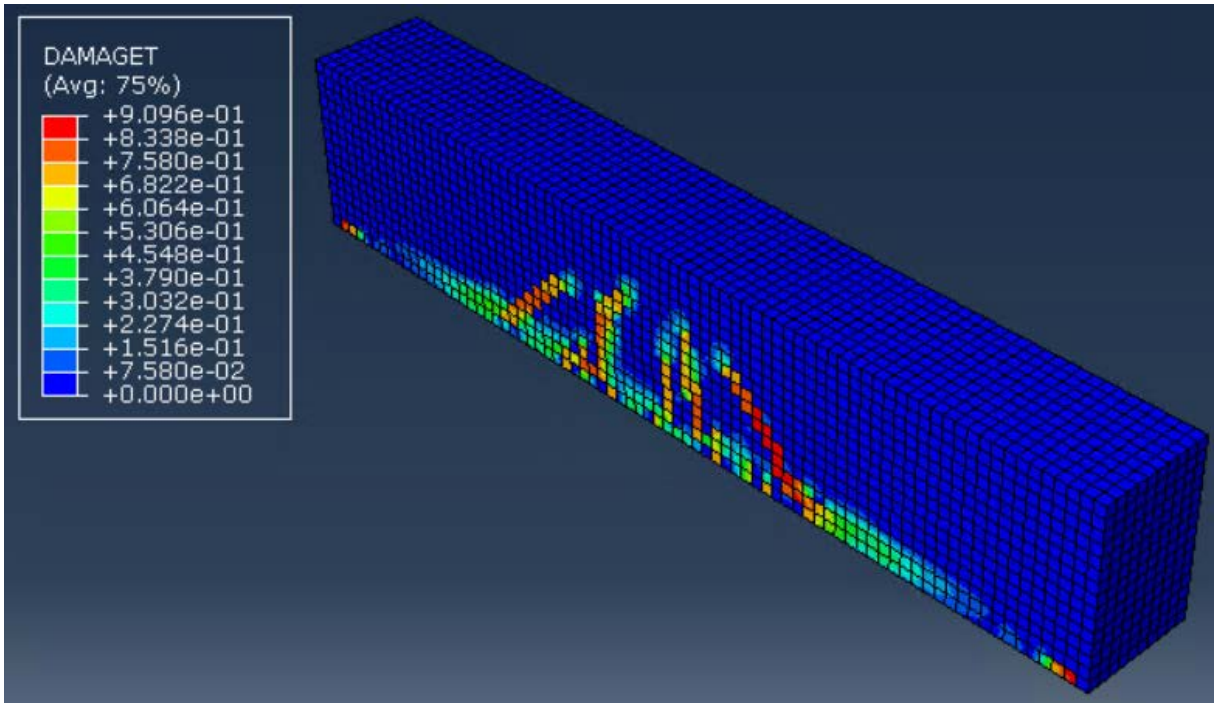

Figure 7: Development of flexural cracks for beam with S=120mm

Figure 8 below depicts the load-deflection relationship of the beam reinforced with S=120mm. It can be seen that the approach employed predicted accurate results.

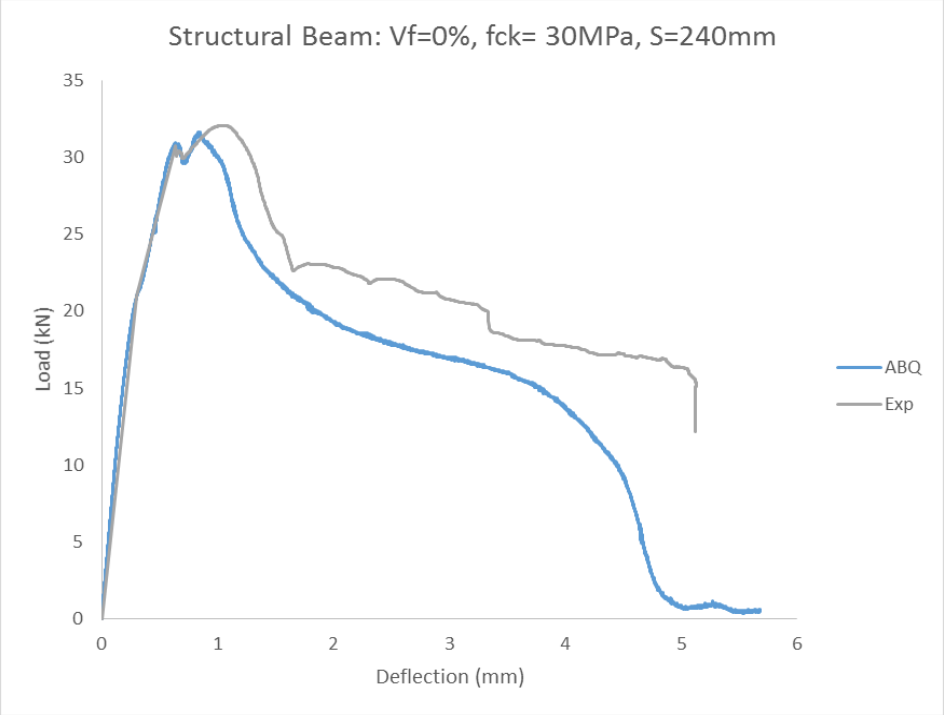

Figure 8: Load-deflection relationship of beam reinforced with S=240mm

5 CONCLUSIONS

- Density and workability are negatively influenced by the addition of steel fibres.
- Compression peak strengths are unaffected by fibres however post peak ductility is enhanced.
- Beam load carrying capacity and ductility are enhanced while mode of failure changes from shear to flexure as V_f increases. Fibres can adequately replace stirrups.
- The designed direct tensile test was successful at showing the behaviour of concrete and its bond with different fibres.
- The approach adopted for the numerical modelling shows good correlation between experimental and numerical results.

Abstract

In this article, the dynamic behavior of a base isolated structure located in Augusta City (Italy) is analyzed during ambient noise and during several release tests. On the 22th of May 2013, through different release tests, several accelerometers have been installed within the structure and on the surrounding soil in order to acquire the dynamic response of the structure and the effects of soil-structure interaction. During the experimental campaign, the dynamic behavior of the structure has been monitored before, during and after each test, comparing the dynamic characteristics in the different phases and evaluating possible damages on nonstructural elements. Particularly, the base-isolated structure has been characterized in terms of eigenfrequencies, equivalent viscous damping factor and mode shapes in ambient noise (considering the superstructure as a fixed-base structure) and during the release tests (monitoring the dynamic behavior of superstructure, base isolation system and underground floor). The aim of this article is to analyze the experimental behavior of the based isolated building and evaluate soil-structure effects in terms of energy released into the ground and maximum acceleration produced on the surrounding structures during the released tests.

Keywords: Base isolation, Full-scale tests, Dynamic identification, Non-linear dynamics.

1 INTRODUCTION

The loss of life and the enormous damages occurred in civil engineering structure disasters during the last decades have exposed the importance of preventative actions to mitigate the effects of structural failures. The serious damages and structural collapses are caused by high vulnerability of the existing buildings, designed and built without seismic details, but also by the frequency and intensity of earthquakes. Therefore, the evaluation of potential effects to structures in different permanent and/or accidental load scenarios is an important issue to be considered in rehabilitation decisions and emergency measure planning. Furthermore, there is the need to ensure more effective protection of existing constructions in regard to earthquakes, in order to mitigate the damages associated with these events. For this reason, it is very important to identify the real structural behavior, using Structural Health Monitoring (SHM) and dynamic identification techniques. Using this kind of approach, it is possible, using ambient and/or forced vibration and/or release test, to evaluate all the dynamic characteristics of a monitored structure: eigenfrequencies, equivalent viscous damping factors and mode shapes.

In this article, we analyzed the dynamic behavior of a base isolated structure during ambient noise and during several release tests; dynamic tests were performed applying an initial displacement to the structure using a special kind of jack. Release tests have already been carried out in Italy on base isolated buildings of TELECOM Ancona [1]-[3]. In that case it was applied to a shift of about 10 cm, through a complex system of synchronized cylinders with explosive charges in order to apply the instantaneous release. Other similar experiments have been carried out on the building of Rapolla in Potenza [4]-[6] and on some building of the University of Basilicata [7]. In the first case, the experiment was carried out on a building composed by two different interchangeable isolation systems. At Rapolla city, the initial displacement was applied by moving the structure just above the isolation system using the same mechanical set-up employed at the University of Basilicata. The device was redesigned to apply an initial displacements ranging from 0 to 20 cm. It consists of a three-hinged arch (two sets of trusses and three cylindrical shafts) vertically pulled on the middle hinge by means of a hydraulic jack equipped with a load cell. The release takes place when the three hinges reach the horizontal unstable alignment and the trusses detach from the middle hinge (central shaft).

In the second case, in order to characterize the real dynamic behavior of the headquarters of the Department of Mathematics of the University of Basilicata, an experimental campaign complete of a sequence of snap-back tests was performed. In this case many release tests were carried out by using a mechanical device purposely designed to give the initial displacement to the building and then produce free damped vibrations. In the summer of 2004 and in July of the same year another example of release tests were performed on two reinforced concrete building by base isolation in a small town of Solarino in Eastern Sicily. Dynamic tests were performed in the form of free vibrations after applying an initial displacement as close as possible to the design displacement [8]-[9]. Free vibration tests performed on base-isolated buildings have also been reported in literature.

A four-story building was built in 1992 in Santiago, Chile, on 8 HDRB and subjected to 5 free vibration tests under imposed displacements, ranging from a minimum of 6.1mm to a maximum of 19.5 mm, with corresponding deformations from 0.140 to 0.445. The main results were the measured periods of vibration and the equivalent damping ratio [10]. In literature there are also other examples of experimentation using snap-back test to estimate the behavior of different type of structures [11]-[13]. Several authors used accelerometric recordings of release tests also to analyze the problem of energy back-radiated from vibrating structures on both models [14] and real buildings [15]-[18]. Scientific literature provides several case studies that confirm the capability of fixed-base structures to modify the motion on the

surrounding area during an earthquake or a release test [19], on the contrary, with reference to the same soil-structure interaction mechanism, there are few case studies related to base-isolated structures.

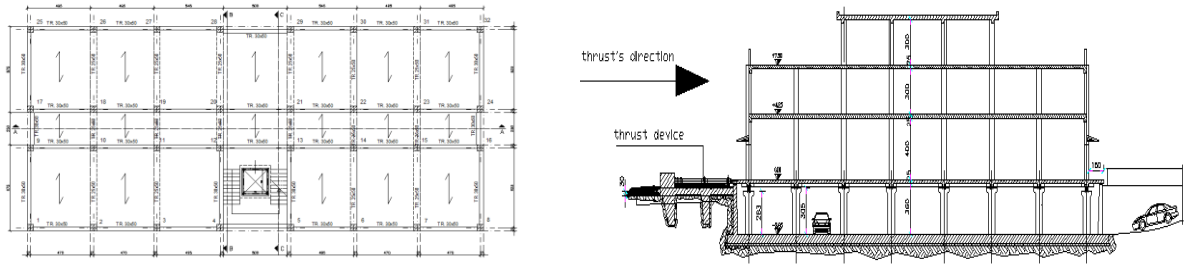
For this reason, exploiting a series of release tests carried out on a base isolated structure in Augusta city (Italy), aim of this article is to test the seismic performance of the base isolation system, to compare the dynamic characteristics of the structure before, during and after each test (individuating possible damage on non-structural elements) and to evaluate soil-structure effects in terms of energy released into the ground and maximum acceleration produced on the surrounding structures during the released tests.

2 EXPERIMENTAL CAMPAIGN

During the experimental campaign carried out on the base isolated structure in Augusta city (Italy), a jack able to apply a maximum thrust force of about 200 tons has been applied. Following the test, the structure has shifted about 10 cm but without any damage, demonstrating the effectiveness of the isolation system. Figure 1a shows the tested structure and Figure 1b the device used to make the release test. The release test was carried out using a specially designed system able to impart to the building a prefixed initial displacement. Then, the structure was instantaneously released in a free-oscillating condition. The displacement impressed to the building during different release tests were prefixed taking into account the target maximum design displacement. The dynamic "snap-back" tests were carried out to verify the compliance of the isolation system to the expected behavior derived from the numerical analyses. In Figure 2 the plan of the building and the section A-A of structure are shown.

a) b)

Figure 1: a) Base isolated structure of Augusta; b) Thrust device of the release test.



a) b)

Figure 2: a) Plan of the building; b) Section A-A of building.

The building, designed and constructed using the new Italian technical regulations, D.M. 14/01/2008 (NTC08), is characterized by a hybrid base isolation system composed by 16

High Damping Rubber Bearings and 20 low friction sliding Bearing [20]. The structure is made using reinforced concrete and characterized by three stories above the isolation plane and one story beneath it (Figure 2b). The ground floor is characterized by an inter-story height equal to 3.85 m respect to the basement, the first floor is characterized by an inter-story height equal to 4.25 m and finally the last level is characterized by an inter-story height equal to 3.25 m. The building has a rectangular shape with a length of 35.70 m, a width of 16 m and a maximum height above the ground at 10.50 m. The mass of the structure is equal to 2400 tons. The isolation plan runs along the top of the pillars of the basement story slightly above the ground level.

In order to evaluate the dynamic behavior and the soil-structure interaction effects, several accelerometers were installed within the structure and on the surrounding area (both in ambient vibration and during the release tests). Figure 3 shows the accelerometers position on the last floor of the structure while in Figure 4 the n°125-126 accelerometers installed on the top floor are detected.

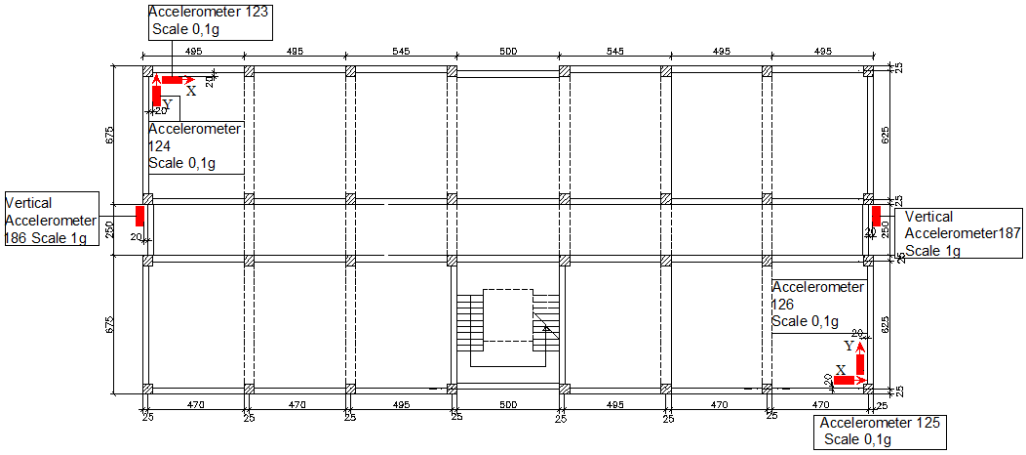


Figure 3: Accelerometers position on the last floor for the first configuration.

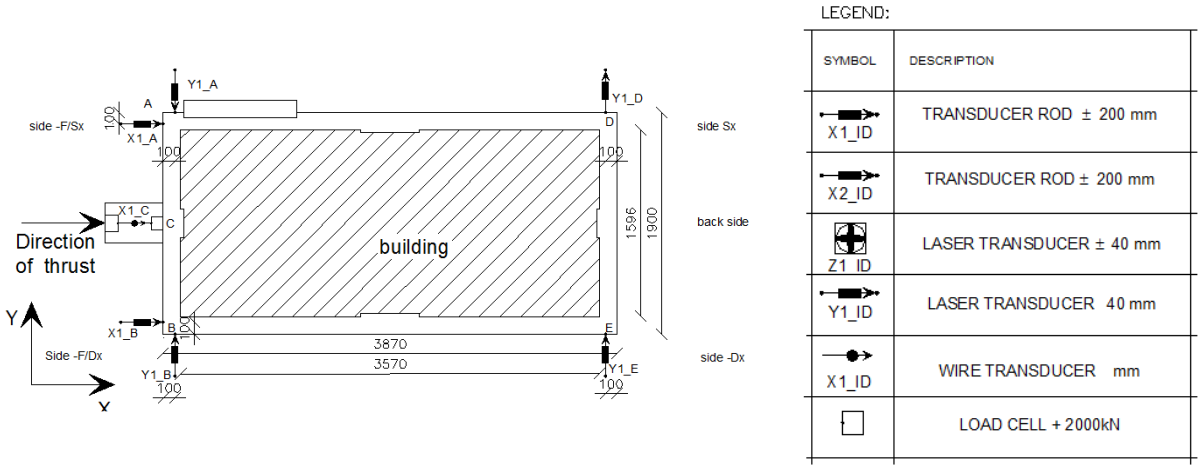
Figure 4: Accelerometers n° 125-126.

In order to assess the displacements of the structure appropriate transducers were installed in correspondence of the elevator shaft, of the pillars and on two corner of the structure, along the same diagonal, as shown in the following figures (from Figure 5 to Figure 7).



a) b)

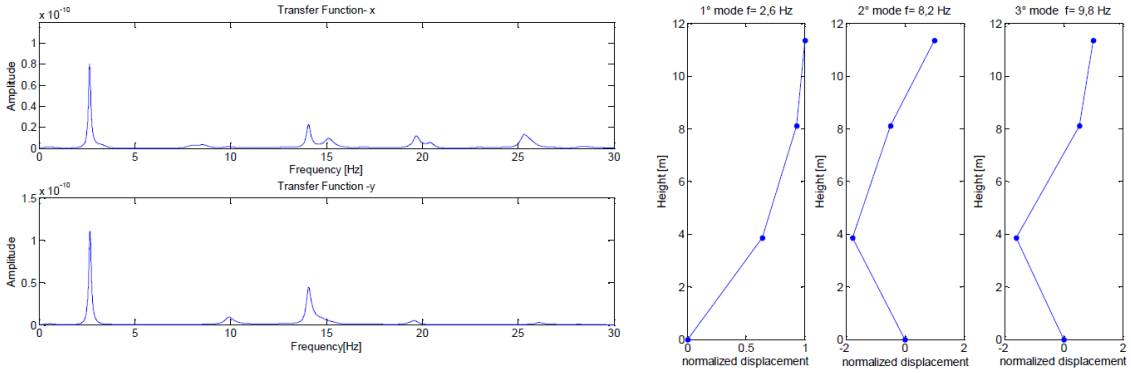
Figure 8: a) Recorded signals at each floor of structure in ambient noise and b) in forced vibration.

3 STRUCTURAL DYNAMIC IDENTIFICATION DURING AMBIENT NOISE AND RELEASE TESTS

In order to assess the dynamic characteristics of the monitored structure, in the fixed base condition, the transfer functions have been calculated using seismic noise recordings retrieved from the accelerometers installed at each floor. Figure 9a shows the transfer function evaluated using the accelerometric recordings performed on the base and the top floor of the building. The mode shapes evaluated on the experimental data using time domain analyses are depicted in Figure 9b.



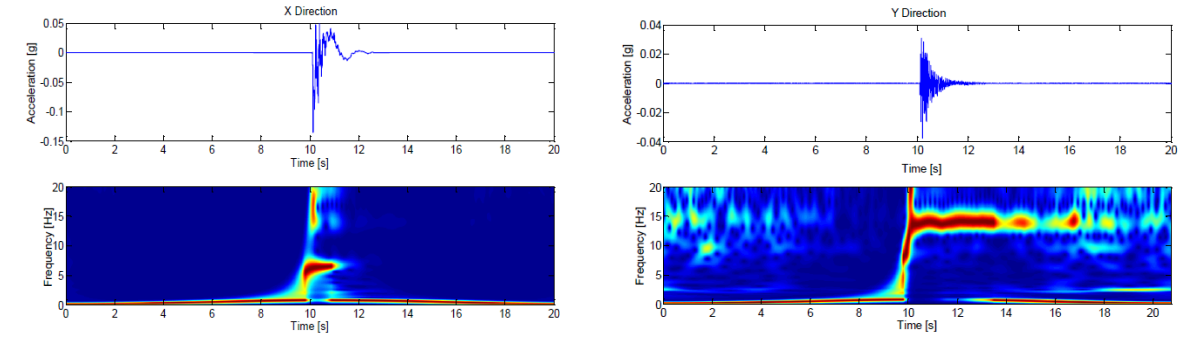
a) b)

Figure 9: a) Transfer function calculated using ambient noise and b) mode shapes.

In ambient noise condition, using the transfer function it has been possible to evaluate the main frequencies of the superstructure. The fundamental frequency of the superstructure is equal to 2.6Hz and, observing the related modal shape it seems to be a torsional mode. It is important to highlight that the dynamic characterization has been performed using ambient vibration test (characterized by very small amplitude), so also the contribution of non-structural elements is considered. The second mode (translational) is characterized by a frequency equal to 8.2 Hz and the third mode (translational) by a frequency equal to 9.8 Hz.

The accelerometric recording acquired on the top floor during release tests was analyzed using the Stockwell Transform [21], operating on the time-frequency domain, and transfer

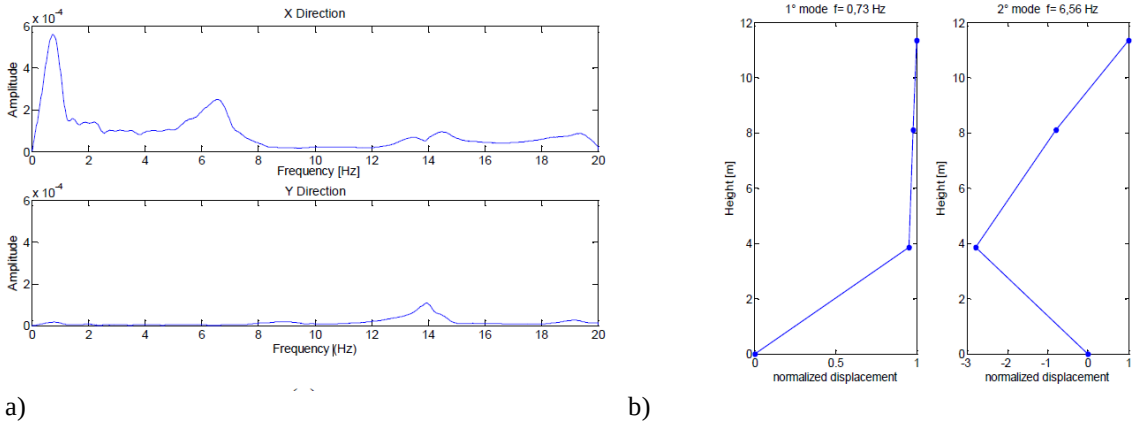
function of the signal, operating on the frequency domain. From the time-frequency analyses (Figure 10) it was been possible to confirm the linear behavior of the superstructure and to detect the main eigenfrequencies.



a) b)

Figure 10: a) Stockwell transform along x direction and b) y direction.

Using the Stockwell transform on the signal recorded on the superstructure and on the base isolation level it was been possible to evaluate the frequency of the base isolation system, equal to 0.73 Hz while the first detected frequency for the superstructure is equal to 2.6 Hz. Analyzing the data using the transfer function the same frequency for the base isolation system has been detected. Figure 11 shows these last results with the related modal shapes.



a) b)

Figure 11: a) Transfer Function evaluated on the accelerometric recordings during the release test and b) modal shapes of the structure for the main frequencies.

The values of the fundamental frequencies of superstructure evaluated in ambient noise and release test and the characteristics of the base isolation system are reported in Table 1 and Table 2.

FREQUENCIES OF SUPERSTRUCTURE	
1° roto-translational Y mode	2,6 Hz
2° translational X mode	8,2 Hz
3° translational Y mode	9,8 Hz

Table 1: Values of superstructure frequencies.

CHARACTERISTICS OF BASE ISOLATION SYSTEM	
1° translational X mode	0,73 Hz
Equivalent viscous damping factor	14,65%

Table 2: Characteristics of the base isolation system.

The evaluation of the equivalent viscous damping factor of the structure was carried out using the logarithm decrement method. Particularly, the accelerometric recordings related to the station installed to the last level have been considered for the equivalent viscous damping factor evaluation along the x direction (test direction). Figure 12 shows the kinematic parameter (acceleration, velocity and displacements) evaluated at each floor of the test building.

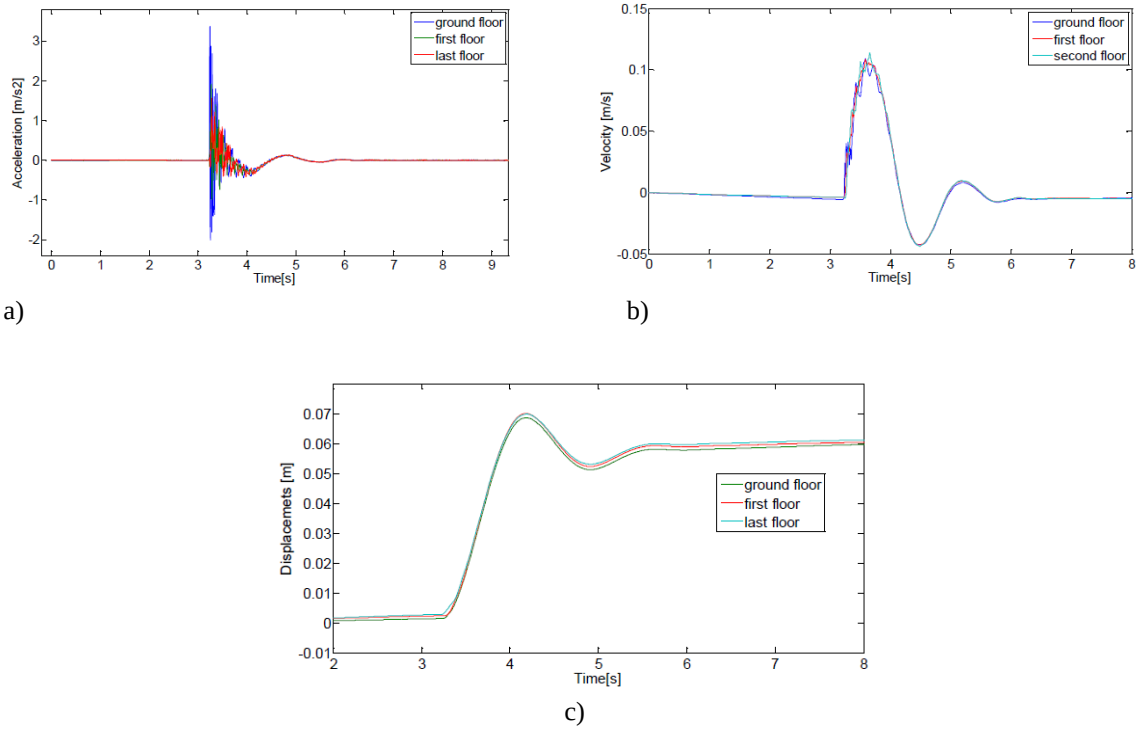


Figure 12: Kinematic parameters: a) acceleration, b) velocity and c) displacements.

Starting from the accelerometric recordings, a routine developed in MATLAB software was used to evaluate velocity and displacement. The main problem related to the determination of the displacement time-history starting from the accelerometric recordings, acquired during a release test, is related to the use of classical filter (standard approach) on impulsive signals. For this reason a special kind of filter was built using a routine implemented in MATLAB. Comparing the displacement time-history retrieved from the accelerometric recordings with those acquired using the displacement transducers it is possible to observe a very good agreement. On the contrary, using the standard approach the displacement retrieved from the accelerometric recordings is very different from those acquired from the transducers (Figure 13).

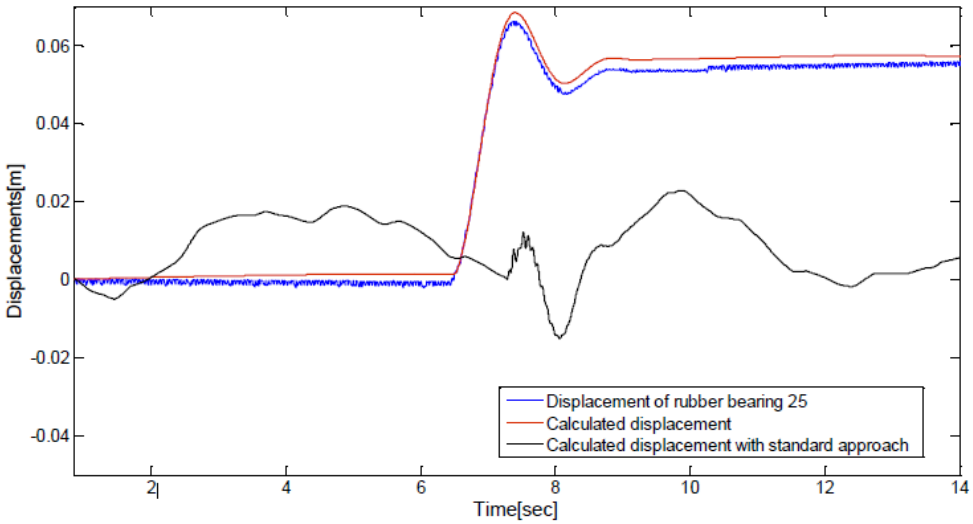

Figure 13: Comparison between the displacements evaluated using a MATLAB routine, the displacements acquired using a displacement transducer (on the rubber bearing n° 25) and the displacements obtained with standard methods.

4 CONCLUSIONS

This paper reports the preliminary results of the experimental campaign performed on a base isolated structure located in Augusta, providing information about the test and consideration on the seismic behavior of the structure. The release test allowed to simulate the maximum displacement occurred during a very strong earthquake on the area where the building is located. Taking the advantage of the release tests it has been possible to analyze and compare the experimental structural dynamic behavior during ambient vibration conditions (microtremors), and simulating the effects of weak and strong motion earthquakes. The maximum displacement reached during the experimental campaign is 10cm at the base isolation level. The dynamic behavior of the structure and of the base isolation system was monitored using several kind of instrumentation: cabled accelerometric stations, displacement transducers and wireless accelerometric station.

The analyses were performed both in ambient vibration and during the release test using transfer function and time-frequency analyses based on the S-Transform. In order to evaluate the displacement time-history, starting from the accelerometric recordings a special kind of filter has been designed. The results were compared with those acquired directly from the displacement transducers installed at the base isolation level.

The preliminary results obtained from the experimental campaign confirmed the high performance level of protection of the base isolation system installed on new buildings. Further studies are necessary to analyze the dynamic performance of the structure in more detail, to build a realistic numerical model (using model updating techniques) and to compare the experimental behavior with those predicted from linear and nonlinear numerical models.

Abstract

Nonlinear dynamic modeling of full-scale mid- and high-rise reinforced concrete structures through the use of the 3D detailed approach that foresees the use of hexahedral elements with embedded rebars is not yet feasible due to numerous reasons. The two main numerical problems that do not allow for this type of analysis to be performed, are the numerical instabilities that immerse when the opening and closing of cracks initiates during the dynamic analysis and the excessive computational demand that is required even when dealing with small numerical models. This work will present the computational response of a newly developed algorithm that is used herein to perform modal analysis of large-scale models. The under study algorithmic development is a part of a project that aims towards alleviating the prementioned numerical constraints in regard to performing nonlinear dynamic analysis of full-scale reinforced concrete structures. An extensive numerical investigation is presented that foresees the performance of modal analysis on different full-scale reinforced concrete structures that are discretized with the Hybrid Model (HYMOD) approach. Based on the numerical investigation findings, the developed algorithm was found to be computationally efficient offering a robust numerical tool for performing modal analysis of large-scale numerical models.

Keywords: Eigenvalue problem, hybrid modeling, large-scale numerical models, reinforced concrete, finite element method, 3D detailed modeling

1 INTRODUCTION

The development of a computationally efficient model for reinforced concrete (RC) structures that can produce accurate results in dynamic nonlinear modeling has been a critical issue for many researchers. It is difficult to simulate and capture the mechanical behavior of RC structures due to the complexity of the concrete material's behavior. Researchers usually simulate RC structures by using 1D and 2D numerical models, in order to decrease the computational cost of the analysis and avoid numerical instabilities when nonlinearities occur. Although, 3D numerical approaches produce objective results, they increase significantly the computational demand of the analysis. Therefore, a numerical tool that can alleviate numerical limitations and produce numerically robust solutions has to be developed.

The use of the detailed RC modeling approach is impractical for engineers due to the computational complexity of the derived models. One of the main numerical limitations when dealing with 3D detailed modeling through the use of solid elements with embedded rebars, is the high computational demand that arises during the nonlinear analysis. Additionally, many researchers try to increase the objectivity of their models by using higher order models and high integration rules, which can significantly increase the computational cost of the numerical analysis. Therefore, several researchers (Hartl [1], Spiliopoulos and Lykidis [2], Červenka and Papanikolaou [3], Papanikolaou and Kappos [4], Markou and Papadrakakis [5], Mourlas et al. [6,7]), used their proposed numerical models in order to study single RC structural members or relatively small structural configurations (i.e. 1-span RC frames).

Dynamic nonlinear analysis is still not an option when deploying the 3D detail approach, while this research work aims towards alleviating this obstacle. When analyzing any multistorey structure under dynamic loading conditions, the models' eigenmodes have to be computed, whereas this numerical problem can become computationally demanding when dealing with large-scale models. Therefore, decreasing the computational cost of this numerical procedure is of great importance. The results presented within this manuscript were developed by using the model presented by Mourlas et al. [8], where a 4-storey RC building was analyzed by using the 3D detailed modeling and the hybrid modeling (HYMOD) approach. The original model found in [8] was modified accordingly by adding more storeys and/or by increasing the model's plan view in order to construct the meshes that were analyzed herein. A modal analysis through the use of the developed models in order to compare the numerically obtained fundamental periods with those derived from different design codes is also performed and presented herein.

In order to overcome the numerical limitations derived from the high computational demand of the 3D detailed modeling, the HYMOD method is implemented in this research work as it was proposed by Markou and Papadrakakis [9], while the proposed modal algorithm [8] was programmatically optimized for the needs of this research work to be able to manage large-scale numerical problems. The HYMOD approach and its main assumptions are presented in the next section. Section 3 discusses the theory in regards to the numerical methodology that lies behind the calculation of the eigenvalues for large-scale models and section 4 presents the numerical results as they derived from the parametric investigation.

2 HYBRID MODELING

The HYMOD approach adopted in this work is based on the formulation presented by Markou and Papadrakakis [9], which was also extended in [8] in order to analyze large-scale RC structures submitted to cyclic loading conditions. Based on the proposed framework of Markou and Papadrakakis [9], the element types that are combined, are the isoparametric hexahedral element and the natural Beam-Column Flexibility-Based (NBCFB) fiber element. The

NBCFB element is a one dimensional element and the 8-noded isoparametric hexahedral element is a three dimensional element that consists of 24 degrees of freedom (dof). By using the HYMOD method, a mesh can be created that will combine the different in dimensionality elements managing to decrease the computational demand and at the same time maintain a sufficient level of accuracy [9].

The NBCFB element offers simplicity and accuracy, given it is computationally efficient, a numerical feature that makes it ideal for 1D concrete material modeling. Furthermore, the NBCFB element foresees that each concrete section is divided into fibres, where each fibre is assigned with a maximum tensile stress that is directly connected to the corresponding compressive strength of the material. Therefore, it has the ability to capture material nonlinearities that may occur at the section level.

As seen in Fig. 1, the coupling between the beam-column and hexahedral elements is achieved through kinematic constraints. The kinematic constraints are enforced at each hexahedral node that is located on the interface between the beam and the solid elements [9]. The kinematic connection is performed as follows:

$$\underset{(3x1)}{\boldsymbol{u}_i^{HEXA}} = \underset{(3x6)}{\boldsymbol{T}_{im}} \cdot \underset{(6x1)}{\boldsymbol{u}_m^{NBCFB}}, \tag{1}$$

with

$$\underset{(3x6)}{\boldsymbol{T}_{im}} = \begin{bmatrix} 1 & 0 & 0 & 0 & z_i - z_m & y_m - y_i \\ 0 & 1 & 0 & z_m - z_i & 0 & x_i - x_m \\ 0 & 0 & 1 & y_i - y_m & x_m - x_i & 0 \end{bmatrix} \tag{2}$$

where $\boldsymbol{u}_m^{NBCFB}$ and $\boldsymbol{u}_i^{HEXA}$ are the displacement vectors of the NBCFB node corresponding to 6 dofs and the hexahedral nodes (3 dofs per node) at the interface, respectively. The subscript *i* of the global coordinates x, y, z refer to the hexahedral node ID located at the interface section Ω_j^1, while subscript *m* refers to the NBCFB elemental node ID that controls the displacements (master node) of the interface section Ω_j^1 (Fig. 1). The connection matrix $\boldsymbol{T}_{im}$ is computed from the compatibility conditions of the NBCFB and hexahedral nodal coordinates.

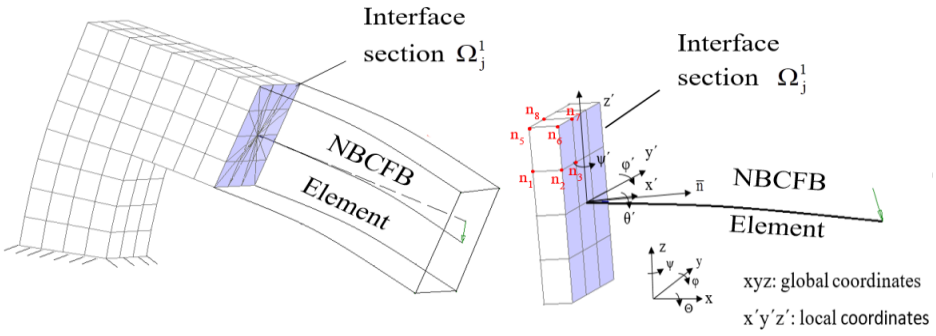

Figure 1: Hybrid model showing the interface between 1D and 3D elements [9].

It is noteworthy to state here that, the main limitation of layered or fibre elements is related to the fact that they cannot simulate the nonlinear response of structural members that undergo considerable shear deformations. One of the first attempts to overcome this limitation was that of Vecchio and Collins [10] who proposed a model with a dual-section analysis procedure discretizing the element into layers, where iterations are performed for each layer until the internal

equilibrium between adjacent sections was satisfied. Nevertheless, the beam-column finite element cannot overcome the modeling limitations when dealing with the simulation of real 3D structures that consist of shear walls and irregular geometry. Both approaches used in HYMOD modeling (beam-column and solid element) have their advantages and disadvantages that cannot be surpassed just by improving their numerical features and formulations, whereas their combination was found to be optimal in developing computationally efficient and numerically accurate models.

It must be noted at this point that, the length of the solid part is a crucial geometrical parameter that defines the length of the plastic hinge that is developed during the nonlinear analysis (see Fig. 1). Therefore, the value of this length is crucial for the overall accuracy of the nonlinear analysis. The numerical investigation conducted in [8, 9], showed that the length of the potential plastic hinge at the ends of the structural members should be equal to *h - 2h*, where *h* is the height of the member's section. This was also the values that were adopted in this research work.

3 MODAL ANALYSIS OF LARGE-SCALE MODELS

In this article, several models are developed and used to perform a modal analysis in order to calculate the natural frequencies and natural modes of their framing system, which provide an overview of the structures' dynamic response. Therefore, it is important to determine the eigenfrequencies of any RC structure so as to provide the structural engineer with the ability to understand the dynamic behavior of their designs, where they will be able to establish that periodic excitations will not cause resonance phenomena that may lead to the development of excessive stresses and strains. The eigenfrequencies depend on the geometry of the framing system and the material of the elements. Mass is also a controlling parameter when dealing with heavy or light structures, thus the investigation that will presented in the following section assumes the detailed representation of the frame's geometry and structural mass.

There are several solution methods for solving the eigenvalue problem that are describe by the following equation:

$$\mathbf{K}\boldsymbol{\varphi}_i = \lambda_i \mathbf{M}\boldsymbol{\varphi}_i \tag{1}$$

where, **K** is the stiffness matrix of the model, **M** is the mass matrix of the model, $\boldsymbol{\varphi}_i$ is a vector that contains the eigenvectors of the system and λ_i is the corresponding eigenvalue. The solution method used in this research work is called the subspace iteration algorithm [11]. This solution technique is indicated when dealing with large-scale structures since it calculates few eigenvalues and eigenvectors of a significantly demanding finite element system.

This solution algorithm finds an orthogonal basis of vectors in $\boldsymbol{E}_{K+1}$, calculating in one step the required eigenvectors when $\boldsymbol{E}_{K+1}$ converges to $\boldsymbol{E}_{\infty}$. The developed algorithm foresees the iteration used in the subspace iteration method, i.e., step 2 of the complete solution phase proposed by Bathe [11]. For k = 1, 2, …, iterate from $\boldsymbol{E}_k$ to $\boldsymbol{E}_{k+1}$:

$$\boldsymbol{K}\boldsymbol{X}_{k+1} = \boldsymbol{M}\boldsymbol{x}_k \tag{2}$$

then, find the projections of matrices **K** and **M** onto $\boldsymbol{E}_{k+1}$:

$$\boldsymbol{K}_{k+1} = \boldsymbol{X}_{k+1}^T \boldsymbol{K}\boldsymbol{X}_{k+1} \tag{3}$$

$$\boldsymbol{M}_{k+1} = \boldsymbol{X}_{k+1}^T \boldsymbol{M}\boldsymbol{X}_{k+1} \tag{4}$$

and solve for the eigensystem of the projected matrices:

$$\boldsymbol{K}_{k+1}\boldsymbol{Q}_{k+1} = \boldsymbol{M}_{k+1}\boldsymbol{Q}_{k+1}\boldsymbol{\Lambda}_{k+1} \tag{5}$$

Thereafter, find an improved approximation to the eigenvectors:

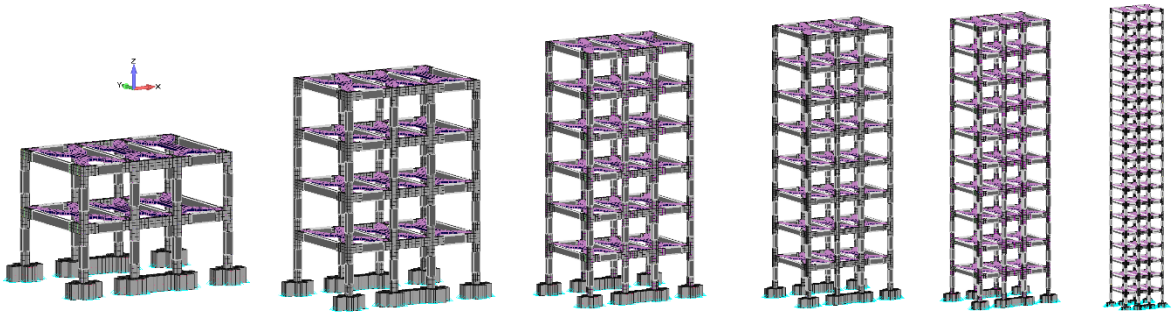
$$\boldsymbol{x}_{k+1} = \boldsymbol{X}_{k+1}\boldsymbol{Q}_{k+1} \tag{6}$$

and then provided that the vectors $\boldsymbol{x}_1$ are not orthogonal to one of the equilibrium eigenvectors, $\boldsymbol{\Lambda}_{k+1} \rightarrow \boldsymbol{\Lambda}$ and $\boldsymbol{X}_{k+1} \rightarrow \boldsymbol{\Phi}$ as k $\rightarrow \infty$.

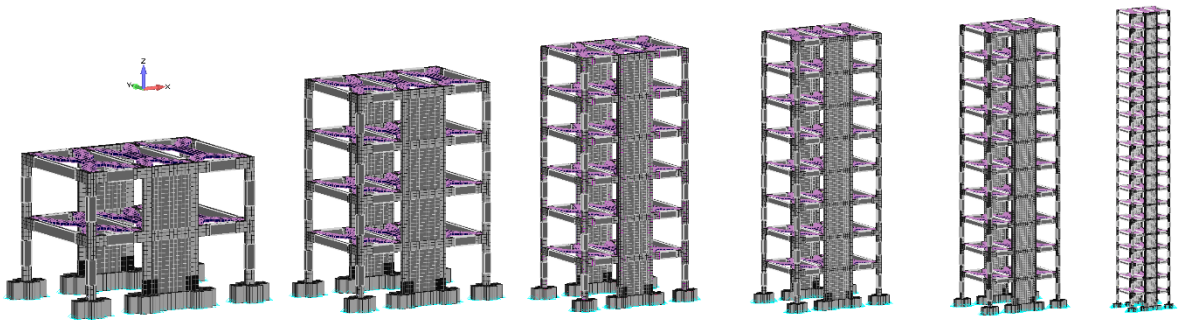
It is important to note that the convergence of this method assumes that within the iteration procedure the vectors in $\boldsymbol{X}_{k+1}$ are ordered in such a way that the i^{th} diagonal element in $\boldsymbol{\Lambda}_{k+1}$ is always larger than the previous i-1 element, i=2, ..., p. This ensures that the i^{th} column in $\boldsymbol{X}_{k+1}$ converges linearly to $\boldsymbol{\Phi}_i$. Although this is an asymptotic convergence rate, it was found that the smallest eigenvalues converge fastest [11]. This numerical response was also verified in section 4 of this research work were all numerical analysis managed to converge for six or less internal iterations.

4 NUMERICAL IMPLEMENTATIONS

The models that formed part of the first parametric investigation were constructed by modifying the geometry of the initial model examined in [8], by adding or removing storeys. These models foresee the use of columns and drop beams only. The initial meshes that were examined herein foresaw the use of 2-,4-,6-,8-,10- and 20-storeys (as can be seen in Fig. 2a). The second group of models that were constructed for the computational efficiency investigation of the developed algorithm foresaw the use of a shear wall throughout the height of the two parallel frames. In this case, the same number of storeys were used as described above and as shown in Fig. 2b. The height per storey for all models was equal to 3 meters.



(a)



(b)

Figure 2: Initial models with 2, 4, 6, 8, 10 and 20 storeys. HYMOD meshes (a) without and (b) with shear walls (not to scale).

The eigenfrequencies obtained from the analysis of the 12 meshes shown in Fig. 2, were compared to the values derived from the codes of South African National Standard (SANS), Eurocode (EC), Cyprus and NEAK (New Greek Antiseismic Code).

The formulae for calculating the periods for the different under study codes are expressed by the following equations:

NEAK [12]:

$$T_{NEAK} = 0{,}09\frac{H}{\sqrt{L}}\sqrt{\frac{H}{H+pL}} \quad (7)$$

where, H is the total height of the building, L is the dimension of the building along the direction that the period is computed for, and ρ is the percentage of the summation of the shear wall areas positioned along the direction of the computed oscillation over the total of the vertical structural members' area.

Cyprus [13]:

$$T_{Cyprus} = \frac{N}{10} \quad (8)$$

where, N is the total number of storeys of the RC structure.

EC [14] and SANS [15]:

$$T_{EC} = C_T H^{0,75} \quad (9)$$

where, C_T = 0,085 for steel frames, C_T = 0,075 for RC moment – resisting frames and for eccentrically braced frames, C_T = 0,05 for all other buildings, while H is the total height of the building. Alternatively, for structures with concrete or masonry shear walls, the value of C_T may be taken as:

$$C_T = \frac{0{,}075}{\sqrt{A_c}} \quad (10)$$

where, $A_c = \Sigma\,[A_i(0{,}2 + (\frac{L_{wi}}{H})^2)]$, which is the total effective area of shear walls in the first storey of the building (subject to walls remaining relatively unchanged over the height of the building) in square meters [14].

Table 1 shows the eigenperiods, as they derived from the numerical analysis and the ones calculated according to the four under study design codes. It must be noted here that, the SANS and EC codes use the same formulae, given that South Africa adopted the Eurocode considerations in regards to the periods calculations, thus the results are shown as EC for brevity purposes. Additionally, all periods (T_1 and T_2) that were computed through the numerical models foresaw an oscillation along the y and x directions, respectively, thus referred here as T_y and T_x. The mode shape that foresees the rotation about the z-axis is referred to as T_z. As it can seen in Table 1, as the number of storeys increases, the magnitude of the first two periods is significantly increasing due to the corresponding height increase. This phenomenon is explained by the fact that the stiffness of the building is decreasing as its height increases, where the mass per storey remains constant.

Number of storeys	Height (m)	Numerical			NEAK		Cyprus	EC
		Ty (s)	Tx (s)	Tz (s)	Ty (s)	Tx (s)	Tx & Ty (s)	Tx & Ty (s)
2	6	0.23	0.18	0.12	0.22	0.18	0.2	0.29
4	12	0.44	0.36	0.16	0.43	0.36	0.4	0.48

Table 1: Periods for all the initial models without shear walls. Numerical and design code results.

The initial models without shear walls for the cases of 2- and 20-storey models, can be seen in Figs. 3 and 4, respectively. In order to avoid a lengthy manuscript, the rest of the models are not shown herein. As it was stated above, the first two modes foresee the translational deformation along the y- and x-axis directions, for all models. Furthermore, the third mode for the cases of the shorted buildings was the rotation about the z-axis, while the multistorey buildings resulted additional translational modes that foresaw a sinusoidal deformation along the x- and y-axis prior to deriving the T_z deformed shape.

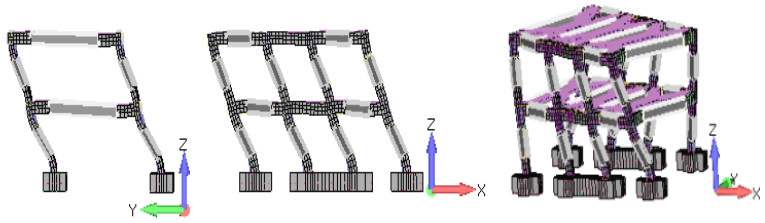

Figure 3: Initial 2-storey model without shear walls. Mode (Left) T_y, (Center) T_x and (Right) T_z.

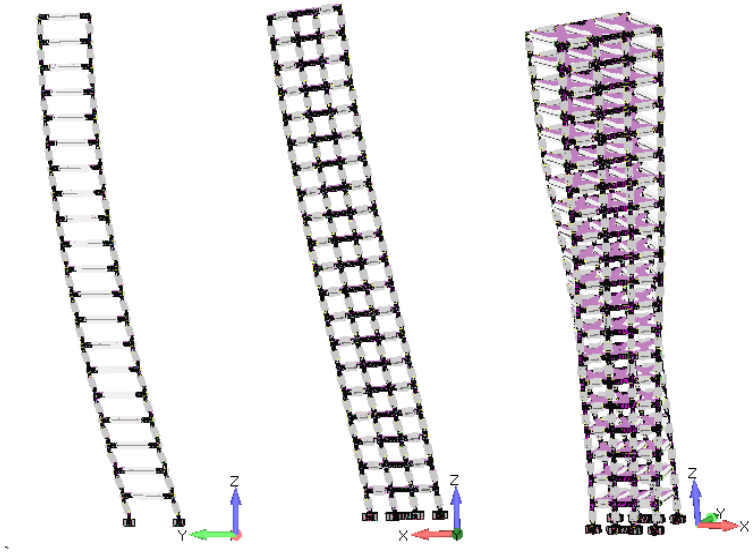

Figure 4: Original 20-storey model without shear walls. Mode (Left) T_y, (Center) T_x and (Right) T_z.

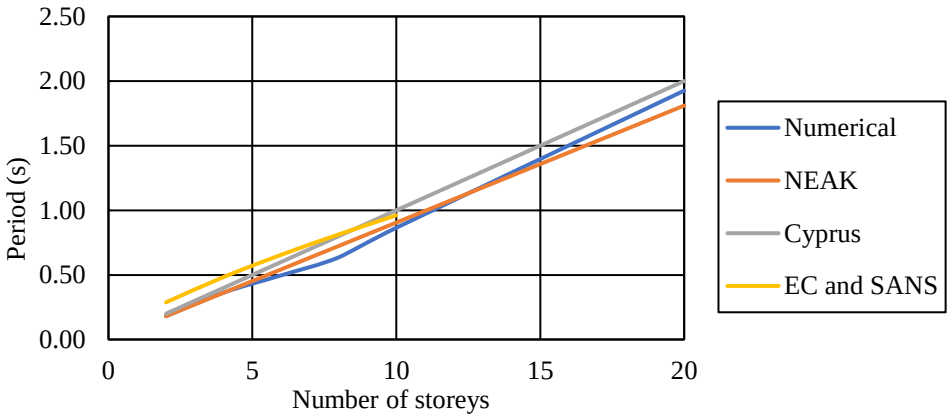

Figure 5: Relationship between period along the x-direction and number of storeys for the initial models without shear walls.

The numerical results are compared with the values of the periods derived from the formulas proposed by the four codes (Eqs 7-10) in Fig. 5 (see also Table 1). As it resulted from the

numerical investigation, the periods obtained from the design codes along the x-axis direction are on average in a good agreement with the numerical results for the case where shear walls are not included within the framing system of the structure. Base on Eurocode, the proposed formula can only be used for structures with heights equal or less than 40 m, therefore, the 20-storey case is not included within Table 1 and Fig. 5. It is also easy to observe that for the computed periods for the cases of the 2, 4 and 6 storey buildings, the codes illustrate a higher divergence from the numerical results, where for the higher storey models the difference decreases. The periods derived from the Cyprus code are the most accurate compared to the other three codes' results, deriving an average of a 1% divergence when compared to the numerical values of the computed periods along the y-axis direction. The NEAK follows with an average divergence of 7% and last Eurocode with 12%.

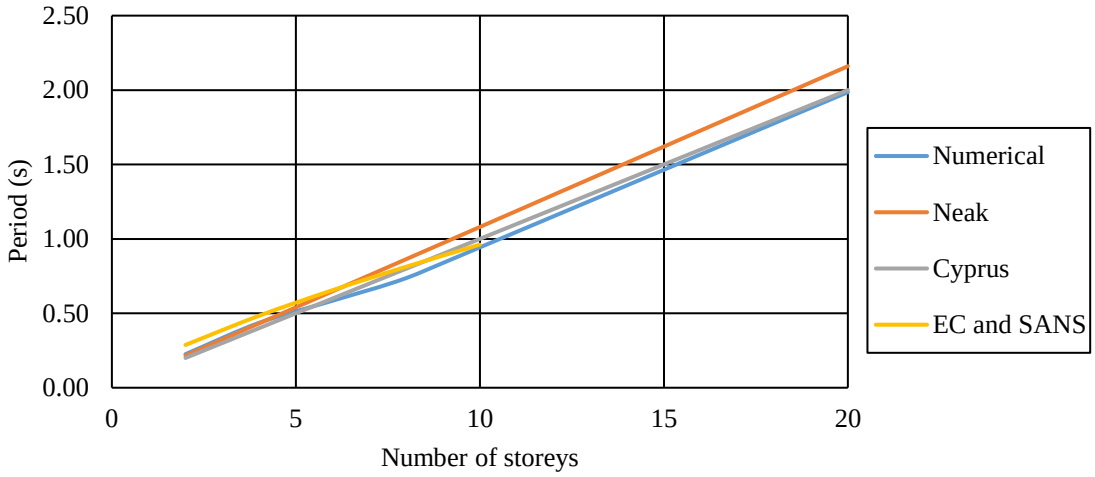

Figure 6: Relationship between period along the y-direction and number of storeys for the initial models without shear walls.

When the code formulae are used to compute the fundamental period along the x-axis direction, the computed periods were found to be close to the numerically obtained magnitudes, but with a higher average divergence. Fig. 6 shows the comparison between the numerical and design code formulae results for the case of the T_x period. Based on the analysis of the results presented in Table 1, the NEAK formulae was found to derive the lowest average divergence in comparison to the numerical results (3%), followed by the Cyprus code with 14%. Eurocode (and SANS) had the highest average divergence in this case, which reached a 32.7%, for the case of computing the T_x period (mode 2 for all numerical models).

Table 2 shows the computational time and finite element numerical details for each mesh according to the modal analyses performed in this work. It can be observed that for the case of the 20-storey model the maximum embedded rebar mesh generation time was 237.7 s, while the corresponding modal analysis for computing the first 12 eigenmodes was 11 minutes and 42 seconds. As it was expected, the computational demand of the numerical problem when the number of storeys is increased to 20, derives a more computationally demanding problem, for which the developed algorithm manages to maintain its computational efficiency and robustness. For this reason, the corresponding models with the shear walls were also analyzed in order to investigate the numerical response of the under study algorithmic implementation.

Number of storeys	Time for embedded rebar mesh gen. (s)	Number of embedded rebars	RAM requirement for the stiffness matrix (Mb)	Number of unknown equations	Time for Modal analysis (s)
2	6.0	8 672	51	16 716	2.9
4	19.8	14 546	276	32 028	33.6
6	40.9	20 376	389	47 052	39.1
8	73.4	26 228	676	62 220	80.4
10	106.6	32 080	1 000	77 388	156.0
20	237.7	61 340	4 000	153 228	702.9

Table 2: Computational performance and numerical details for the initial models without shear walls.

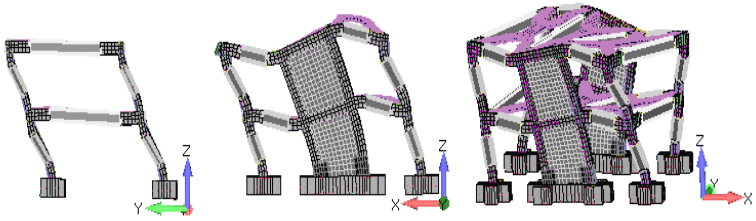

Figure 7: Initial 2-storey model with shear walls. Mode (Left) T_y, (Center) T_x and (Right) T_z.

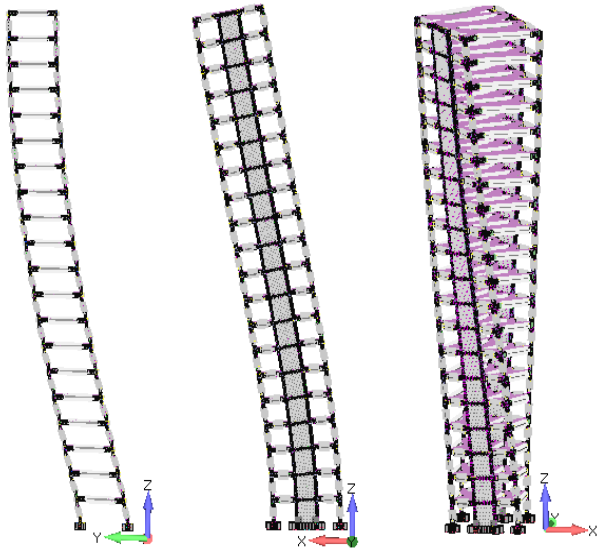

Figure 8: Initial 20-storey model with shear walls. Mode (Left) T_y, (Center) T_x and (Right) T_z.

Figs. 7 and 8 illustrate the deformed modal shapes of the 2- and 20-storey models, respectively, as they resulted from the numerical analysis. As it can be seen, the obtained results demonstrate a similar behavior in terms of deformation when compared with those derived from the models that did not assume for any shear walls (see Figs. 3 and 4). However, Table 3 shows that the values of the corresponding eigenperiods are smaller than the ones presented in Table 1 due to the increase of the stiffness of the models with the addition of the shear walls along the x-axis direction.

Number of storeys	Height (m)	Numerical		NEAK		Cyprus	EC	
		Ty (s)	Tx (s)	Ty (s)	Tx (s)	Tx & Ty (s)	Ty (s)	Tx (s)
2	6	0.193	0.115	0.216	0.123	0.2	0.288	0.363

Table 3: Periods for all the initial models with shear walls. Numerical and design code results.

According to the comparison of the modes depicted in Table 3, the SANS code and Eurocode show a significant divergence in term of values for the case of the T_x period, the global direction of the shear wall sections. Even though Eurocode has the provision of taking into account the effect of the shear walls' stiffness, it fails to predict a realistic period along the x-axis direction. This is attributed to Eq. 10, which derives a C_T variable that is larger than 0.075 given that the minimum computed value of $\sqrt{A_c}$ was equal to 0.55 for the case of the 20-storey and the maximum was equal to 0.79 for the case of the 2-storey. When this value is used to divide the 0.075 (initial C_T value) it results into a higher C_T magnitude, which is not realistic. The low $\sqrt{A_c}$ value is attributed to the fact that there are only two shear walls thus the summation of the $A_i(0{,}2 + (\frac{L_{wi}}{H})^2)$ equation for each shear wall does not result into a value that is larger than 1. Therefore, in this case, the T_x period value should be taken equal to the T_y for all models, which derives a more realistic period value. It is also easy to observe (see Table 3) that Eurocode (hence SANS code as well) fail to capture the period of the models along the stiffer x-axis direction.

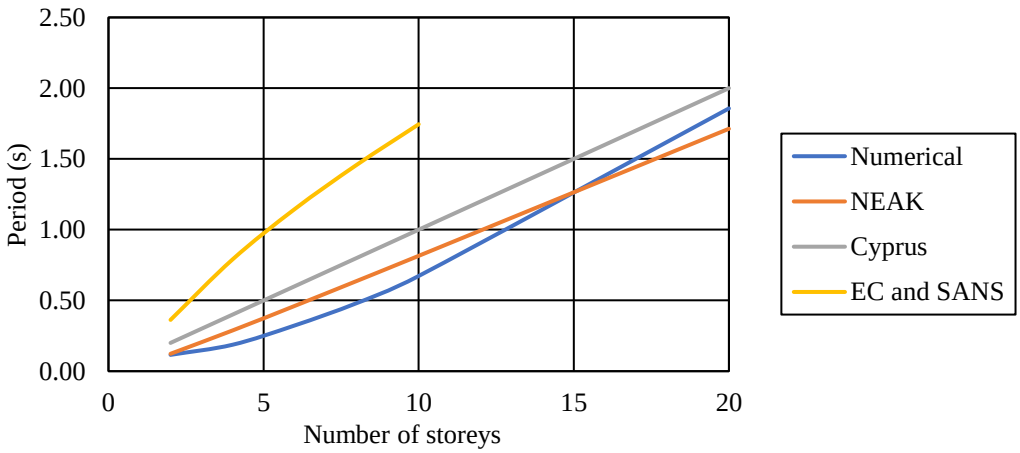

Figure 9: Relationship between period along the x-direction and number of storeys for the initial models with shear walls.

On the other hand, the formula proposed by NEAK code shows a better approximation when compared with the numerical values, with an average divergence of 25% for the values of T_x. The Cyprus code that uses the most simplified formula out of the four codes, basically ignores the presence of the shear walls thus fails to capture the effect of the relevant stiffness increase within the framing system. Therefore, the periods derived from the Cyprus code diverge from the numerical ones by an average value of 66%. It is obvious that the divergence of the T_y is

significantly smaller than the T_x because the shear walls have a minimal contribution to the overall stiffness of the structure along the y direction. The corresponding average divergences along the y-axis are 22%, 10% and 7% for the Eurocode, NEAK and Cyprus codes, respectively. The values of the periods of T_x and T_y calculated by using the different approaches, are plotted in Figs. 9 and 10.

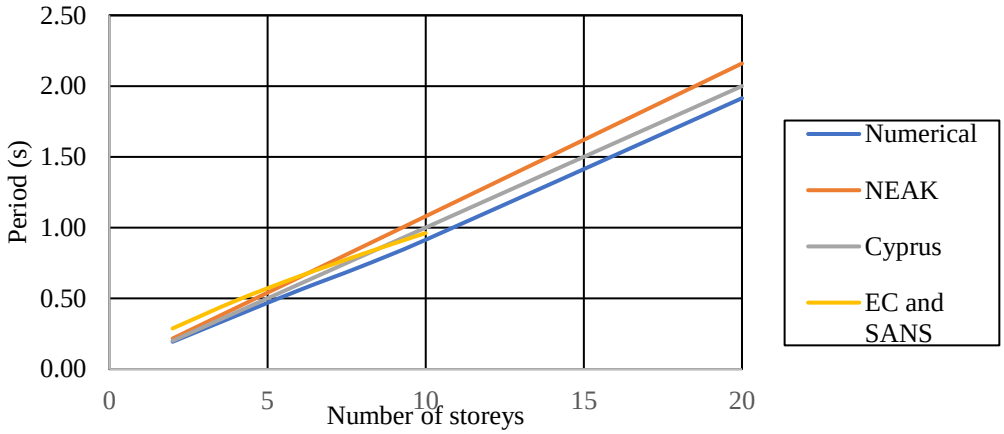

Figure 10: Relationship between period along the y-direction and number of storeys for the initial models with shear walls.

Number of storeys	Time for embedded rebar mesh gen. (s)	Number of embedded rebars	RAM requirement for the stiffness matrix (Mb)	Number of unknown equations	Time for Modal analysis (s)

Table 4: Computational performance and numerical details for the initial models with shear walls.

Table 4 shows the computational performance of the proposed algorithm when the models with the shear walls are analyzed. As it can be seen, the largest model required 8 Gb just for the stiffness matrix allocation, while consisted of 90,936 embedded rebar elements. The computational demand for computing the 12 modes for the case of the 20-storey model was approximately 37 minutes. Even though this is a relatively large model, the algorithm managed to finish the analysis in a reasonable computational time. For this reason, the initial models with shear walls were modified accordingly and they were increased along the x, y and z-directions in constructing larger models.

Therefore, the second phase of this numerical investigation foresaw the construction of models with high computational demand to examine the computational response of the developed algorithm and investigate the ability of the codes to predict the first two modes of realistic RC buildings. For the needs of this second investigation phase, three additional models were developed by assuming 8 shear walls placed along the x-axis direction. When constructing the models, the geometry of the initial models with shear walls presented above were modified by

enlarging the surface area of the initial model along both directions (x- and y-axis), where the dimension. Along the x-axis the size was doubled (17.386 m) and along the y direction it was tripled (18.255 m). The three models assumed 4-, 10- and 20- storeys, respectively.

The numerically derived eigen-shapes of the 4- and 20-storey models can be seen in the Figs. 11 and 12, respectively. In order to demonstrate the abilities of the code to generate and analyze the 368,773 embedded rebars found in the 20-storey modified model, Fig. 13 was developed where the deformed shape of the embedded rebar elements is shown for the case of the fourth modal shape. As it can be seen, the embedded rebar elements follow the deformed shape of the concrete domain.

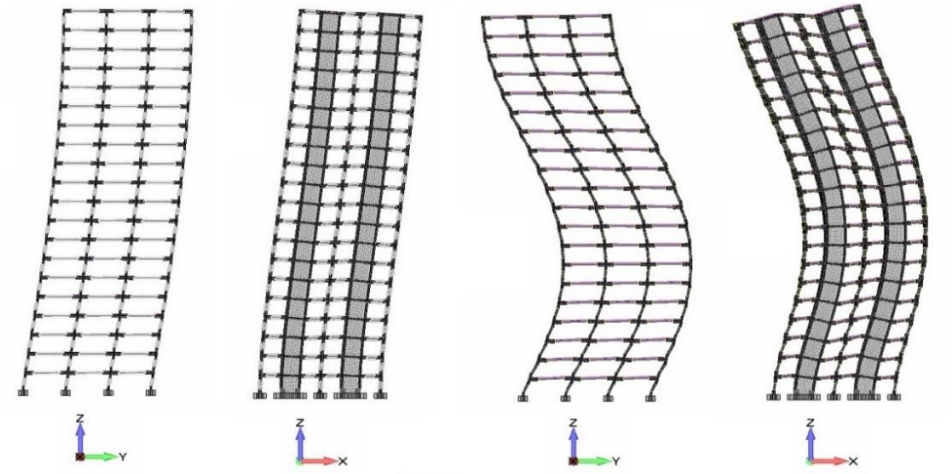

Figure 12: First four modes of the modified 20-storey model with shear walls.

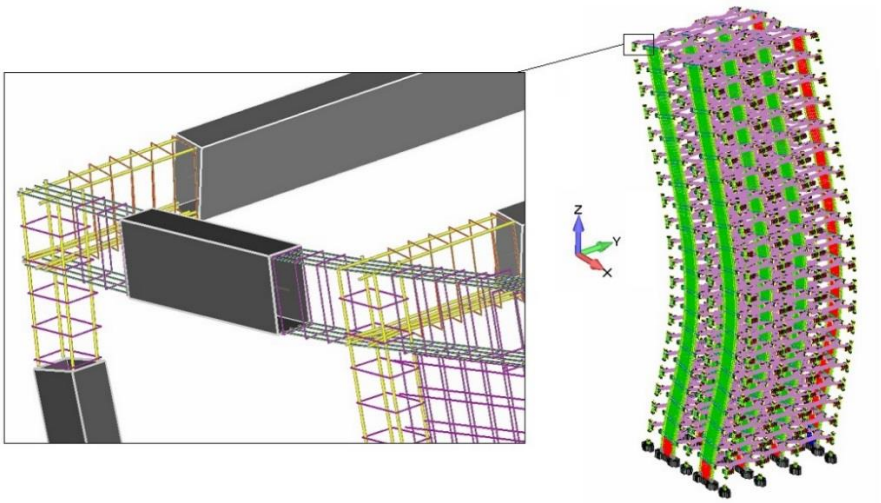

Figure 13: Deformed shape of the embedded rebar elements of the modified 20-storey model with shear walls. Mode 4.

The 20-storey model was identified as a large computationally demanding model given that the model, which was constructed by using the HYMOD approach took a full nine days to finish the analysis and used a total of 185 Gb RAM for the solution of the problem. Given that the computer that was used to perform all the analysis had a 4.2 GHz computational power standard pc with a 64 Gb RAM, the operating system used the compressed memory feature so as to handle this large numerical problem that significantly slowed down the computational procedure. This was the main reason why the computational demand was controlled from the procedure of compressing and uncompressing the RAM in order to handle this extremely large numerical problem. Table 5 shows the computational times for the modal analyses and the corresponding numerical problem size for each one of the modified model that was developed for the needs of this investigation.

Number of storeys	Number of virtual embedded rebars	RAM requirement for the stiffness matrix (Mb)	Number of FEM elements	Number of unknown equations	Time for Modal analysis (minutes)
4	82 514	3 000	59 062	198 840	473.7
10	191 802	18 000	140 364	484 032	13 822.2
20	368 773	87 000	275 288	959 352	9 days

Table 5: Computational performance and numerical details for the modified models with shear walls.

A 15-storey model was also constructed and analyzed, as seen in Fig. 14, so as to decrease the RAM requirements and investigate whether the RAM compression feature is significantly affecting the performance of the algorithm. This analysis required approximately 11 hours to complete demonstrating the significant effect of the RAM compressing feature that was noted in the case of the 20-storey model. The compression in memory extends the computational time by a large margin as illustrated herein. Fig. 14 shows the deformation modal shapes as they resulted from this last analysis for the case of the 15-storey RC building.

Tables 6 and 7 show the comparison between the periods computed numerically and through the use of the design formulae. Table 7 shows the error that each design formulae resulted in comparison to the numerically computed periods. It is evident that all design codes fail to provide with a realistic estimation of the mode value along the x- and/or y- directions.

Table 7: Design code formulae error in comparison to the numerical results.

The corresponding values of the periods T_x and T_y as they can be depicted in Tables 6 and 7 are illustrated in Figs. 15 and 16, to visually compare the period values as they resulted for the two global axis directions (x- and y-axis, respectively). As it can be easily observed from these figures, the only curve that manages to capture the numerical results with less than 10% error is the Cyprus code for the case of the T_y period. Based on the findings of this numerical investigation, it is recommended to use this approximate formula when dealing with framing systems or directions that do not consist of shear walls. In regards to the directions where the use of shear walls is foreseen; none of the codes was found to be effective, thus further research is required to develop objective formulae that will provide with more accurate period predictions in the case where the period is not computed by using finite element models.

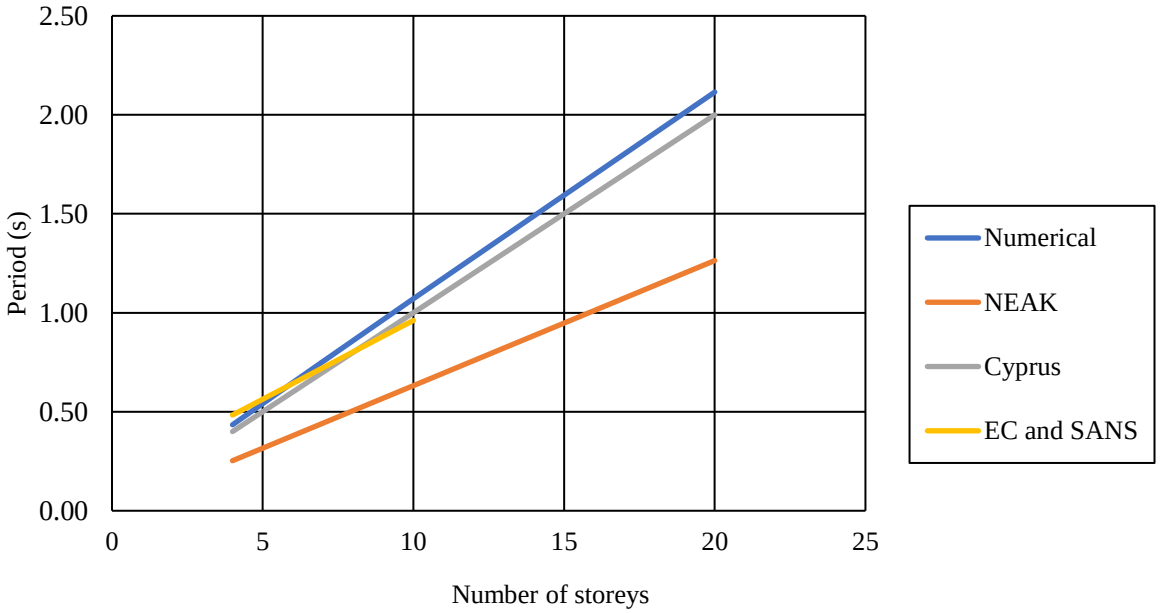

Figure 16: Relationship between period along the y-direction and number of storeys for the modified models with shear walls.

5 SOIL STRUCTURE INTERACTION

In order to model realistically the boundary conditions of any RC structural system, the soil structure interaction (SSI) phenomenon has to be taken into account. The effect of the SSI is crucial for the mechanical behavior of any structure [16]. In this article, a flexible soil is assumed and modeled by assuming a Young Modulus of elasticity E=65 MPa and the numerically obtained results were compared with the fixed base 4-storey model with shear walls. Fig. 17 shows the SSI model as it was developed for the needs of this initial parametric investigation. The objective was to develop an initial model to be tested prior to a more rigorous parametric investigation that will be performed in the near future. Based on the discretization of the soil domain, the model assumed that the length and width of the soil medium would be three times larger than the relevant dimensions of the RC structure along both the x- and y-axis.

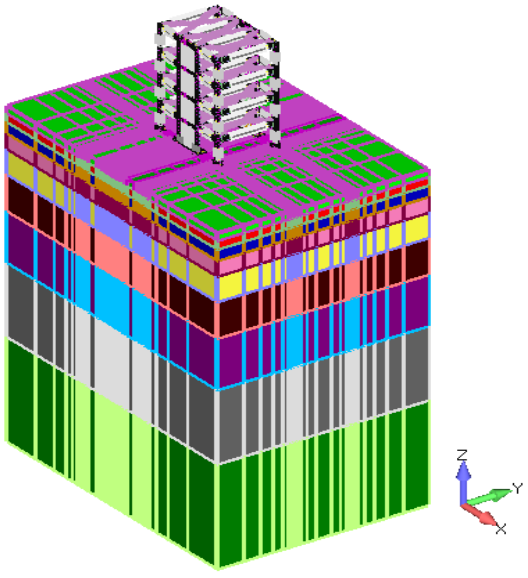

Figure 17: 4-storey model with shear walls and soil domain.

	Fixed Base Model		SSI (soft soil) Model E = 65 MPa		
Mode	***f*(Hz)**	**T(s)**	***f*(Hz)**	**T(s)**	**Dif. %**
1	2,656	0,3766	2,532	0,395	4,66%
2	5,349	0,1870	2,885	0,347	**46,07%**
3	7,508	0,1332	6,259	0,160	16,63%
4	7.983	0.1253	6.310	0.158	20.97%
5	8.626	0.1159	7.652	0.131	11.30%
6	8.734	0.1145	8.691	0.115	0.49%
7	8.767	0.1141	8.749	0.114	0.21%
8	8.791	0.1138	8.779	0.114	0.13%
9	10.478	0.0954	9.031	0.111	13.81%
10	10.599	0.0944	10.577	0.095	0.20%
11	10.636	0.0940	10.654	0.094	-0.17%
12	10.690	0.0935	10.667	0.094	0.21%

Table 8: Comparison between the fixed base and the SSI models. Computed modes and frequencies.

As it can be seen in Table 8, there is a significant difference between the fixed base model and the model with the flexible soil foundation (isolated footings). The maximum derived difference was found to result at mode 2 (46%), where the structure oscillates along the x-axis direction. Given that the shear walls are very stiff, it was found that their foundations rotated significantly due to the settlement of the soil, resulting into a significant stiffness decrease along this direction (global x-axis). Fig. 18 shows the first three modes as they resulted from the analysis, where the deformed shape of both the frame and the soil domain can be depicted. Further investigation will be performed as a continuation of this research work in order to study the effect of the SSI and the foundation system's effect on the modal response of different framing geometries. One of the main objectives of this future research work will be to establish a relation between the dimensions of the structure and the SSI effect when SSI considerations are accounted for, whereas propose improved formulae for the computation of the fundamental periods when the SSI effect is accounted for.

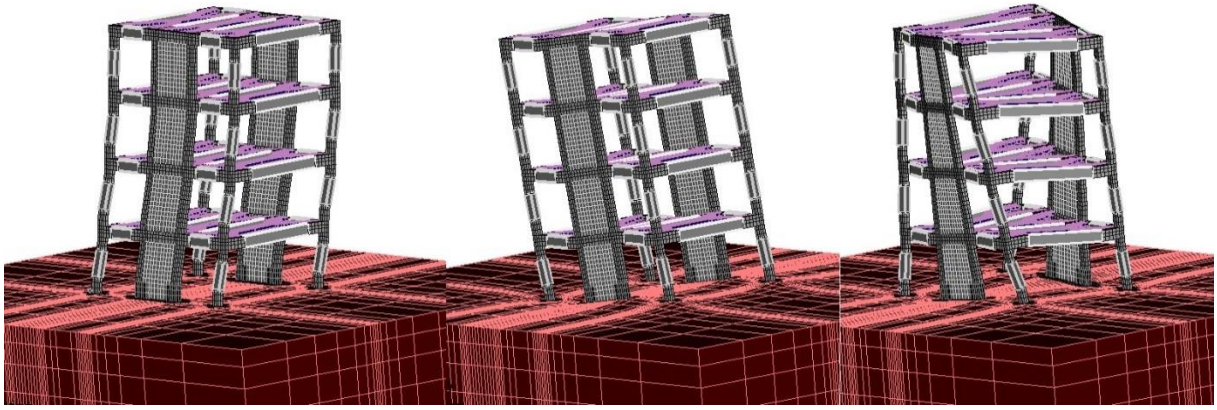

Figure 18: 4-storey model with shear walls and soil domain. Deformed shapes of modes 1, 2 and 3 (from left to right).

6 CONCLUSION

Based on the findings of this research work, it is evident that the HYMOD approach provides with computational efficiency and numerical accuracy when dealing with modal analysis of large-scale numerical problems. The HYMOD method manages to alleviate the computational limitations when analyzing large 3D models without losing the required accuracy of the numerical analysis. Therefore, this method is found to be suitable for modeling large-scale structures and will be used for the dynamic analysis or RC buildings in future research projects.

By conducting the analysis and interpreting the results in section 4, it can be concluded that the design codes yielded inaccurate results were Eurocode (EC) and the South African National Standard codes did not manage to satisfactorily predict the periods of the numerous models that were studied herein. These codes approximated the periods inaccurately, especially when dealing with frames that assumed shear walls. Eurocode, which is adopted by the South African code as well, needs to be scrutinized for improvements in order to take into account more efficiently the effect of the RC shear walls found within any RC frame geometry. On the other hand, the NEAK formula produced results that were found to be closer to the numerical analysis data, given its objective formulation that takes into account the ratio of the shear wall section areas along the under study direction. Nevertheless, the NEAK code equation should also be improved to approximate accurate results when dealing with RC structures with different geometries. The Cyprus code, which is now obsolete, proposed a simplified formula that does not take into account for the shear walls' contribution when computing the fundamental period. This makes the formula inadequate for computing the fundamental modes along directions that foresee the use of shear walls. Nevertheless, when shear walls are not present, it is a formula that provides with a good fundamental period approximation.

Further research foresees the use of the HYMOD approach to study the dynamic behavior of structures by performing modal analysis with SSI models. Based on the preliminary findings from the analysis of a model that also discretized the soil domain through the use of hexahedral elements, it was found that the periods can be significantly affected especially when the soil material characteristics assume for a soft soil and the structure uses a relatively flexible foundation system (i.e. isolated footing). It is also evident that the assumption of a fixed base structure is not a realistic approach in cases where structures are founded on flexible soils.

Abstract

In the seismic response analysis of large-scale reinforced concrete (RC) structures, such as nuclear power plant buildings, while considering the soil-structure interaction (SSI) using high-fidelity models, the application of high-performance computing (HPC) is indispensable owing to the number of the degrees of freedom (DOF). This study shows the development of a seismic response analysis method for large-scale RC structures with FEM utilizing HPC.
Herein, we implemented a previously proposed constitutive relation of concrete to the HPC-FEM program, FrontISTR. In the HPC-FEM program, conjugate gradient method is usually used as the solver algorithm that requires a positive-definiteness of the stiffness matrix. However, the constitutive relation of concrete expresses the material damage by stress-strain curve softening; hence one cannot assure that the stiffness matrix is positive-definite. Several techniques have been proposed to overcome this limitation. Herein, we adopted the method to calculate the stiffness matrix using elastic tensor of the material by comparing the speed of computation. We applied the developed software to a seismic response analysis of a nuclear power plant with surrounding ground, which is approximately 150 million-DOF problem. This paper shows the results and discusses the analysis performance.

Keywords: Seismic Response Analysis, Large-Scale Reinforced Concrete Structure, Soil-Structure Interaction, High Performance Computing, High-Fidelity Model.

1 INTRODUCTION

Lumped mass models are usually used in the seismic response analysis of reinforced concrete (RC) structures. Using such models for structures, which are sufficiently validated with experiments, is rational because of their low computational cost. Even in a nonlinear analysis, applying experimental results to the structural elements, which represent the members or groups of members, is not difficult.

Meanwhile, it is necessary to care to the applicability of the models. A method that can be applied to the analysis for a seismic load larger than the design load is needed because of the large earthquakes that happened in Japan in the recent years. In such cases, it is required to consider the models' applicability to such a load. High-fidelity models using solid elements should be applied when the applicability check is difficult. For considering the safety of nuclear power plant (NPP) buildings, it is meaningful to simulate the response for a seismic load larger than the design load using high-fidelity models due to their importance.

To apply the high-fidelity models is also useful to consider soil-structure interaction (SSI) precisely. In lumped mass models, a few spring elements are used for the soil-structure interaction even in the seismic response analysis of large-scale structures such as NPP buildings.

However, it is difficult for the existing finite element method (FEM) programs for the RC structures to deal with large-scale structures and surrounding ground using high-fidelity models because the number of the degrees of freedom is large. Therefore, applying a high-performance computing (HPC) technology is indispensable.

In HPC-FEM programs, the conjugate gradient (CG) method [1] is usually used as the fast solver algorithm that requires the positive-definite stiffness matrix. The CG method cannot be easily applied to a concrete material, whose strain-stress curve has a negative stiffness representing the fracture in the material. When using the concrete material in HPC-FEM programs, we need to focus on the combination of implementation of the concrete constitutive relation model and that of nonlinear analysis method. We have several possible combinations, and the faster one must be chosen.

Herein, we study the optimization of combination of the implementation of concrete constitutive relation model and that of nonlinear analysis method. A basic performance study is done using a small-scale RC structure. Finally, we apply the method to the seismic response analysis of NPP buildings considering the SSI and show the results and its performance.

2 PROBLEM IN DEVELOPMENT

We outline the problem to develop the HPC-FEM for RC structures. We explain the constitutive relation model of the concrete material used herein and its problems from the viewpoint of the stability of analysis and computational cost.

This study employs the constitutive relation model of the concrete material proposed by Maekawa et al. [2], and is one of the de-facto standards in Japan. The elasto-plastic fracture model is used before cracking occurs and the model switch to the cracked concrete model after cracking occurs, as shown in Figure 1.

This model can be utilized to solve two problems in HPC-FEM. One is the computational cost of the model itself and the other is the difficulty in assuring that the stiffness matrix is positive definite.

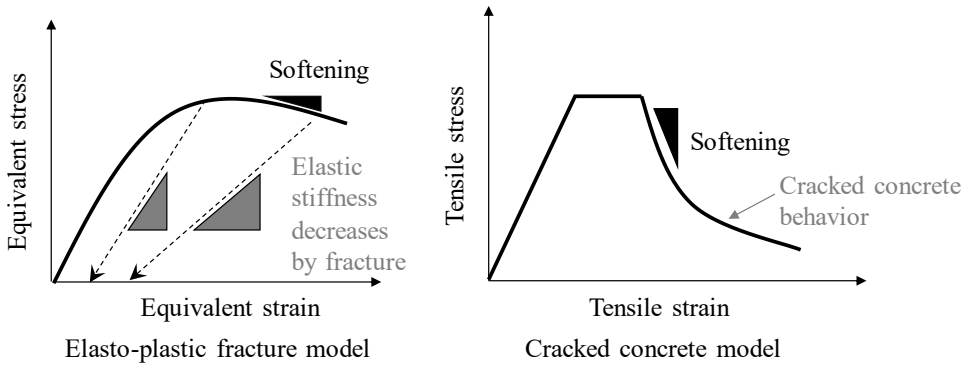

Figure 1: Concrete constitutive relation model.

Although it is relatively easy for HPC-FEM to achieve high scalability on computation about constitutive model in each element, saving the computational cost is still important because the number of elements or integration points is large. The original model has an inverse matrix computation that would acquire the elasto-plastic tensor, whose computational cost is high. In the study by Yamashita et al. [3], the original model was reconstructed to reduce this computational cost. The outline is shown below. Equation (1) presents the method of computing the elasto-plastic tensor $\mathbf{c}^{EP}$ in the original Maekawa model.

$$\mathbf{c}^{EP} = (\mathbf{c} + \nabla\mathbf{c}{:}\,\boldsymbol{\varepsilon}^{E})(\mathbf{I} + l)^{-1}, \tag{1}$$

where $\mathbf{c}$ is the elastic tensor, $\boldsymbol{\varepsilon}^{E}$ is elastic strain tensor, $\mathbf{I}$ is unit tensor, and l is the tensor that associates the elastic strain and plastic strain increments, which is a unique part of this model. Yamashita derived Equation (2) using the same constitutive relation with Maekawa as follows:

$$\mathbf{c}^{EP} = (\mathbf{c} + \nabla\mathbf{c}{:}\,\boldsymbol{\varepsilon}^{E})(\mathbf{I} - \mathbf{L}) \tag{2}$$

where $\mathbf{L}$ is the tensor that associate stain and plastic strain increments. Equation (2) avoids the inverse matrix computation. An implementation technique is shown in the authors' work [4].

Another problem in the constitutive model of concrete, which is a difficulty in assuring the positive-definite of the stiffness matrix, is still remained after reconstructing. We first studied the method that directly uses the elasto-plastic tensor shown in Equation (2) for calculating the stiffness matrix. In this method, the stiffness matrix is not assured as positive definite in the large strain area. However, in the seismic response analysis, the dynamic effect is added to the stiffness matrix. The dynamic stiffness matrix $\widehat{\mathbf{K}}$ is derived as $\widehat{\mathbf{K}} \approx 1/dt^2\ \mathbf{M} + \mathbf{K}$. Hence, a smaller *dt* will improve the condition of the stiffness matrix $\widehat{\mathbf{K}}$. In the first study, the authors tried to acquire computational stability by setting a smaller *dt*.

This method also has a problem, in which the stability and the elapsed time depend on targets. A decrease in the elapsed time with stability conservation becomes a limitation because of the large number of time steps. In other words, the method is necessary in which the stability of computation does not depend on *dt*. We focus on the method of the nonlinear analysis or the Newton method. New method uses an elastic tensor to calculate the stiffness matrix. In this method, the computation stability is expected to be assured even with a larger *dt*. On the contrary, the estimation of the increment of displacement is supposed to have a larger error introducing the increase in the number of the nonlinear steps. It is needed that the suitable nonlinear analysis method for the RC structures in HPC is selected by comparing the performances of existing method and the new one.

The proposed method is explained in the next chapter. The chapter after the next one presents the method application to the target problem and its performance.

3 NONLINEAR ANALYSIS METHOD FOR RC STRUCTURES

3.1 Trial method

This section explains the trial method of the nonlinear analysis. In consideration of convenience, we call this method as proposed method in this study.

Unlike the existing method explained in Section 2, the elastic tensor is used in the proposed method for calculating the stiffness matrix. This method can directly avoid dealing with the softening behavior that expresses a negative stiffness; hence, the positive definite of the stiffness matrix is assured. In the implementation, we need to ensure that the elastic stiffness is changed by the strain increase. This method is a kind of modified Newton method ignoring the change of elastic stiffness. Figure 2 depicts the method outline.

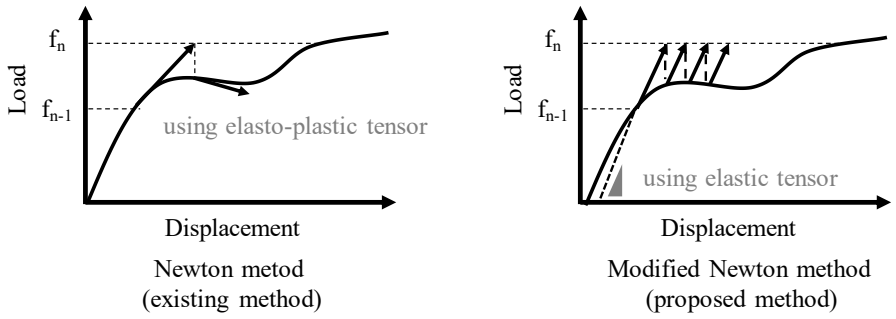

Figure 2: Outline of the nonlinear method.

3.2 Model for performance check

The cyclic loading test of the RC structure by Habasaki et al. [5] was used as the target. We constructed a simulation model and tried the response analysis. This target is constructed by four RC walls as a box structure. The thickness, width, and height of each wall was 75, 1500, and 1000 mm, respectively. The reinforced bars were 6 mm in diameter (D6), equivalent to SD345. The steel ratio in the wall was 1.2%. The material parameter in the simulation was set from the test literature.

Figure 3 exhibits the outline of the simulation model. The loading slab whose thickness was 200 mm was modeled on the walls as a rigid body. Figure 3 also shows the cross-section of the wall. The groups of reinforced bars were modeled by shell elements. The bottom face was fixed and the loading condition is set by displacement at the center of loading slab as the boundary conditions.

Figure 4 depicts an example result. The simulation result was compared with the loading test which is traced by the literature. Although the accurate estimation of the hysteresis curve needed additional study, the skeleton was estimated to be accurate enough. This result implied that this model can express the damage history of the structure. Hence, this simulation model is suitable for the test model of the performance check of the nonlinear analysis method for the RC structure.

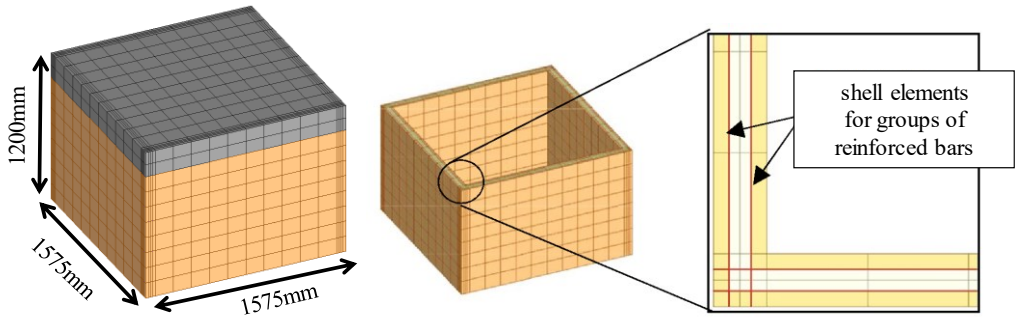

Figure 3: Outline of the simulation method.

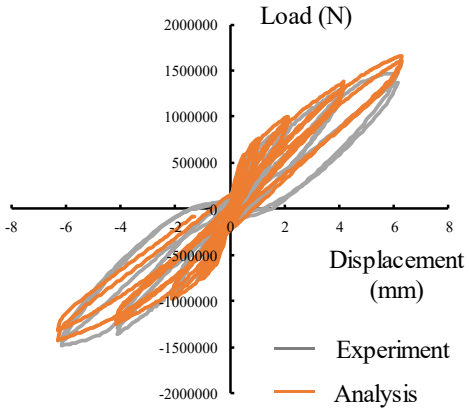

Figure 4: Example of the simulation result.

3.3 Performance check

The basic performance study of the nonlinear analysis for the RC structure was tested herein by comparing the elapsed time and number of analysis steps of the two mentioned methods above, existing method using the elasto-plastic tensor and proposed method using the elastic tensor. A monotonic loading simulation, in which the target displacement was 2 mm, was the target case. Considering the existing method, a dynamic simulation was applied with a loading time of 10 s. While applying the existing method, we tried three cases in which dt was different (i.e., $dt = 0.1, 0.01, 0.001$). The stiffness was fixed at each time step (the model was linearized), indicating no repeated calculation for convergence. Only $dt = 0.01$ was tried in the proposed method. In this method, the limitation of the maximum of the repeated calculation for convergence was five times. The force was carried over to the next step if the residual force was not converged.

Figure 5 shows the simulation results. In this trial, although a smaller time step improved stability of simulation, the existing method could not acquire the convergence of the CG method even in the case of $dt = 0.001$. On the contrary, the proposed method was stable for this target case.

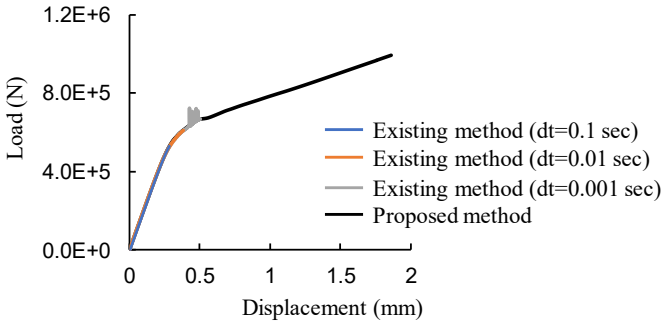

Figure 5: Result of the performance check simulation.

	Existing (dt=0.1)	Existing (dt=0.01)	Existing (dt=0.001)	Proposed (dt=0.01)
Number of analytical steps	100 (25)	1000 (304)	10000 (3278)	3485
Elapsed time of solver per one step	0.328 s	0.332 s	0.300 s	0.322 s
Number of CG steps per one step	898.5	894.5	786.4	800.9

Table 1: Comparison of the performances in each case.

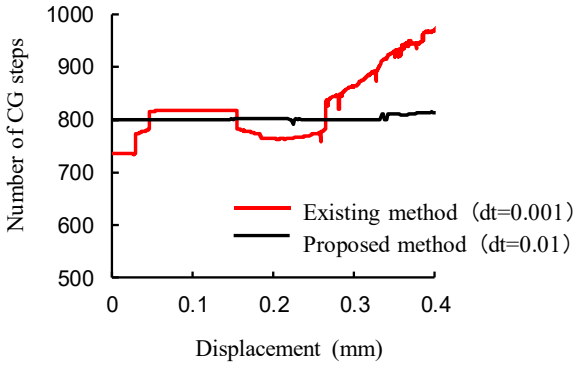

Figure 6: Number of CG steps at each step.

Table 1 lists the number of analytical steps and averaged elapsed time per one step. The number of analytical steps means the total number of calculation steps for the Newton method convergence, which is equal to the number of solver functions called. We also show the number of calculation steps for the CG method convergence per one step. The results of the existing method show the supposed number of analytical steps and the number of analytical steps before calculation stopped in round brackets.

We discuss using case dt = 0.001 as the existing method. Using the proposed method, the number of analytical steps was decreased by approximately one third in comparison with the existing method. Considering an increase of the elapsed time per one step, the performance of the proposed method is still high. By existing method, dt should be set smaller; hence, the difference in performance was larger than the results in Table 1.

Additionally, we compared the change of the number of CG steps depending on the progress of the loading step. Figure 6 shows the result. The x-axis denotes the loading displacement,

whereas the y-axis denotes the number of CG steps at each displacement. In the existing method, the number of CG steps increases at a larger displacement. In contrast, in the proposed method, the change of the number of CG steps is smaller because the change of stiffness by proposed method is smaller than that by existing method. In other words, the proposed method is suitable to the analysis for the RC structures using HPC.

The obtained results imply that the proposed method is a better method for the RC structures from the view of analytical stability and computation performance.

4 SEISMIC RESPONSE ANALYSIS OF NPP BUILDINGS

4.1 Target building

We tried the seismic response analysis of NPP buildings with a surrounding ground. Figure 7 illustrates the model outline. The surrounding ground size was 600 m × 800 m horizontally and 200 m vertically. This model was constructed by a real structure; hence, the size is omitted because of safety. Table 2 lists the computation scale.

The seismic wave was set compatible to the spectrum proposed by Kato et al. [6], whose duration time of the seismic wave was 22.08 s, boundary condition of the seismic load was set to the bottom and each side of the surrounding ground, each time step was 0.005 s, and the total number of time steps was 4,416.

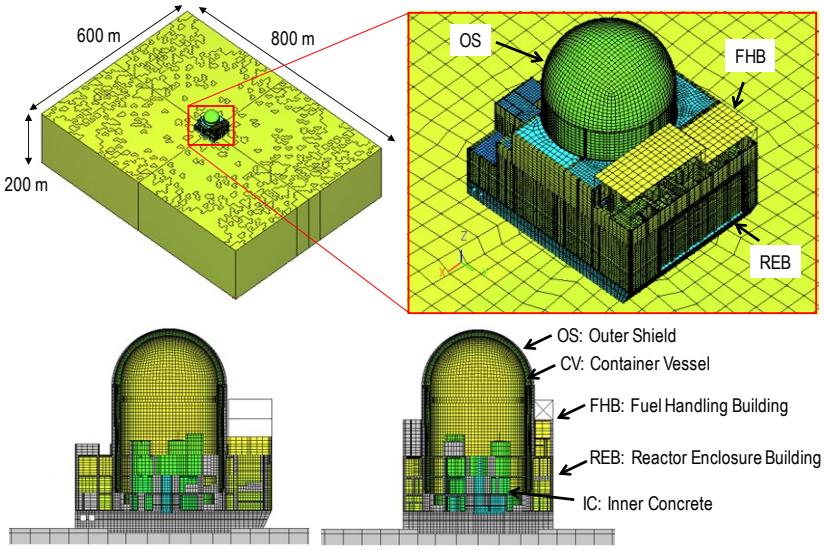

Figure 7: Outline of the model of the NPP buildings.

Node	Element	DOF
405,326	444,060	1,472,529

Table 2: Computation scale.

4.2 Results of the seismic response analysis

The elapsed time of this analysis was approximately 10 h using 64 cores. This is enough fast for the practical use. The proposed method herein utilized the HPC technique considering the nonlinearity of the concrete material.

Figure 8 presents the examples of the results. The crack distribution on the outer shield is shown as well as the shear strain distribution at the same time step. These results imply that we can analyze the deformation and the damage caused by the deformation with a high resolution.

Figure 9 exhibits the acceleration response and acceleration response spectrum. The target points are at the same level of the reactor enclosure building. These results show that the response has spatial distribution, which means that the accurate estimation of the seismic response needs such a high-fidelity model. The linear analysis results are also shown in this figure. The acceleration response spectrum changes at some frequency in comparison with the nonlinear analysis results. Considering fine nonlinearity might make the device design more rational.

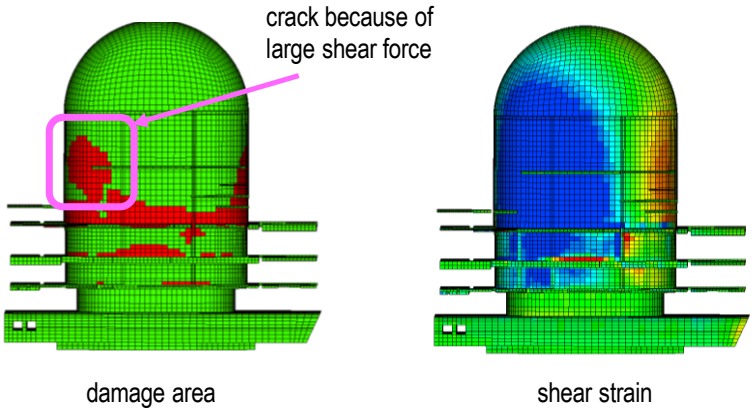

Figure 8: Distribution of the crack and shear strain on OS.

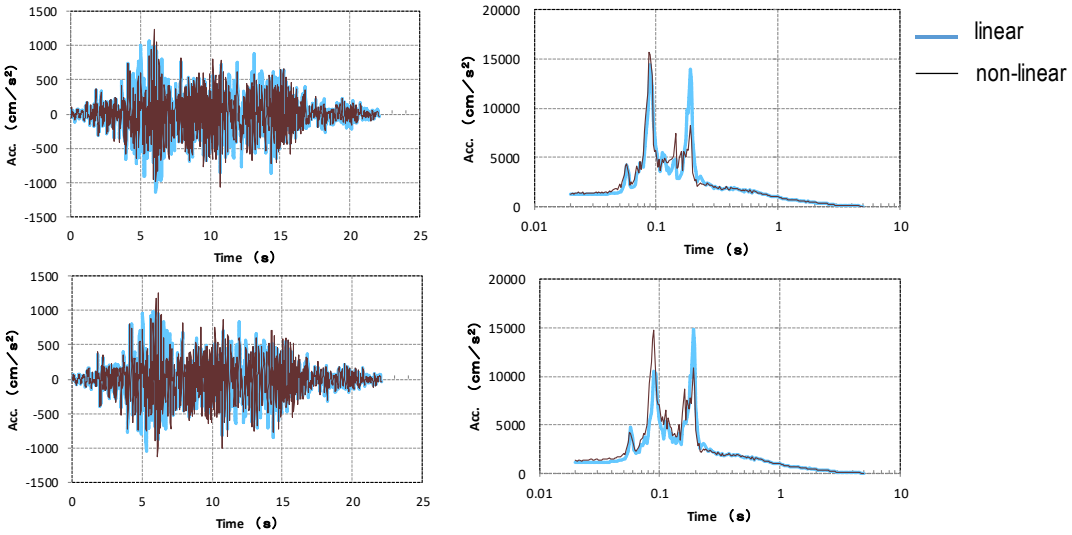

Figure 9: Acceleration and acceleration response spectrum.

5 CONCLUSIONS

Herein, we developed the nonlinear analysis method suitable for RC structures using HPC. The performance of the proposed method was checked by the loading test of a small RC structure. We applied the developed method to the seismic response analysis of the NPP buildings considering the soil-structure interaction. The results showed that the computation performance is high enough for practical use. We finally discussed the effectiveness of the analysis with a high-fidelity model.

ACKNOWLEDGEMENTS

This study is supported by commissioned projects from the Agency for Natural Resources and Energy, Ministry of Economy, Trade and Industry, Japan.

Abstract

The study of the hysteretic behavior of reinforced concrete members that undergo static cyclic and dynamic loading conditions in cases where the loading level is close to their carrying capacity, is a challenging open research subject, which currently is being investigated by many researchers. The development of an objective and robust 3D constitutive modeling approach that will be able to account for the accumulated material damage and stiffness deterioration is of great importance in order to realistically describe the physical failure mechanisms thus numerically study the seismic performance of RC structures. The adopted concrete material model in this research work is based on the material model proposed by Markou and Papadrakakis, which was an extension of the Kotsovos and Pavlovic work. Furthermore, the use of two newly proposed damage factors that are computed through the use of the number of opening and closing of cracks during the nonlinear cyclic analysis, are further investigated and their ability in capturing the accumulated material damage in both steel and concrete is further discussed in this research work.

The numerical accuracy of the proposed method is validated by comparing the numerical results with the experimental data of two beam-column frame joints, a shear wall and a three-storey three-bay RC frame. According to the experimental setups, the RC joint and the shear wall specimens were tested under ultimate limit state cyclic loading, whereas the RC frame was tested under dynamic loading conditions. Based on the numerical findings, the proposed algorithm manages to capture the experimental results in an accurate manner and the numerical response of the understudy algorithmic implementation was found to exhibit computational robustness and efficiency.

Keywords: Nonlinear dynamic analysis, concrete material modeling, finite element method, damage factor, accumulated material damage

1 INTRODUCTION

Many numerical constitutive models have been proposed for the simulation of reinforced concrete (RC) structural members. Most of these approaches are based on uniaxial constitutive laws with strain softening and tension stiffening characteristics. The analysis of RC structural members under ultimate limit state conditions is characterized by heavy nonlinearity, which is mainly caused by the cracking of concrete and steel rapture. Mainly due to the complex behavior of concrete structures under cyclic and dynamic loading conditions, the numerical procedure becomes unstable causing the nonlinear solution procedure to diverge. Therefore, a realistic 3D approach that is characterized by simplicity and computational efficiency is an open research subject for Civil Engineering scientific community.

As a solution to this numerical modeling limitation, most researchers use uniaxial constitutive laws that can describe only certain aspects of concrete behavior. Many of these numerical approaches are based on elastoplasticity theories, thermodynamic laws and fracture mechanics. These models place emphasis on strain softening, tension stiffening characteristics and generally they foresee for numerous material parameters that describe the post cracking behavior of concrete. By adopting this approach, they introduce properties of concrete that are related to the triaxial behavior of concrete such as plasticity, concrete crushing and effect of confinement, but have no actual physical meaning nor interpretation. Additionally, most of these models are restricted to 2D analysis in order to capture the biaxial behavior of concrete structures that are subjected to monotonic loading conditions. This makes these numerical material models difficult to handle (lacking in objectivity) and not of practical interest given their limited applicability. Therefore, the necessity of a 3D constitutive material law that will not require additional material parameters that are not associated with the behavior of concrete at a material level is required.

Furthermore, the implementation of the pre-mentioned modeling methods is limited to examples of small practical interest (i.e. single structural members). Thus, it is important to formulate a constitutive model that will represent accurately the realistic mechanical behavior of concrete and offer the required computational efficiency allowing its implementation in full-scale structure nonlinear dynamic analysis.

The proposed approach described in [1, 2] and further investigated herein, emphasizes on the objectivity and the applicability of the proposed modeling method under nonlinear static cyclic and dynamic analysis of RC structures. In this research article, the proposed damage parameters for concrete and steel reinforcement that are proposed in [2], are further validated in capturing the accumulated material damage that is developed during cyclic and dynamic loading conditions, through the use of experimental data found in the international literature. The numerical accuracy and robustness of the proposed modeling method [2] is investigated by comparing the numerical results with the experimental data of two beam-column frame joints, a shear wall and a three-storey three-bay RC frame.

2 MATERIAL MODELING

2.1 Concrete Material Modeling and Damage Factor

The proposed numerical model adopted herein is based on the experimental findings of Kotsovos and Newman [3], which were derived from tests on specimens subjected to triaxial loading conditions, through the use of techniques capable of both inducing definable states of stress in the specimens and measuring reliably the deformational response of concrete [4]. Based on the experiment findings [4], the concrete material loses all of its carrying capacity

when the criterion of failure is satisfied, thus the adopted material model assumes that the cracked concrete will behave in a brittle manner. The expression of the strength envelope of concrete that was used during the nonlinear analysis in this research work is provided in Eq. 1 and it's based on the Willam and Warkne [5] formulae.

$$\tau_{0u} = \frac{2\tau_{0c}(\tau_{0c}^2 - \tau_{0e}^2)\cos\theta + \tau_{0c}(2\tau_{0e} - \tau_{0c})\sqrt{4(\tau_{0c}^2 - \tau_{0e}^2)\cos^2\theta + 5\tau_{0e}^2 - 4\tau_{0c}^2\tau_{0e}^2}}{4(\tau_{0c}^2 - \tau_{0e}^2)\cos^2\theta + (2\tau_{0e} - \tau_{0c})^2} \tag{1}$$

The concrete stress-strain relationships are expressed most conveniently by decomposing each state of strain and stress into hydrostatic and deviatoric components describing a realistic behavior of concrete under generalized three-dimensional states of stress. The constitutive relations take the following form:

$$\varepsilon_0 = \varepsilon_{0(h)} + \varepsilon_{0(d)} = (\sigma_0 + \sigma_{id}) / (3K_s) \tag{2}$$

$$\gamma_0 = \gamma_{0(d)} = \tau_0 / (2G_s) \tag{3}$$

where K_s and G_s are the secant forms of bulk and shear moduli, respectively. The secant forms of bulk, shear modulus and σ_{id} are expressed as functions of the current state [4] take into account the coupling effect of τ_0-$\varepsilon_{0(d)}$ (h and d stand for hydrostatic and deviatoric components, respectively). It must be also noted herein that, the model uses the smeared crack approach for simulating cracking, therefore, the model simulates the geometrical discontinuity by the assumption of displacement continuity and by modifying the material properties along the crack plane. This approach avoids the need of remeshing when cracks open and close during the cyclic analysis.

Furthermore, a new criterion of crack closing which was introduced in [1] is used that defines the crack closure in a numerical manner. The criterion has the following form:

$$\varepsilon_i \leq a \cdot \varepsilon_{cr} \tag{4}$$

where ε_i is the current strain in the i-direction normal to the crack plane and ε_{cr} is the strain that caused the crack formation. Parameter a is a reduction factor described by Eq. 5.

$$a = 1 - \frac{\varepsilon_{cr}}{\varepsilon_{\max}} = \frac{\varepsilon_{\max} - \varepsilon_{cr}}{\varepsilon_{\max}} \tag{5}$$

The maximum strain ε_{max} is determined through the iterative Newton-Raphson procedure. For more details in regards to the closing crack criterion one may refer to [5]. According to the solution strategy and the material modeling of concrete [2], when the criterion of crack-closure is satisfied at a Gauss Point (assuming that this point had prior to that only one crack formation), a part of the stiffness is lost along the crack plane at this Gauss Point to account for the damage accumulation due to the opening and closing of the under study crack. Therefore, the proposed damage factor [2] modifies the constitutive matrix of concrete accordingly to model the stiffness deterioration. The damage factor is denoted as D_C and describes the accumulated energy loss due to the number of times a crack has opened and closed. After a numerical investigation, the proposed damage factor was found to perform in a numerically optimum manner when it takes the form of Eq. 6:

$$D_c = e^{-(1-a)/f_{cc}} = e^{-\left(1-\left(1-\frac{\varepsilon_{cr}}{\varepsilon_{\max}}\right)\right)/f_{cc}} = e^{-\left(\frac{\varepsilon_{cr}}{\varepsilon_{\max}}\right)/f_{cc}} \tag{6}$$

where f_{cc} is the number a crack has closed during the cyclic loading history and it is updated in every iteration for every Gauss Point.

After the crack closure, the stresses are corrected by using the following expression:

$$\sigma^i = \sigma^{i-1} + C' \cdot \Delta\varepsilon^i \tag{7}$$

where *C'* is the modified constitutive matrix of concrete with the damaged material properties across the direction of the closed cracks. The constitutive matrix takes the following form:

$$\boldsymbol{C}_i^{'} = \begin{bmatrix} 0.25\cdot(1-D_c)\cdot(2G_t+\mu) & 0.25\cdot(1-D_c)\cdot\mu & 0.25\cdot(1-D_c)\cdot\mu & 0 & 0 & 0 \\ 0.25\cdot(1-D_c)\cdot\mu & 2G_t+\mu & \mu & 0 & 0 & 0 \\ 0.25\cdot(1-D_c)\cdot\mu & \mu & 2G_t+\mu & 0 & 0 & 0 \\ 0 & 0 & 0 & 0.125\cdot(1-D_c)\cdot\beta\cdot G_t & 0 & 0 \\ 0 & 0 & 0 & 0 & 0.125\cdot(1-D_c)\cdot\beta\cdot G_t & 0 \\ 0 & 0 & 0 & 0 & 0 & 0.125\cdot(1-D_c)\cdot\beta\cdot G_t \end{bmatrix} \tag{8}$$

where β is the concrete shear retention factor. Additionally, the material deterioration that occurs due to the opening and closing of cracks affects the bonding relation between the steel reinforcement and the damaged concrete domain that contains them. In order to take into account this loss of bonding, a modification of the steel stress-strain relation of Menegotto-Pinto [6] was proposed in [2]. Therefore, pinching characteristics that are caused by the loss of bonding between steel reinforcement and its surrounding concrete medium can be taken into account indirectly by reducing the stiffness contribution of the steel reinforcement [2]. In order to numerically establish such a connection, the average of all parameters *a* (Eq. 5) at the 8 Gauss Points within each concrete hexahedral element is computed and used to determine the overall level of damage of each concrete hexahedron found within the concrete mesh. Eq. 9 gives the expression through which the steel damage factor is computed through the use of the damage factor *a*.

$$D_s = \left[1 - a_{Element}\right] \tag{9}$$

where,

$$a_{Element} = \frac{\sum_{1}^{ncr} a_i}{ncr}, \; ncr \text{ is the number of cracked Gauss Points} \tag{10}$$

The material deterioration of the steel reinforcement is computed based on the following proposed formulae:

$$E_s^{'} = (1-D_s)E_s \tag{11}$$

where E_s' is the modified steel modulus of elasticity. As explained in [7], an alternative way of introducing the pinching effect through the stress-strain law of steel reinforcement, is by reducing the parameter *R* of the Menegotto-Pinto [6], which has the following form:

$$R = R_0 - \frac{a_1 \xi}{\alpha_2 + \xi} \tag{12}$$

where ξ is the strain difference between the current asymptote intersection point and the previous load reversal point with maximum or minimum strain, depending on whether the corresponding steel stress at reversal is positive or negative. R_0, a_1 and a_2 were assumed to be 20, 18.5 and 0.15, respectively, in this study. Therefore, by using the same reduction factor the parameter R' is calculated though the following expression:

$$R' = (1 - D_R)R \text{, where } D_R = D_s \tag{13}$$

In this case, the material deterioration is applied when the criterion $\sigma_s \cdot \varepsilon_s < 0$ is satisfied during the nonlinear analysis. This criterion describes the situations when crack closures and re-openings occur, where the pinching phenomena are present. The modified material model is shown in Fig. 1 for different damage levels.

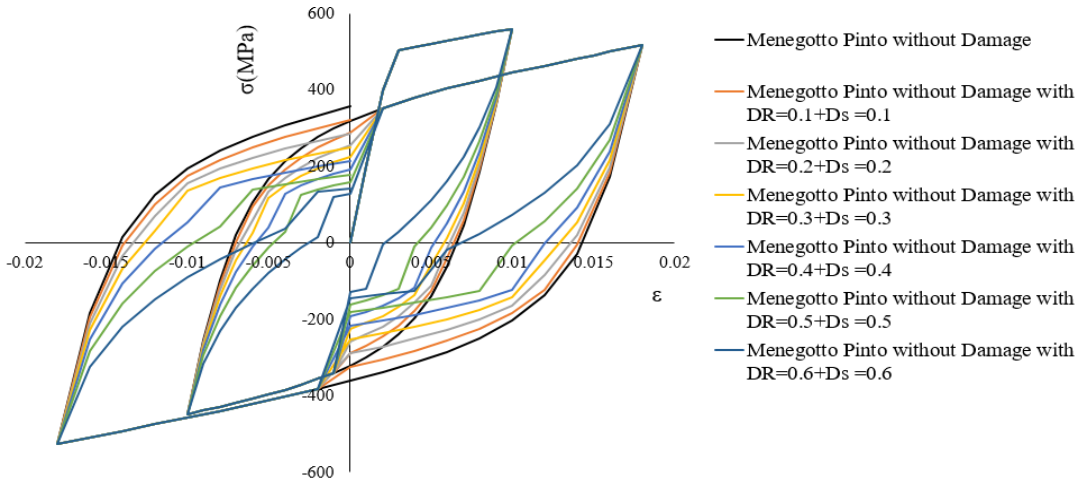

Figure 1: Menegotto-Pinto steel model by taking into account the accumulated damage due to opening/closure of cracks. Different damage levels. [7]

3 NUMERICAL IMPLEMENTATION

3.1 Beam-Column frame joints

Two beam-column joints shown in Fig. 2, were tested by Shiohara and Kusuhara [8] under static cyclic loading. The uniaxial compressive concrete strength was reported to be equal to f_c = 28.3 MPa and the yielding stress of the steel reinforcement was 456 MPa for the 13 mm in diameter rebars found in the beam section. The rebars placed within the column section, were reported to have a 357 MPa yielding stress [8]. The Young modulus of elasticity for the longitudinal reinforcement was reported to be equal to E_S = 176 GPa, where 6 mm stirrup reinforcement had a yielding stress of 326 MPa and a Young modulus of elasticity equal to 151 GPa.

The frame joint was subjected to different cyclic loading sets according to the experiment [8]. The loading history that was numerically applied in this work, is presented in the form of 15 cycles of imposed displacements as shown in Fig. 3 and as it was reported in [8].

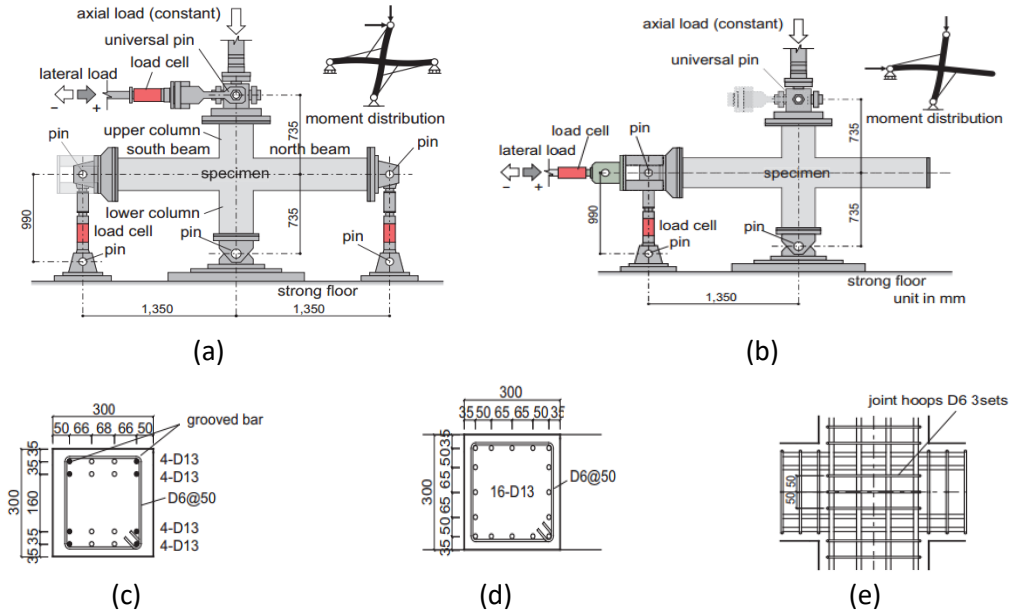

Figure 2: Beam-Column joints. Geometry of (a) A1 and (b) A3 specimens, and reinforcement details of the (c) beam, (d) column and (e) joint section. [8]

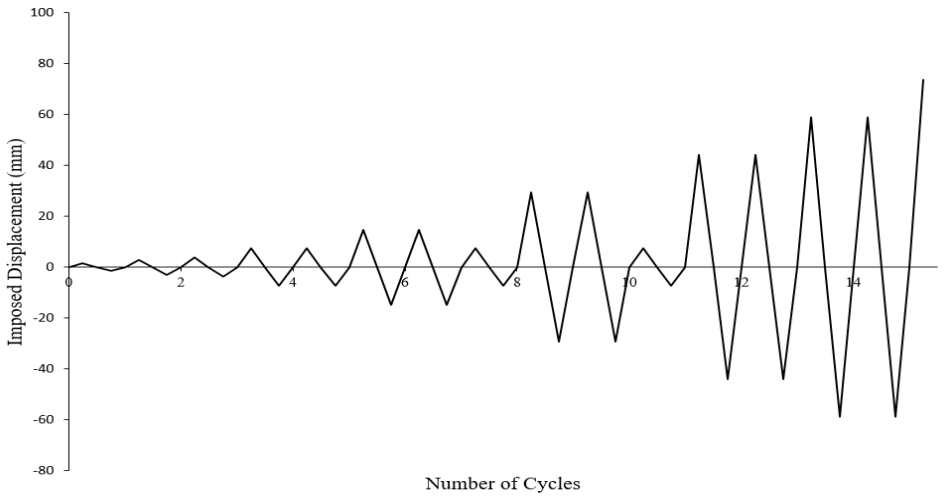

Figure 2: Beam-Column joints. Imposed displacement history.

For the modeling requirements, the concrete domain was discretized with 8-noded hexahedral finite elements and the steel reinforcement was discretized with beam-column finite elements. A total number of 128 concrete (23cm x 15cm x 15cm) and 888 steel Natural Beam-Column Flexibility-Based (NBCFB) finite elements were used to discretize the entire frame joint. Specimen A1 was simulated as an interior beam-column joint, while specimen A3 was developed to simulate the conditions of an exterior corner joint. The boundary conditions of the numerical model can be seen in Fig. 4, where the displacements were imposed at the top section of the column for specimen A1 and at the left edge of the beam for specimen A3 (according to the experimental setup described in [8]). A 216 kN compressive force was applied at the top section of the column for both specimens. Additionally, 8-noded hexahedral finite

elements were used at the support and at the sections where displacements are imposed to simulate the metallic plates, which were placed in order to avoid local failure.

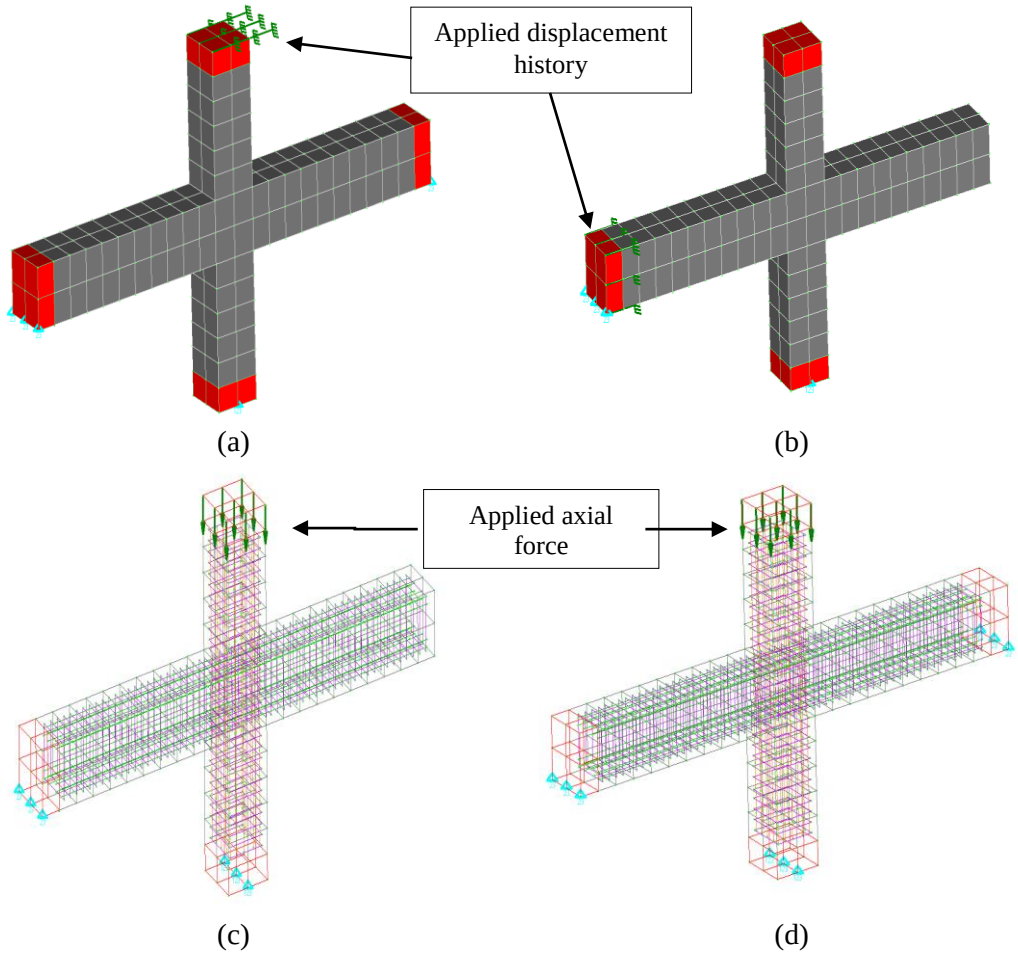

Figure 4: RC beam-column frame joint. Finite element concrete mesh with imposed displacements for specimens a) A1 and (b) A2. Steel reinforcement mesh and applied axial loads for specimens c) A1 and (d) A2.

The numerically computed force-displacement curves are compared with the corresponding experimental data in Fig. 5. As can be seen, the numerical results match very well with the experimental data, where the stiffness and the resulted load-carrying capacity of the specimen were predicted in an accurate manner. Furthermore, the numerical energy dissipation values were found to be close to the experimental ones. Fig. 6 also shows the force-displacement curves and the corresponding hysteretic behavior when the proposed damage factors for concrete and steel reinforcement are being activated and deactivated for the modeling of specimen A1. The numerical results show that the concrete damage factors manage to capture the stiffness and load-capacity degradation, whereas the pinching characteristics are captured through the use of the steel material damage factor (see Fig. 6b).

When modeling the A3 specimen, the pinching effect is observed to be smaller than the experimental one. This is probably attributed to the loss of bond, which resulted during the experimental test (Fig. 5) due to the slippage of the steel reinforcement. Nonetheless, the numerical model manages to capture the hysteretic behavior with an acceptable accuracy.

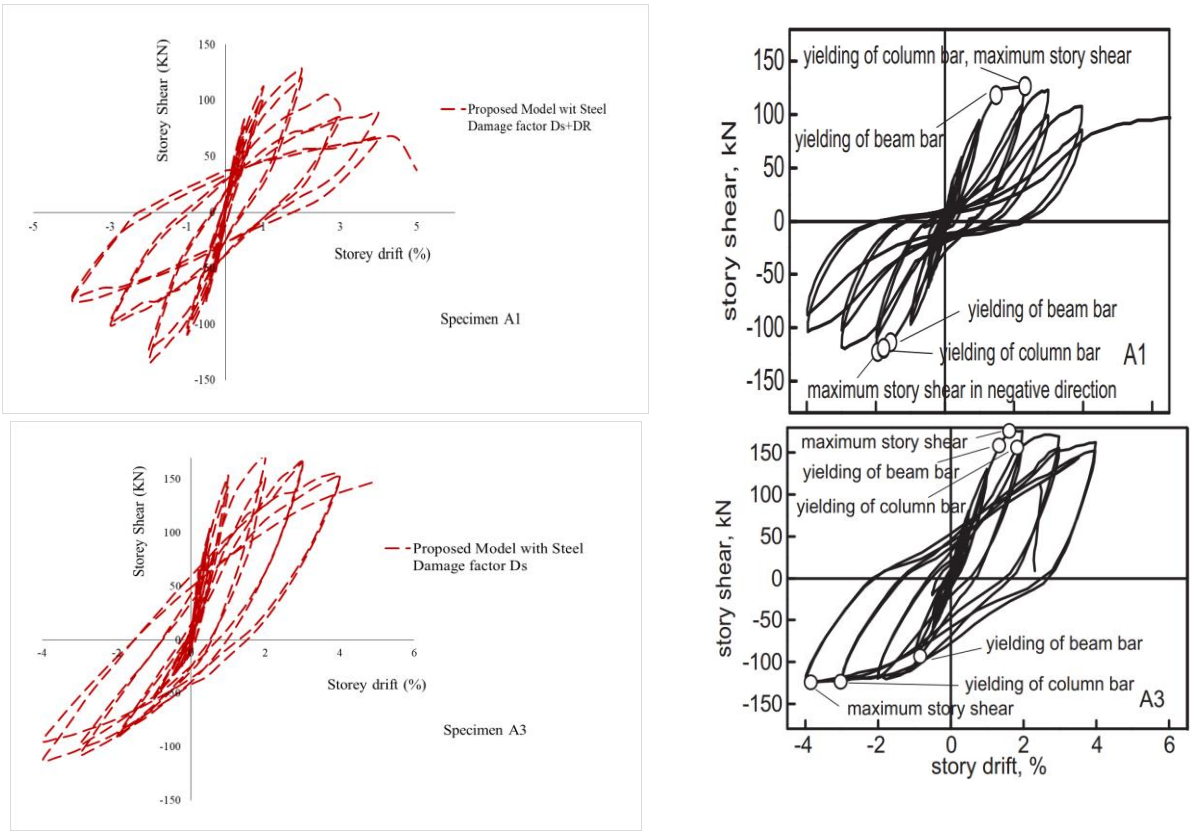

Figure 5: Beam-Column frame joint. Comparison between numerical (Left) and experimental results [8] (Right). Complete force-displacement history for specimens A1 (up) and A3 (down).

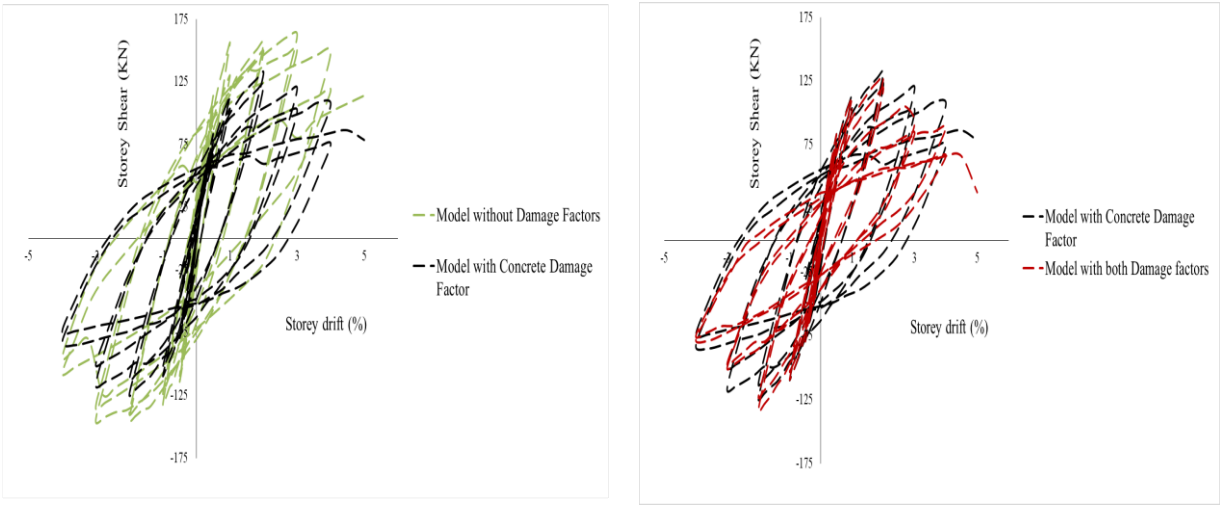

(a) (b)

Figure 6: Beam-Column frame joint. Comparison between numerical results that were obtained by activating and deactivate the two damage factors for specimen A1. Comparison between numerical results when a) Model assumes no damage factors and compared to the model that assumes only for the concrete damage factor. b) Model with concrete damage factor only and compared to the case with both damage factors activated.

Furthermore, as it resulted from the numerical investigation, the hysteretic loops of specimen A3 produce larger hysteretic loops when compared with that of specimen A1, a mechanical behavior that can be easily observed through Figs. 5 and 6. Based on the numerical findings obtained through the analysis of the two specimens, it can be concluded that the use

of both damage factor (D_C, D_S) play an important role in capturing the strength and stiffness deterioration of the RC specimens.

According to the numerically obtained results, Table 1 was developed to compare the numerically predicted maximum (negative and positive) storey shear forces with the corresponding experimental data. The comparison shows that the discrepancy between the numerical and the experimental data is lower than 10%.

Specimen		Maximum Storey Shear		Divergence from Experiment (%)
		Experimental (kN)	Numerical (kN)	
A1	(+)	126.6	127.84	0.98
	(-)	-122.8	-134.12	-9.21
A3	(+)	176.4	171.16	-2.97
	(-)	-124.5	-112.98	9.25

Table 1: Beam-Column frame joint. Comparison of the maximum storey shear between experimental and numerical results.

3.2 RC Shear wall SW4

The RC shear wall investigated by Pilakoutas and Elnashai [9], was also analyzed by using the proposed model. The shear wall was denoted as SW4 and it has a rectangular geometry with a 1.2 m height and a 0.6 m length, where its thickness was reported to be equal to 0.06 m, as showed in Fig. 7. The material properties and reinforcement details are given in Table 2, as they were reported in [9].

Region	Concrete		Horizontal Reinforcement		Vertical Reinforcement		Confining Reinforcement	
	f_c (MPa)	E_c (MPa)	ρ (%)	f_y (MPa)	ρ (%)	f_y (MPa)	ρ (%)	f_y (MPa)
Web	36.9	35240	0.39	545	0.5	545	-	-
Boundary	36.9	35240	0.79	545	6.86	470	0.43	545

Table 2: Material properties and reinforcement ratios of Shear wall SW4

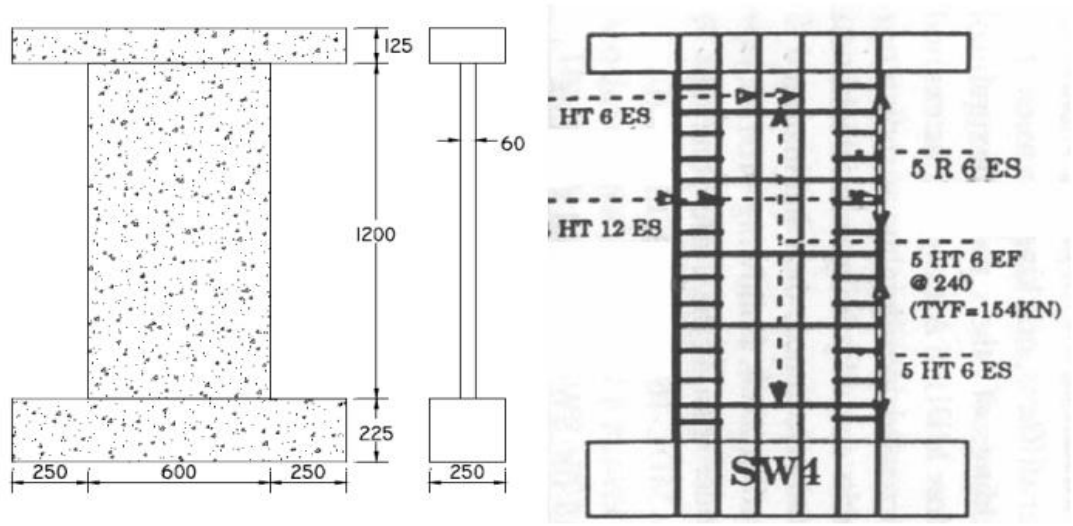

Figure 7: Geometric and reinforcement details of Shear wall SW4 [9].

The shear wall was subjected to different cyclic loading sets according to the experimental setup [9]. The loading history represents extreme conditions experienced during a severe earthquake and it was modeled as shown in Fig. 8. The concrete domain was discretized with 8-noded hexahedral finite elements and the steel reinforcement was discretized with NBCFB elements. A total number of 50 concrete (23cm x 15cm x 15cm) and 250 steel embedded rebar elements were used to discretize the entire shear wall as shown in Fig. 9. Additionally, rigid hexahedral elements were used to simulate the metallic plates near the boundaries in order to avoid local failure (red elements in Fig. 9).

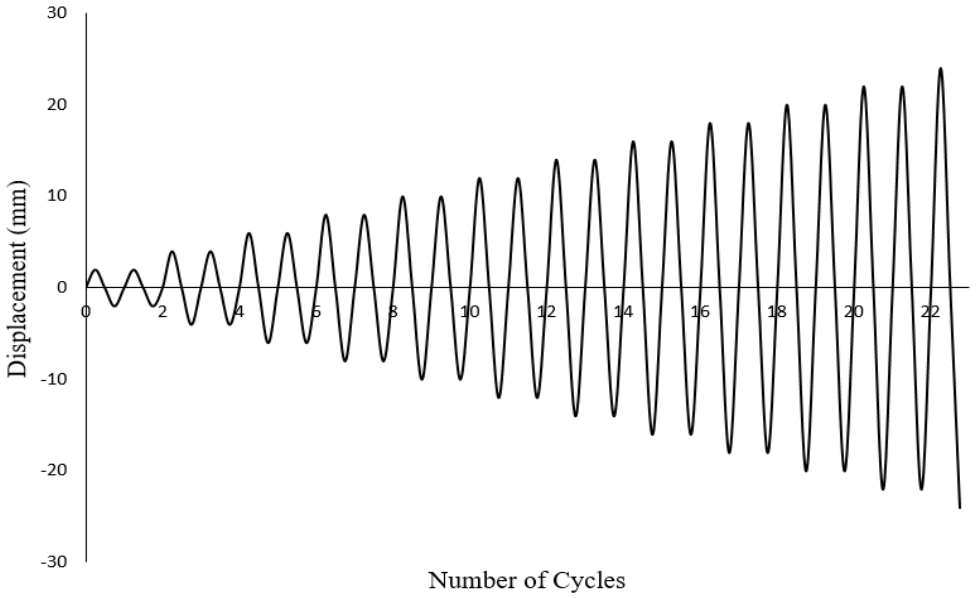

Figure 8: Loading history imposed at the top beam of specimen SW4.

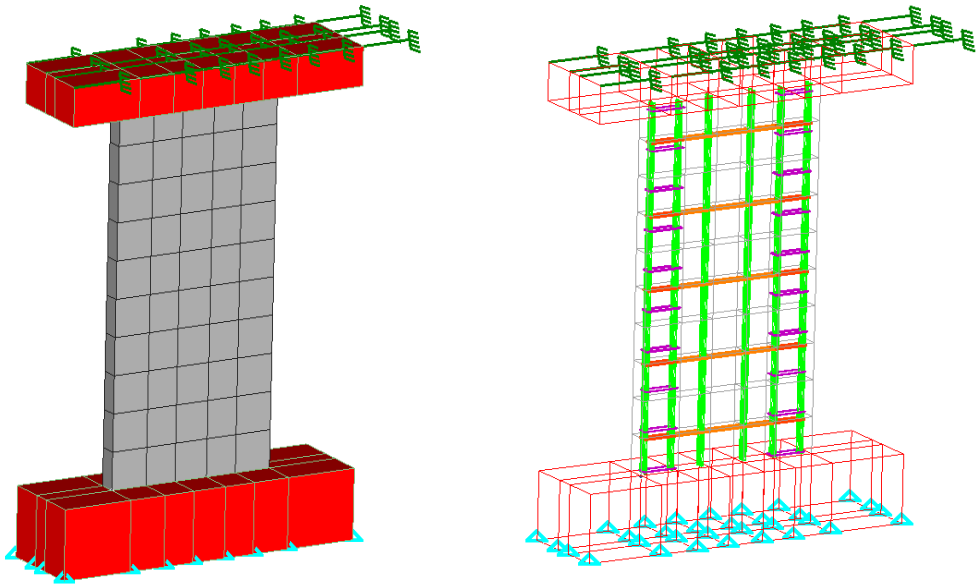

Figure 9: Shear wall SW4. 3D views of the finite element meshes of concrete and embedded rebar elements.

The numerically obtained curves are compared with the corresponding experimental data in Fig. 10. As can be seen, the numerical results match very well with the experimental data,

where the stiffness and the load-carrying capacity of the specimen were predicted in an accurate manner (less than 10% deviation from the experimental data). Furthermore, the numerical energy dissipation of the structure was found to be very close to the experimental one. In addition, the experimental results show a more flexible behavior in terms of structural response without significant pinching effect characteristics. The same mechanical behavior was captured from the numerical results that also did not indicate for any significant pinching behavior.

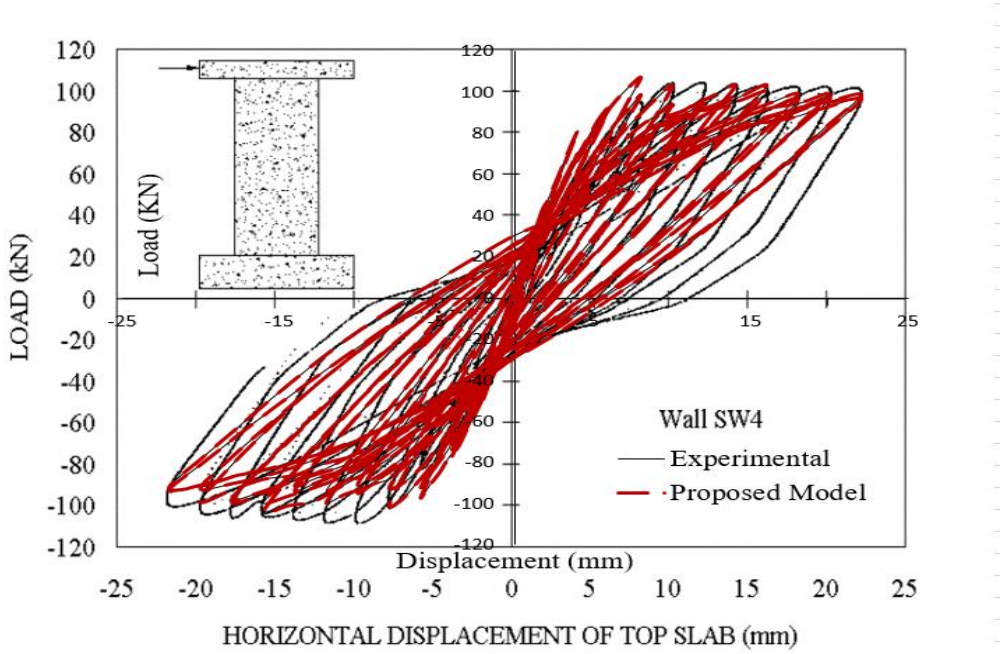

Figure 10: Shear Wall SW4. Comparison between numerical and experimental results in terms of the force-deflection curves.

3.3 Three-storey, Three-bay RC Frame Subjected to High Intensity Ground Motions

A three-storey, three-bay frame was designed, built and tested at the University of California, Berkeley [10] in order to study the collapse behavior of RC frames with light transverse reinforcement. The geometrical and reinforcement details of the specimen can be depicted in Fig. 11. The RC frame was subjected to a dynamic loading test. The cylindrical compressive strength of concrete that was used to construct the RC frame, was equal to f_c = 24.6 MPa, where the yielding stress of the longitudinal steel reinforcement was reported to be equal to f_y = 445 MPa. Additionally, the beam and column ties were 4.8 and 3.2 mm in diameter with a yielding strength of 558 and 655 MPa, respectively.

Two of the columns, as shown in Fig. 11, have been designed according to ACI 318-08 [11] and they were referred to as "ductile" columns with a longitudinal reinforcement ratio of ρ_l = 1.09% and a transverse reinforcement ratio of ρ_t = 1.1% at the end of the column members. The other two columns were referred to as "older type" columns, with longitudinal reinforcement ratio equal to ρ_l = 2.45% and a transverse reinforcement ratio of ρ_t = 0.15%. Furthermore, the beam's transverse reinforcement was also designed according to ACI 318-08 [11], while beam-column joint failure was not expected based on the design provisions of the frame.

Each beam span has been loaded with four packets of lead weights (6.67 kN per packet). The total load (load packets and weight of concrete frame) of the structure produced the equivalent amount of load in a typical office building. Additionally, the resulting gravity axial load on the first-storey interior columns was approximately $0.16A_g f_c$, while the axial load of the exterior loads was approximately of $0.08A_g f_c$ (where A_g is the column gross section area). Therefore, every beam span was considered that it had a uniformly distributed load of 16.67 kN/m, which was the load used to account for the mass contribution within the numerical model developed for the needs of this numerical investigation. The ground motion record from the 1985 Chilean earthquake at Valparaiso (Llolleo Station, Component 100) was chosen for this dynamic test. The motion was scaled up 4.06 times from its original acceleration amplitudes for the dynamic test and it is given in Fig. 12. In addition to that, the ground motion time scale was divided by a factor of $3^{0.5}$ to satisfy the amplitude requirements [10].

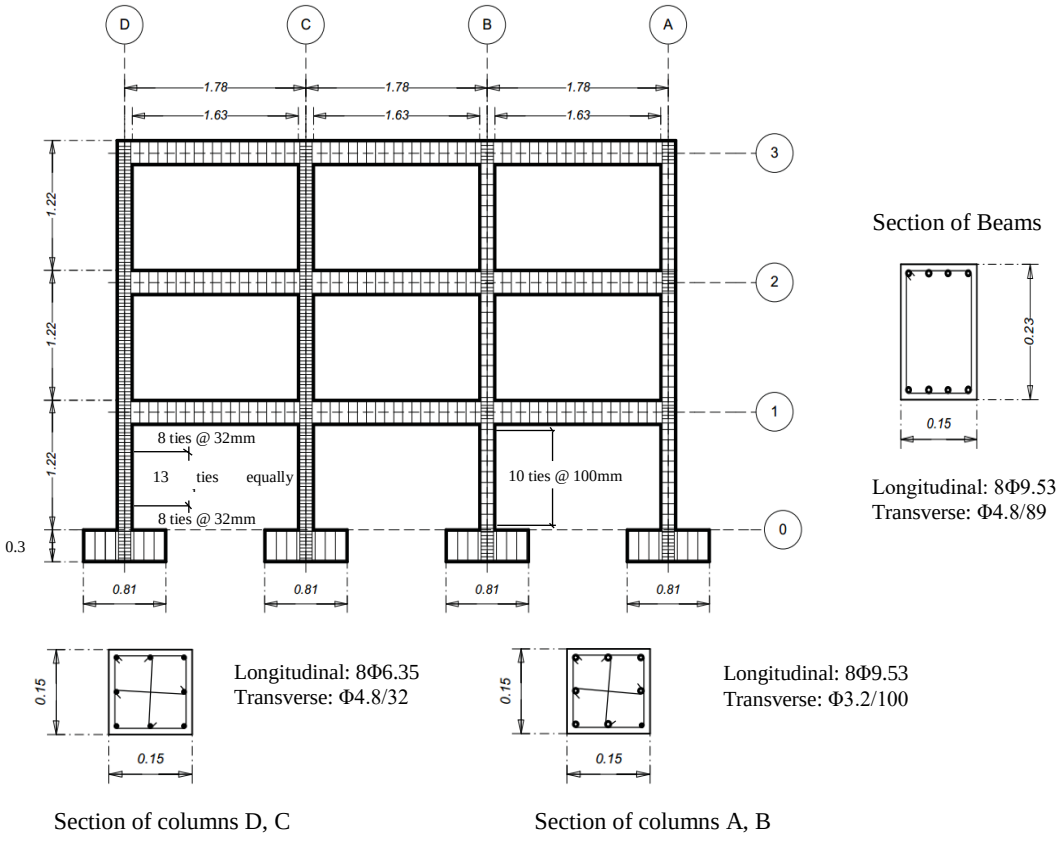

Figure 11: Three-storey, three-bay RC frame. Geometrical and reinforcement details. [10]

For the modeling requirements, the concrete mesh foresaw the use of 336 hexahedral elements and 4,554 steel embedded rebar NBCFB elements were used to model the reinforcement of the specimen, as shown in Fig. 13. Furthermore, 108 hexahedral elements are used (red elements, see Fig. 13) in order to account for the additional mass placed on the structure. In order to account for the exact applied load through the packets, the red hexahedral elements where assigned a mass density that would derive the corresponding load after it was multiplied by its volume. Finally, 60 hexahedral elements (blue elements, see Fig. 13) were used

for the support of the columns so as to simulate the boundary conditions of the specimen and to avoid any local failure at the area where the accelerogram was applied.

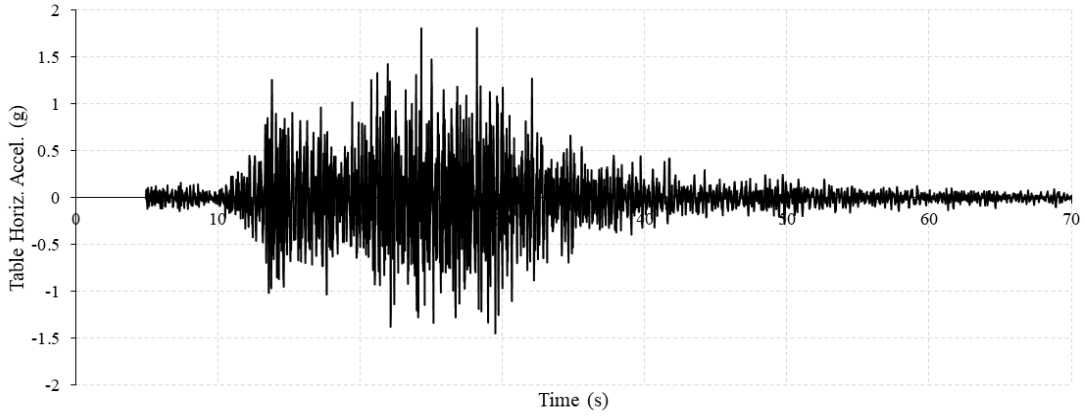

Figure 12: Three-storey, three-bay RC frame. Acceleration history used during the experiment [10].

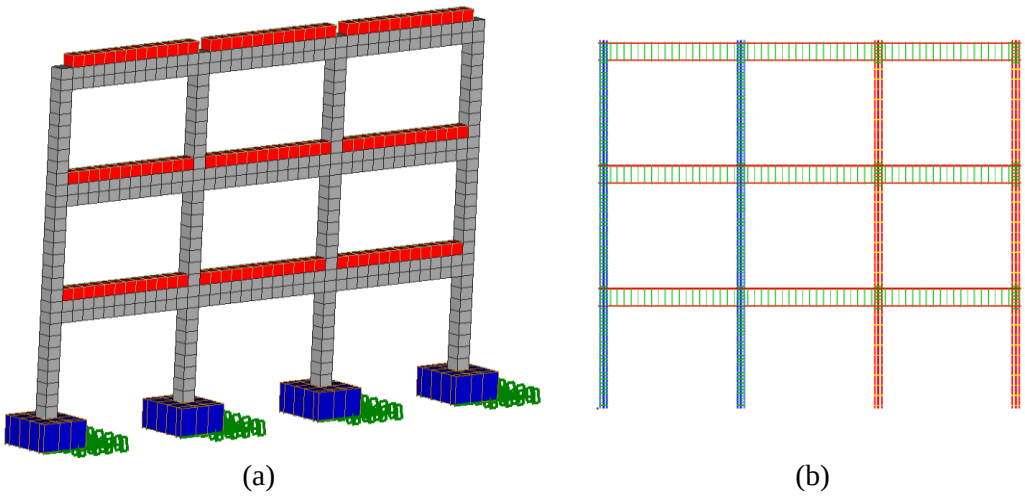

Figure 13: Three-storey, three-bay RC frame. 3D view of the finite element mesh of the (a) 8-noded hexahedral and (b) embedded rebar elements.

The natural periods for the first three modes were compared with the corresponding experimental ones and given herein in Table 3. The comparison shows that the natural periods that derived from the numerical model, were very close to the experimental ones, where the average computed error was equal to 8.7%.

Mode	Experimental period T (s)	Numerical period T (s)	Divergence from experimental (%)
First	0.30	0.30	0
Second	0.10	0.09	10
Third	0.069	0.08	15.94
		Average	8.65

Table 3: Three-storey, three-bay RC frame. Comparison between the numerically and the experimentally derived natural periods.

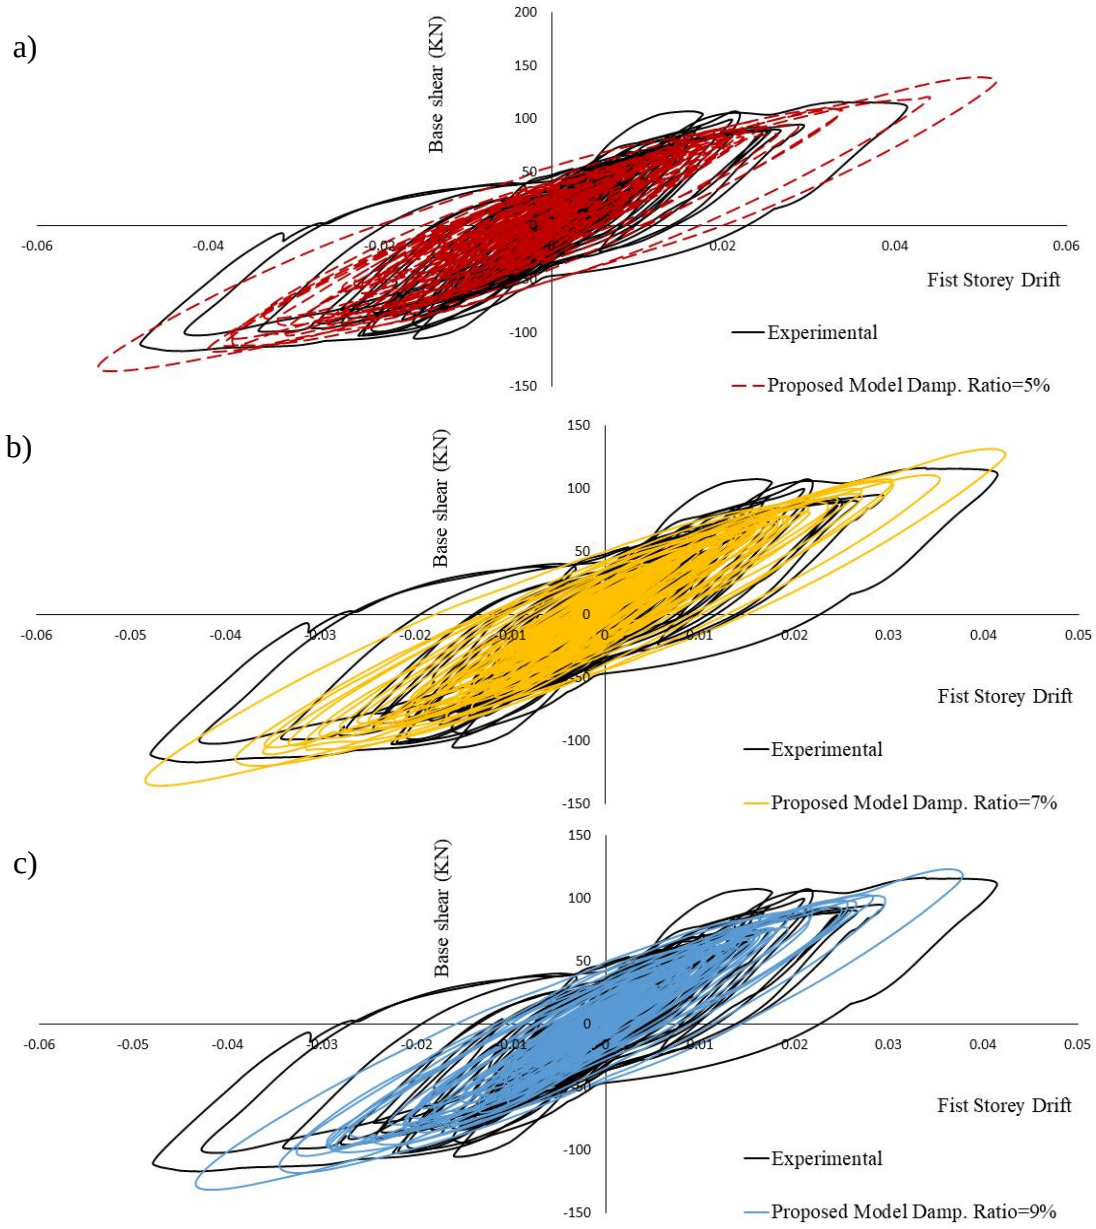

Figure 14: Three-storey, three-bay RC frame. Comparison between the numerical and experimental results of base shear-fist storey drift curves when using damping ratio equal to (a) 5%, (b) 7% and (c) 9%.

Fig. 14 shows the force-displacement curves comparison between the numerical and experimental data. For the needs of this numerical investigation, three different damping ratios were examined (9%, 7% and 5% damping). Based on the analysis of the computed curves, it was found that the two numerical models that adopt damping ratios equal to 7% and 9% produce more accurate results in comparison to the model with a 5% damping ratio. It is also easy to observe that the proposed modeling method manages to capture the overall dynamic response of the specimen, maintaining a good accuracy when compared with the experimental curves. It important to note at this point that, during the experiment, there was a steel frame that was post-tensioned to the shake table on each side of the concrete frame to restrain the out-of-plain movements. This frame could have had an impact on the stiffness of the specimen and on the damping mechanisms that were developed. This effect was not accounted for

during the numerical results and can explain the differences between the curves given in Fig. 14.

The required Newton-Raphson internal iterations per displacement increment are shown in Fig. 15 for the case where the damping ratio was set to 9% (similar results derived when the use of 5% and 7% damping ratios is adopted). It can be easily seen that all the displacement increments require a minimal number of iterations to achieve convergence, regardless the degree of nonlinear behavior of the model. As it can be seen, the required internal iterations per dynamic step during the solution procedure were limited to 1 to 2, underlining the numerical stability of the proposed modeling method [2]. The computational time for the nonlinear solution procedure is given in Table 4, which refers to the solution of 12,125 dynamic time increments. The total required time for solving the nonlinear dynamic problem was 658.5s with an average error of 1.1×10^{-5}. It is important to note herein that, the CPU used to perform all the analyses in this study had a 3.7 GHz computing power.

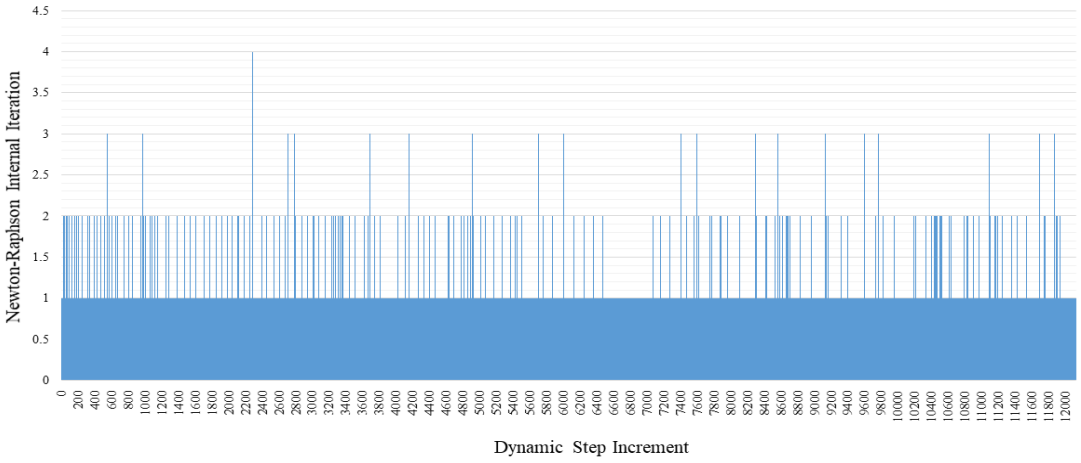

Figure 15: Three-storey, three-bay RC frame. Number of internal iterations per dynamic step increment.

Task	CPU Time (s)
Embedded rebar element mesh generation	0.24
Nonlinear incremental-iterative solution	658.22
Total Time	658.46

Table 4: Three-storey, three-bay RC frame. CPU time for different tasks of the nonlinear analysis.

4 CONCLUSIONS

In this research paper, a proposed 3D constitutive modeling approach is used for the analysis of RC structures that are subjected to limit states static cyclic and dynamic loading conditions. The concrete material constitutive model was found to describe a realistic behavior of concrete under generalized 3D states of stress. Based on the adopted modeling method of concrete, the cracking phenomenon was modeled through the smeared crack approach. The introduction of two damage parameters for concrete and steel reinforcement materials in order to take into account the accumulated damage during the nonlinear analysis was found to pro-

vide the analysis with objectivity and numerical accuracy when dealing with extreme nonlinearities.

Furthermore, the proposed numerical model managed to capture the mechanical behavior of two RC beam-column frame joints, a shear wall and a three-storey three-bay RC frame that was tested under extreme dynamic loading conditions. This validation study is an extension on the research work presented in [2] that reported similar findings.

Based on the numerical findings of the research work presented herein, for the case of the RC beam-column joints, the damage parameter for steel reinforcement was found to be able to take into account for the loss of bonding within the damaged concrete areas, where it manages to partially capture the pinching characteristics observed within the experimental hysteretic curves. For extreme pinching modeling through the use of the proposed modeling approach, one may refer to [7].

Finally, the thee-storey RC frame specimen was modeled for both modal and nonlinear dynamic analysis. According to the parametric investigation, the first three natural modes were captured with an overall deviation from the experimental data equal to 8.7%, a finding that highlights the ability of the developed algorithm in capturing the modes of a real structural system. Finally, the dynamic analysis of the RC frame that was designed to exhibit a brittle behavior was performed successfully through the use of different damping rations. The ability of the proposed modeling method in capturing the nonlinear dynamic response of the RC frame through the use of the exact material properties (as they were reported within the report [10]) demonstrates its computational superiority, indicating that it is a powerful tool when it comes to the modeling of RC structures.

Abstract

The development of sustainable concretes is becoming an emerging issue in civil construction sector. The use of recycled aggregates is one way to fulfill sustainability goals in concrete industry, and among others, Electric Arc Furnace (EAF) slag aggregates has been proven to be promising. Past research demonstrated a significant increase of mechanical properties of EAF concretes when compared with ones made with natural aggregates (NA); however, at the same time, their use implies also an increase of self-weight loads. The present study aims therefore to investigate the seismic reliability of reinforced concrete frame buildings made with EAF, and compare it with the same structural configurations built with NA mixes, in order to show how the change in mechanical properties and self-weight can impact the seismic response of the analyzed case-studies.

Keywords: EAF slag, reinforced concrete moment frames, seismic fragility, seismic reliability.

1 INTRODUCTION

Construction waste reduction is one of the main goals construction industry has to face in the upcoming years [1]. Recycling and reuse are seen as the main policies for waste reduction disposal and a lot of studies and research has been done on achieving this objective. Recycled Aggregates (RAs) production is one of the main uses of Construction and Demolition Waste (C&DW) and their use is allowed in most countries around the world [3-5]. Among RAs from C&DW, recently, other kind of waste, mostly originating from industrial processes, have been object of research to evaluate their possible use to produce RAs or so-called industrial aggregates. Only in Europe, nearly 2.7 billion tonnes of natural aggregates are consumed each year [2]. Previous research has shown that among all industrial waste or by-products, those coming from steelmaking industry, particularly electric arc furnace (EAF) slag, offer the best performance when used in structural concrete. Particularly has been observed that EAF slag use enhances both mechanical strength [6-10] (i.e compressive strength, tensile strength and elastic properties) and durability [11-13] of concrete mixtures when compared to ordinary ones. Another difference worth highlighting is heavy-weight metals presence in the EAF slag composition which gives EAF concrete mixtures a higher specific weight with respect to NA mixtures. [14-15] have demonstrated that reinforced concrete (RC) elements with EAF slag aggregates manifest better flexural and shear capacity with respect to ordinary RC when tested to monotonic loading under four-point bending. Columns under uniaxial compression has shown a similar ductility to that of NA mixtures [17] while a higher shear strength of exterior beam-column joint is observed [18]. Experiments of EAF concrete joints under cyclic loading have shown a gain with respect to NA ones in terms of ductility, dissipated energy and reduced cracking patter. The same results were obtained even for a joint made with a minor cement amount [18]. Bond properties, between reinforcement and concrete, are also improved when using EAF slag aggregates [16]. Other beam-column joint conditions (i.e strong beam – weak column and strong column – weak beam situations) have been numerically investigated [19].

EAF concrete has found different applications, especially in gravity structures that require shielding from radiations where its high specific weight and high strength can be better exploited [20]. However, no studies have been made to investigate the efficacy of EAF slag concrete when applied in elevation RC structures, particularly, in seismic regions where an important change of the building mass can lead to a variation of the vibration modes and fundamental periods, impacting so the seismic loads acting in the structure elements.

Therefore, the present study aims to investigate this topic, analyzing the seismic response of code conforming RC frame buildings designed with ordinary NA concretes then replaced with three different EAF concrete classes characterized by different aggregates replacement ratios. For the mechanical properties' definition of EAF concrete mixtures a dataset of experimental tests based on two previous research works of some of the authors [21-22] is used. Mean mechanical properties, ratios of variation and self-weight were extracted via statistical processing for three EAF concrete classes (C1, C2, A) with respect to a benchmark mixture realized with NAs. For the purpose, three RC frame structures with three, six and nine stories were designed according to the current Italian Code for Constructions [5] for a medium-to-high seismic hazard site. From these an overall of 12 models resulting from the combinations of 3 structural configurations and 4 concrete mixes, were created. Fragility functions were then computed from the seismic responses of the analyzed configurations under a set of non-linear time history analysis (NLTHAs) and a seismic reliability assessment was carried out for all 12 combinations, investigating the variation of structural safety margins related to the use EAF concrete mixtures in replacement to a conventional NA concrete.

2 EAF SLAG AND ITS USE AS AGGREGATE IN STRUCTURAL CONCRETE

EAF slag properties depend on several factors, such as the type of steel to be produced, scrap composition, slag cooling method and speed, and further weathering process. Its composition includes mainly iron, calcium, silicon and aluminum oxides [23]. Usually, before the raw product is ready to be used as a recycled aggregate, it must pass through a weathering protocol [23] to reduce the volumetric instability of the matrix. The main properties of the slag for two size fractions compared, with a dolomitic aggregate, are reported in Table 1.

	Apparent density (kg/m3)	Water absorption (%)	Porosity (%)	shape
EAF slag 0-4 mm	3800	1.0 – 1.5	2.0	Crushed
EAF slag 4-16 mm	3950	<1.0	0.5 – 2-7	Crushed
NA 0-4 mm	2760	1.0 1.5	< 2.0	Roundish
NA 4-16 mm	2790	<0.5	0.9 – 1.8	Roundish

Table 1: Physical properties of EAF slag compared to dolomitic aggregate (NA).

The properties of the concrete matrix with EAF slag aggregates depends on type and amount of substitution. Generally coarse aggregates improve mechanical properties, while fine fraction affect is minor [12]. Workability of EAF concrete is highly reduced by high porosity and the crushed shape that characterizes the slag. Another important variation is observed on the specific weight of EAF concrete. Compared to a conventional NA concrete, the use of EAF slag can increase the specific weight of the matrix up to 15-20%. While gain in mechanical properties depends on slag type and fraction size, it seems that specific weight increase is almost constant and is not affected by these factors. Elastic modulus is also improved when using EAF slag. This is mainly because concrete elastic modulus depends mainly on the aggregates elastic modulus. The overall property improvements are also due to the interfacial transition zone between EAF aggregate and cementitious matrix. If a bad quality cementitious matrix or a high water/cement ratio is employed property enhancements are less important.

3 RC FRAME CODE-CONFORMING ANALYZED CASE STUDIES

To analyze the seismic response of different buildings built with EAF concrete three moment frame RC structures with 3-, 6-, and 9- stories were considered. The structures are characterized by a rectangular shape with five spans in the longitudinal direction and three in the transversal one. Span length is equal to 5 m in both directions.

The structures were designed in accordance with the Italian Building Code [5] considering a moderate-to-high seismic hazard site (Municipality of Pordenone, Northeast Italy) and a low ductility class (Class B). Seismic actions were computed from a dynamic linear analysis while beams and columns were designed accordingly using a C25/30 conventional concrete class.

4 THEORETICAL BACKGROUND ON SEISMIC RELIABILITY ANALYSIS

The occurrence of main shock events at a given site is assumed to be a Homogenous Poisson Process for the Performance-Based Earthquake Engineering (PBEE) framework [24]. So, the process of events causing structural failure is also a HPP and its unique parameter, failure rate λ_f, can be used for computing the failure probability at any time. The failure rate depends on the seismicity of the site (hazard curve λ_{im}) and on the structural behavior (fragility curve $P[f|im]$) [25-29]. λ_f is computed by applying the Total Probability Theorem as:

$$\lambda_f = \int_{im} P[f|im] \cdot |d\lambda_{im}| \tag{1}$$

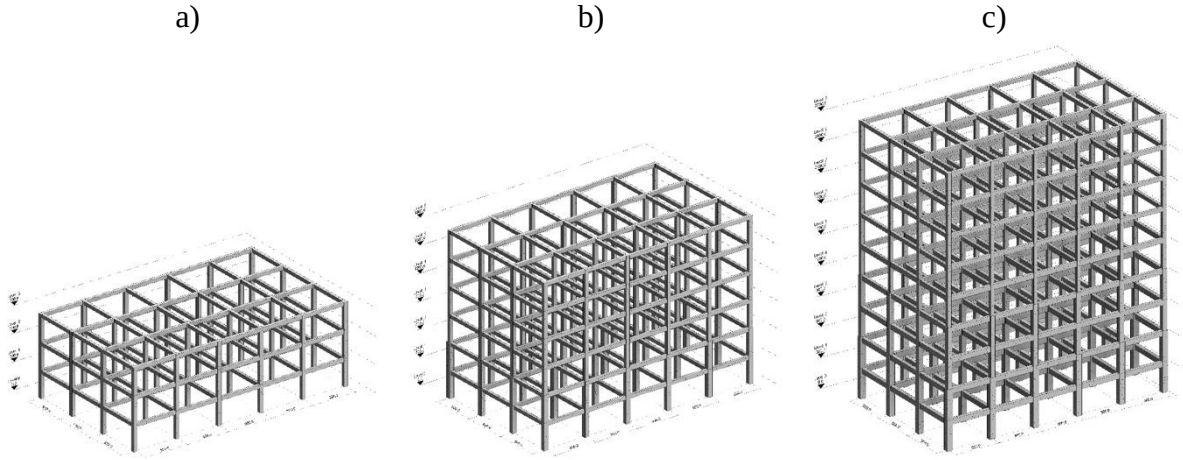

Figure 2: RC frame layouts analyzed: 3- (a), 6- (b) and 9-story (c) building archetypes.

4.1 Seismic hazard estimation

The so-called Probabilistic Seismic Hazard Analysis [30-31], for the computation of λ_{im} associates to each im value, the annual rate of events that exceed it at a given site. The seismicity of a given area di defined by three main components: the earthquake occurrence model, the spatial seismogenic model and the attenuation model. $|d\lambda_{\mathrm{im}}|$ represents the mean number of events per year with an intesity of exactly im and is obtained as:

$$|d\lambda_{\mathrm{im}}| = -\frac{d\lambda_{\mathrm{im}}}{d(im)} d(im) \tag{2}$$

On the other hand, $\lambda_{im}$is obtained via the following PSHA integral:

$$\lambda_{im} = \sum_{i=1}^{n_{SZ}} \nu_{m_{min,i}} \int_{m_{min,i}}^{m_{max,i}} \int_{r_{min,i}}^{r_{max,i}} P[IM > im|m,r] f_{M_i}(m) f_{R_i}(r)\, dm\, dr \tag{3}$$

where $\nu_{m_{min,i}}$ is the rate of occurrence of earthquakes greater than a suitable minimum magnitude $m_{min,i}$ of the i^{th} seismogenic zone *(SZ)*, $f_{M_i}(m)$ is the magnitude distribution for the i^{th} *SZ* and $f_{R_i}(r)$ is the distribution of the source i^{th}-to-site distance. Given a combination of magnitude m and distance r, $P[IM > im|m,r]$ is the probability to exceed im. The seismic hazard map for Italy is provided by the National Institute of Geology and Volcanology (INGV) [32]. To compute the failure rate a continuous hazard function is needed. Since INGV provides hazard data (values of the 16th, 50th and 84th percentile) only for nine return times, it is possible to fit the median values (i.e., the 50th percentile) with a quadratic function in the logarithmic space as:

$$\lambda(s) = k_0\, e^{(-k_1 \ln(s) - k_2 ln^2(s))} \tag{4}$$

In assessing seismic reliability, instead of the median hazard curve, it is more suitable to refer to the mean one which is possible to derive with the following equation:

$$\bar{\lambda}(s) = \lambda(s)\, e^{(\frac{1}{2}\beta_H^2)} \tag{5}$$

where β_H can be estimated as:

$$\beta_H = \frac{\ln(S_{84\%}) - \ln(S_{16\%})}{2} \quad (6)$$

4.2 Seismic fragility analysis

The fragility function ($P[f|im]$) represents the probability to reach and exceed a certain damage state given a specific intensity im. Several frameworks for fragility function estimation exits in literature, the most popular ones are the Incremental Dynamic analysis [33], the Cloud Analysis [34] and the Multi-Stripes Analysis [35].

In this work the Cloud Analysis method is adopted. The fragility parameters are estimated starting from a set of n natural ground motion records. The fragility function is computed as follows:

$$[f|im] = P\left[EDP > \overline{edp}|im\right] = 1 - P\left[EDP \leq \overline{edp}|im\right] = 1 - \Phi\left[\frac{ln(\overline{edp}) - ln(edp)}{\beta}\right] \quad (7)$$

$\overline{edp}$ is the median threshold value of the assumed structural limit state, and edp represents the median estimate of the demand that can be computed with a ln-linear regression model, as:

$$ln(edp) = a + b \cdot ln(im) \quad (8)$$

β is the standard deviation of the demand conditioned on im and can be estimated from the regression of the seismic demands as:

$$\beta_H = \frac{\ln(S_{84\%}) - \ln(S_{16\%})}{2} \quad (9)$$

5 SEISMIC RELIABILITY ASSESSENT OF THE ANALYZED EAF RC FRAME ARCHETYPES

NLTHAs were carried out with SeismoStruct software [36]. A diffused plasticity model, using a fiber section discretization, was adopted to consider material non-linearities. Unconfined and confined concrete was modeled via the Mander et al. [37] model whereas the Menegotto-Pinto [38] steel model was used for the non-linear behavior of rebars. EAF concrete characteristics are computed using the ratio coefficients in Table 2 and the reference concrete material (C25/30) characteristics.

	Class EAF-C1	Class EAF-C2	Class EAF-A
$\rho_{c,EAF} / \rho_{c,Ref}$	1.166	1.166	1.154
$f_{c,EAF} / f_{c,Ref}$	1.395	1.404	0.915
$f_{ct,EAF} / f_{ct,Ref}$	1.280	1.100	1.080
$E_{c,EAF} / E_{c,Ref}$	1.330	1.100	1.040

Table 2: Ratios between EAF and Reference concrete properties.

Fragility analysis is computed from a set of point data representing the Intensity Measure (IM) of a given seismic event and the corresponding non-linear response parameter (i.e Engineering Demand Parameter (EDP)). Since the Performance Based Earthquake Engineering was introduced, many researchers have tried to study IM and EDP parameters that best describe structure response under seismic excitation [39-41]. In the present paper, the chosen EDP parameter is the maximum interstory drift ratio (IDR) while the peak ground acceleration (PGA) is used as IM. In addition, four damage states: Slight, Moderate, Extensive and Complete, with corresponding EPD threshold of 0.4%, 0.8%, 1.5% and 3%, were defined.

Threshold values result similar to those proposed for ductile RC moment frame structures by [39] and were defined from non-linear static analysis. For the mid-rise and high-rise buildings, a reduction factor of respectively 2/3 and 1/2 as proposed by [42] was considered to account for higher mode effects and differences between average computed in a non-linear static analysis and maximum individual IDR from NLTHAs.

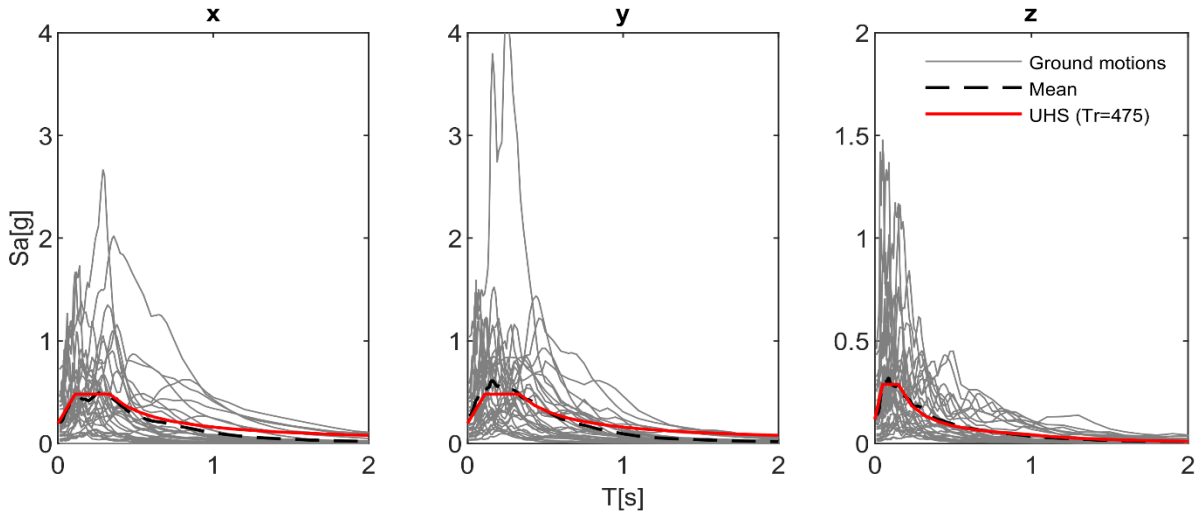

Figure 3: Selected seismic records: X- , Y- and Z- direction.

6 RESULTS AND DISCUSSION

For the NLTHAs a set of 30 natural unscaled ground motion records were adopted. In the seismic simulation all three components of the seismic wave, which spectral response is shown in figure 3, were considered. The structural response was then evaluated with respect to the four DSs previously defined, varying from Slight to Complete. Fragility functions were computed for each of the 12 cases, resulting from different geometrical and material combinations, using the Cloud Method described in Section 4.2.

Fragility curves for Slight, Moderate, Extensive and Complete damage are shown in Figure 4 in green, yellow, orange and red color respectively. Additionally, solid lines were used for frames realized with the reference concrete; instead, dotted, dashed and dash-dot lines were used for EAF-C1, EAF-C2 and EAF-A concretes, respectively.

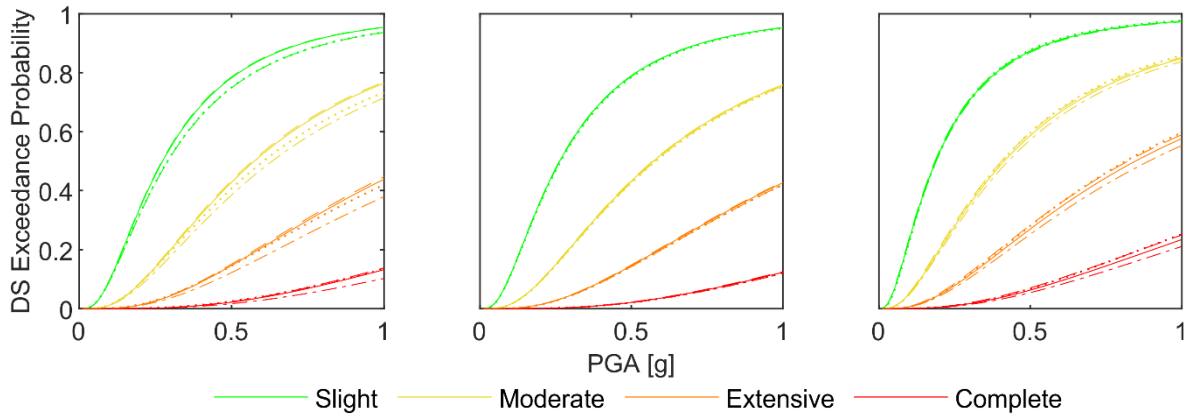

Figure 4: Slight, Moderate, Extensive and Complete DS fragility curves for 3- (a), 6- (b) and 9- (c) story RC frame archetypes (Solid - reference material (C25/30); Dotted - EAF-C1; Dashed - EAF-C2; Dash-dot – EAF-A).

A comparison of the seismic performance of structures built with the reference concrete and EAF concrete is given in Figure 4. It can be noted that the overall performance of EAF concrete structures is close to the performance of the reference material one. The 6- story model has shown almost the same response for all considered materials, proven by the overlapping fragility curves, while the 3- and 9- story curves tend to vary more when considering different materials. Comparing the fragility curves for the different geometrical configurations considered, is noted that 3- and 6- story buildings fragilities result similar for all DSs considered, while the 9 story building results more vulnerable under seismic solicitation with respect to the low- and mid-rise buildings.

Mean failure rates were also computed for all building frames (Table 3). When compared to the reference material the EAF concrete buildings report similar mean failure rate values. This confirms that in terms of safety margins with respect to seismic actions, buildings designed with ordinary concrete but built with EAF aggregates are exposed to almost the same risk as those realized with NAs ones. This highlights that NAs replacement with EAF aggregates, in the same structural system, has a small impact in terms of seismic reliability levels achieved. It is also observed that the mean failure rate for the 9-story building is almost twice the ones computed for the 3- and 6- story archetypes. This great difference may be affected by the reduced damage states EDP threshold adopted for the 9- story by considering it a high-rise building but it also points out that current code recommendations does not guarantee building design characterized by the same level of seismic reliability but often some differences can be observed, especially when comparing different rise buildings.

The construction of the three hypothesized models would require more than 2000 m^3 of concrete. In terms of environmental benefits, considering about 1700kg of NA/m^3 in a mix design for a reference concrete, nearly 3400 tons of NA could be saved if natural material would be fully replaced with EAF slag.

DS	Story	C25/30	C1-EAF	C2-EAF	A-EAF
Slight	3-	4.31E-03	4.28E-03	4.37E-03	4.22E-03

Table 3: Comparison between mean failure rates derived for 3-, 6- and 9-story RC frame archetypes.

7 CONCLUSIONS

The main goal of this paper was to investigate the seismic performance of different code conforming RC-frame archetypes (3-, 6- and 9- stories) built with different substitution rates of NAs with EAF slag. The impact of EAG slag in weight and stiffness variation can change the

eigen values of the structure, therefore, seismic loads and global response of the building. A seismic reliability assessment was carried out and mean failure rates were computed for each combination of geometrical configuration and concrete type considered starting from the fragility functions derived with the cloud analysis for four DSs. Based on the results of the present study the following conclusions can be highlighted:

- Using materials that were proved to have higher mechanical strength than the reference one, might not improve the global seismic behavior of the structure.
- The seismic reliability analysis demonstrates that when replacing NAs of ordinary concrete with EAF ones the seismic safety levels achieved are comparable ti those of the same structural configuration built with ordinary concrete.
- For the low- and mid- rise buildings considered (3- and 6- stories) results showed a similar mean failure rate, while a significant variation was observed for the high-rise case (9- story). This marks out how current building codes may non ensure the same seismic reliability level for higher structures as for low- and mid- rise ones.

Abstract

In consideration of the increased community expectations towards the reduction of post-earthquake damage to non-structural elements, even for strong seismic events, and in the context of performance-based design, this paper focuses on the experimental investigation of the seismic behavior of fasteners and practical implementation to improve their performance.
In the last decade several laboratory tests have been carried out to better understand the seismic behavior of anchors and a new concept of low-damage solution has been proposed. This earthquake-resistant fastener, referred to as EQ-Rod, relies upon the use of supplemental damping to reduce the acceleration demand and consequently the force applied to the non-structural component placed on the floors of multi-storey reinforced concrete buildings.
Building on this original research, the paper presents a second experimental campaign carried out at the Structural Laboratory of the University of Rome "La Sapienza" to extend the investigation and propose solutions to a larger variety of fastening systems (expansion and chemical anchors) and focusing on the behavior in both un-cracked and cracked concrete.
A comprehensive set of uniaxial shaking table tests have been performed using a specific apparatus and considering a test matrix with spectra compatible accelerograms.
The experimental tests provided satisfactory confirmation of the beneficial effects of the concept of dissipative anchor rod to seismically protect the non-structural components and suggestions are provided to further improve the system.

Keywords: Non-structural system, Post-installed fastener, Earthquake-Resistant Rod, Shake table tests, Seismic Performance.

1 INTRODUCTION

Non-structural components are typically connected to reinforced concrete buildings using post-installed fasteners, which are usually preferred by designers for their flexibility, easy handling and large field of possible applications compared to cast-in-place anchors.

In the research field, the study of the seismic behaviour of this type of anchors is spreading, with the aim of better understanding through experimental and numerical investigations both the seismic performance of anchors and the effect onto the attached non-structural system. Following the higher community expectations towards the reduction of post-earthquake damage, economic losses and downtime, mainly due to non-structural systems, the study and improvement of the seismic behavior of post-installed anchors/fasteners is becoming fundamental.

Over the past few decades, large amount of work has been carried out to study the behaviour of different types of individual or groups of post-installed anchors, subjected to quasi-static and dynamic forces or displacement-controlled loading protocols, either in uncracked or cracked concrete [1, 2, 3, 4, 5]. In recent years, the dynamic behaviour of post-installed fasteners has been also investigated through shake table tests, including tests performed using tri-axial shake table excitations [6], or uniaxial shaking table tests on anchors installed in regions where cracking of the structure is expected due to the seismically induced demands [7].

In the current context of performance-based seismic design and with the aim of improving fastening techniques, a comprehensive experimental and numerical campaign has been carried out at the University of Canterbury to develop a new generation of post-installed fasteners referred to as EQ-Rod, able to reduce the damage onto the non-structural component under severe seismic events [8]. This type of fastener relies upon the use of supplemental damping, either viscous and/or hysteretic, added in series or in parallel to a traditional fastener to reduce the acceleration demand and consequently the force applied to the non-structural component and represents a first generation of low-damage system for this type of component (Figure 1).

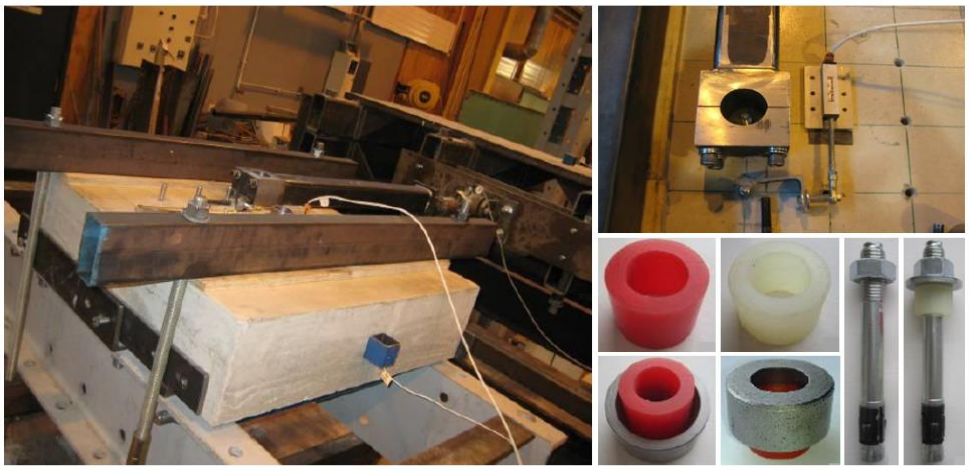

Figure 1: Shake-table test details on traditional and EQ-Rod fasteners (left and top-right) and configurations adopted for the supplemental damping devices (bottom-right) [8, 9].

Building on this original research, the paper presents the findings of a second experimental campaign carried out at the Structural Laboratory of the University of Rome “La Sapienza” with the aim of extending the previous investigation and propose solutions to a larger variety of fastening systems (traditional and low-damage expansion and chemical anchors), focusing on the behavior in both un-cracked and cracked concrete.

2 INNOVATIVE EARTHQUAKE-RESISTANT FASTENERS

Fasteners can be grouped in function of the way they transfer tension loads to the anchorage material [10]. Load-transfer mechanisms are typically identified as: 1) mechanical interlock, where the load is transferred by bearing the fastener onto the anchorage material; 2) friction, due to fasteners that have a geometry that generates an expansion force, which in turn produces a friction force between the anchor and the sides of the drilled hole; 3) bond, where the tension load is transferred to the anchorage material by a chemical interlock.

During an earthquake, a fastener may be subjected to tension, shear, combined tension-shear, and combined shear and bending cycling loading [10]. Referring to a non-structural component anchored to a reinforced concrete structure using a fastener, during the seismic motion the anchor loads develop due to the inertial response of the non-structural element to the acceleration of the building floor to which it is attached.

The seismic behaviour of the acceleration-sensitive non-structural component is typically described by floor acceleration response spectra, which provide the maximum associated acceleration as a function of the fundamental period of vibration of the element. The response spectra depend on the system viscous damping (non-structural component + connections), therefore by increasing the value of the damping the demands on the non-structural component can be reduced. Taking into account this concept and in order to achieve a significant reduction of the seismic demand and increase in performance, the idea of adding supplemental damping to the fasteners started to develop and a first innovative damage-resistant fastener was developed [8, 9], the so-called EQ-Rod fastener. An external supplemental damper is added to a traditional anchor, increasing the system damping, and this results in reducing the amplitude of the spectral response and the acceleration on the non-structural element under a given ground motion (Figure 2).

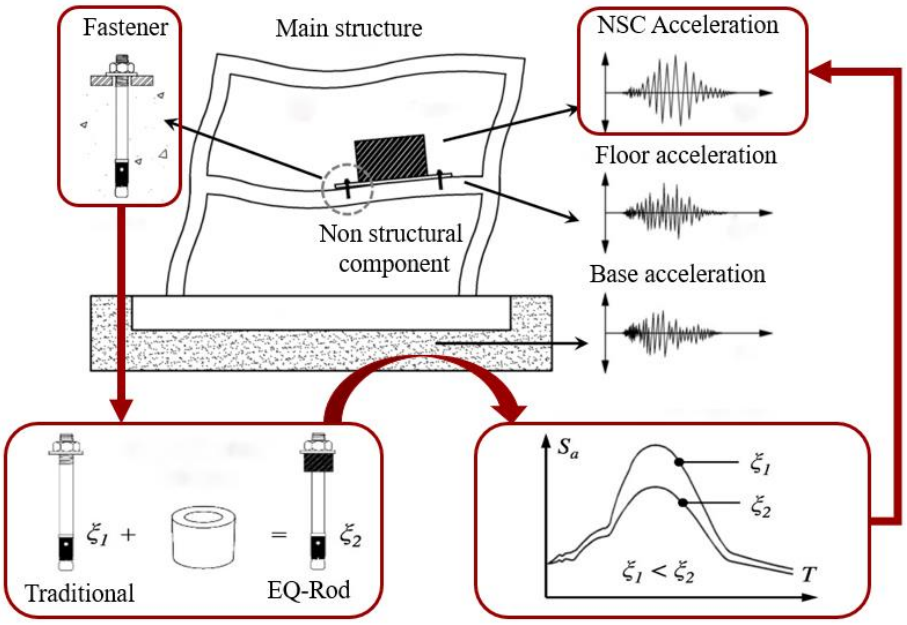

Figure 2: Effect of supplemental damping on fasteners in reducing the seismic demands of the attached non-structural component (modified after [8]).

3 RESEARCH MOTIVATION

Following on the first initial yet comprehensive experimental campaign on the EQ-Rod solution for post-installed fasteners, further investigations are needed to explore the beneficial

effects of the concept of dissipative anchor rod to seismically protect the non-structural components for a greater variety of fastening systems (expansion and chemical anchors) in both un-cracked and cracked concrete.

The shaking table tests carried in 2008 at the University of Canterbury focused on the response of expansion fasteners in uncracked concrete. As a follow-up it was considered important to extend the application of the low-damage solution to other types of anchors and system conditions. In fact, fasteners can be located in a crack that either forms during an earthquake or has formed at some prior time and the crack width can typically change over the duration of an earthquake, therefore investigations are also needed to apply the low-damage strategy in cracked concrete.

In such a context, a new low-damage prototype (EQ-Rod 2.0) has been proposed and a new Research and Development project has been carried out between the University of Rome "La Sapienza" (Research Leader), the University of Natural Resources and Life Sciences (Vienna, Austria), and Fischer (Fischerwerke Artur Fischer GmbH & Co. KG).

The paper describes the shaking table test setup, the testing protocol and the key results and findings of the experimental investigation carried out at Sapienza University

4 EXPERIMENTAL CAMPAIGN

Uniaxial shake table tests have been carried out at the Structural Engineering Laboratory of the University of Rome "La Sapienza" through a specific testing protocol capable of simulating the dynamic response of fasteners under seismic actions.

The experimental campaign involved different phases: 1) preparation of the ad-hoc test setup and monitoring system; 2) preliminary tests on different types of anchors to confirm the correct functioning of the whole testing apparatus, including fastener installation, loading protocol, control and acquisition system, post-processing of the results; 3) finally, further and comprehensive experimental tests have been performed according to a detailed test matrix on cracked and uncracked blocks.

Six different types of M12 anchors – i.e. two categories, expansion (FAZ II) and chemical (Superbond) anchors, in three configurations, traditional, EQ-Rod 2.0, traditional with mortar filling - have been tested under real recorded earthquake ground motions, through shear loads to the anchors, to investigate the anchor behaviour as well as the accelerations and displacements transferred to the attached non-structural component.

4.1 Test setup

The experimental Single-Degree of Freedom (SDOF) test setup comprises of three main parts: a concrete block representing the floor slab; a driving mass representing the attached non-structural element (NSE); the anchorage system. The shake table reproduces the selected input motion transmitted to the floor concrete block where the anchor rod is installed and connected through a lever arm to the driving mass, that is excited (Figure 3).

The 1.5m x 1.5m shake-table at the University of Rome "La Sapienza" is a uni-axial earthquake ground motion simulator (MOOG n. L081-324-011), consisting of guiding rails designed for a maximum stroke (travel) of ± 200 mm and a maximum payload capacity of 2 tons.

The concrete floor slab on which the anchor is installed is represented by a cracked or uncracked concrete block (80x80x30 cm, f_{ck}=20 MPa) rigidly attached to the shake table. Lateral sliding is prevented by steel angles fixed on the shake table in both directions.

A driving mass of 1046 kg, made by assembling steel plates, represents the non-structural mass attached to the anchor rod. The mass is located on low-friction linear rail guides (LLT of the SKF Group), fixed on an exterior steel frame, to allow the movement along the shaking

direction. These guides have precision-ground raceways and a carriage with four rows of balls in an X-arrangement, the dynamic coefficient of friction of the whole system is approximately μ_d=0.5% while the maximum acceleration guaranteed is 75 m/s^2.

A steel lever-arm connects the driving mass to the anchor and consists of L profiles of S355 steel seated to a steel plate where the load cell ends. The rigid lever arm spreads the inertia force from the driving mass to the fastener and the inertia force acts in the center of the attached element, therefore the vertical displacement of the anchor is not influenced by additional push and pull forces.

Finally, a steel plate with two different holes is located on the concrete block to install the fasteners. A larger hole, with a diameter of 24mm, is adopted for the EQ-Rod solutions, while the smaller one, with a diameter of 14mm, is adopted for the traditional anchors.

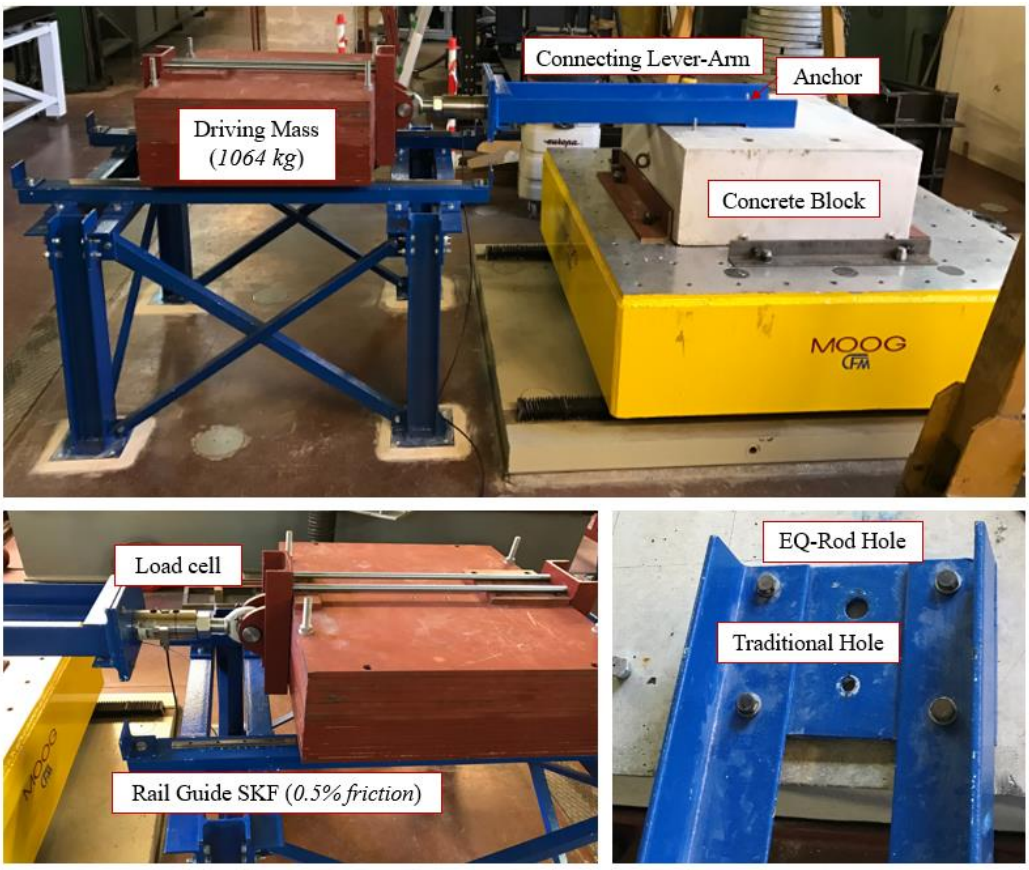

Figure 3: Details of shake-table test setup.

4.2 Test instrumentation

The load transferring to the anchor rod is measured by a load cell, with a maximum capacity of 200kN (tension and compression), installed between the driving mass and the steel lever-arm.

Three accelerometers attached to the driving mass, the concrete block and the shake table are used to monitor the system acceleration. The shake table acceleration is measured to compare the input record and the output signal of the table. The acceleration of the concrete block is needed to check that the connection between concrete block and shake table is effectively "rigid". The acceleration of the driving mass provides information on the effect of the fastener in the transfer of acceleration to the non-structural component.

Three LVDT transducers are used to measure the relative displacement between driving mass and concrete block. In particular, the vertical displacement of the anchor rod is monitored and the horizontal displacement of both the fastener and the steel plate is measured; the difference between these horizontal displacements provides information on the gap between steel plate and fastener.

4.3 Input motions

Different types of input signals have been considered for the experimental test campaign. Initially, sinusoidal inputs, either acceleration history with constant frequency and varying the amplitude (from 0.05 g to 0.5 g) or sweep signals with amplitude of 0.15g and 0.3g, a frequency range of 1-5Hz and a time-period of 10s, were considered to study the dynamic behaviour of the fasteners. Finally, the experimental tests were carried out using time-history earthquake inputs, selecting three Far Field and two Near Fault ground motions, properly scaled. The characteristics of the selected records can be found in Table 1, while the acceleration spectra of each record are shown in Figure 4.

Input name	Year	M_w	Record ID
Cape Mendocino	1992	7	EQ_1
Landers	1992	7.3	EQ_2
Friuli	1976	6	EQ_3
Kobe	1995	6.8	EQ_4
Christchurch	2011	6.3	EQ_5

Table 1: Main characteristics of the selected input earthquake records.

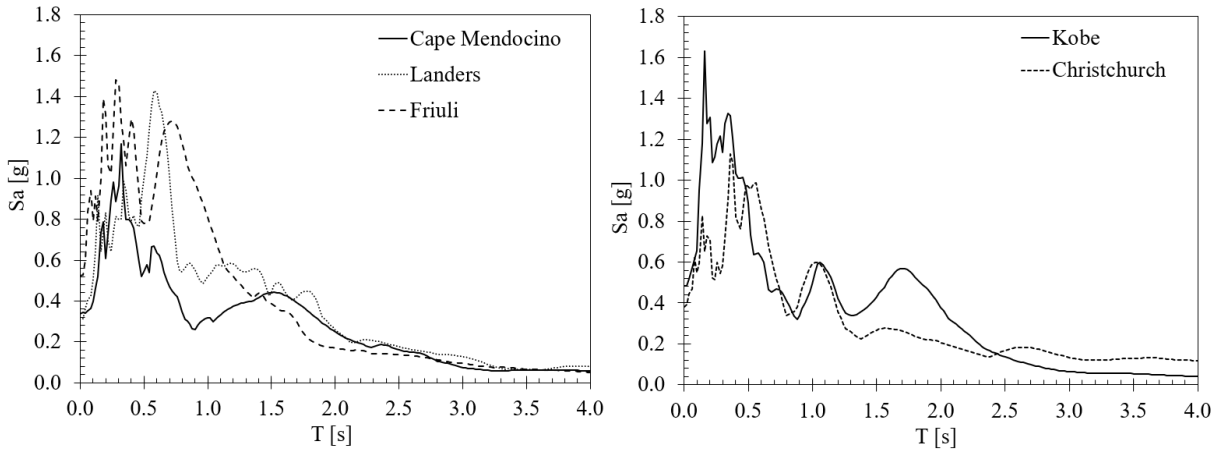

Figure 4: Acceleration response spectra for the Far Field (left) and Near Fault (right) input ground motions.

4.4 Testing protocol

The installation of anchors is a crucial phase for the experimental test. In fact, test results can be directly affected by the installation operation of the fasteners, therefore for each type of anchors the installation procedure has to be applied in a rigorous manner before performing the shaking table tests.

Each M12 fastener was installed into the concrete block following the procedure specified by the manufacturer. Regarding the concrete blocks, to study the seismic performance of anchor rods located along cracks parallel to the shaking direction, an appropriate apparatus was developed to generate these cracks (Figure 5): a bar with a sharp edge was positioned exactly

between two cotters inserted in the concrete block and the crack was opened by blowing onto both cotters on the left and on the right of the bar until the crack reaches 0.5 mm width.

Figure 5: Testing protocol for crack opening.

Therefore, the shaking table tests were performed following a specific test matrix that included three different expansion anchors (*FAZ II Traditional, FAZ II EQ-Rod and FAZ II Traditional with Mortar Filling*) and three different chemical anchors (*Superbond Traditional, Superbond EQ-Rod and Superbond Traditional with Mortar Filling*) anchored in uncracked and cracked concrete blocks. The configurations with mortar filling indicated the presence of mortar into the gap due to construction tolerances between steel plate and anchor.

Referring to the five input motions previously described and their simulated aftershocks (EQ_i-50), assumed as 50% of the input motion (amplitude-only reduction, same duration), for each type of expansion/chemical fastener the experimental test matrix in Table 2 was considered.

Test ID	Input motion	Type of fastener
1	EQ_1 + EQ_1-50	Traditional
2	EQ_1 + EQ_1-50	Traditional with Mortar Filling
3	EQ_1 + EQ_1-50	EQ-Rod
4	EQ_2 + EQ_2-50	Traditional
5	EQ_2 + EQ_2-50	Traditional with Mortar Filling
6	EQ_2 + EQ_2-50	EQ-Rod
7	EQ_3 + EQ_3-50	Traditional
8	EQ_3 + EQ_3-50	Traditional with Mortar Filling
9	EQ_3 + EQ_3-50	EQ-Rod
10	EQ_4 + EQ_4-50	Traditional
11	EQ_4 + EQ_4-50	Traditional with Mortar Filling
12	EQ_4 + EQ_4-50	EQ-Rod
13	EQ_5 + EQ_5-50	Traditional
14	EQ_5 + EQ_5-50	Traditional with Mortar Filling
15	EQ_5 + EQ_5-50	EQ-Rod

Table 2: Test matrix for the FAZII or Superbond type of fasteners.

The tests in Table 2 were performed three times on different anchors of the same typology to provide at least three responses for the same input motion and derive mean and standard deviation probabilistic results. In total, the test matrix of the experimental campaign consisted

of a total number of 360 shake table tests (input + aftershocks), 180 for uncracked concrete and 180 for cracked concrete.

5 EXPERIMENTAL RESULTS

The acceleration of the driving mass representing the non-structural system and the hysteretic behaviour (force-displacement relationship) of the fastener anchored in the concrete block fixed to the shake table have been determined from the experimental tests.

This paper presents only some of the main findings and discussions related to the obtained experimental tests on all the anchor types (Figure 6), while a more complete description of all the experimental data can be found in the Research Project report [11].

The efficacy of EQ-Rod prototypes in improving the seismic response of the system is determined as the capacity of reducing the acceleration demand onto the connected non-structural component (driving mass) when compared to the demand related to the application of traditional (expansion or chemical) fasteners.

Concerning the data processing, it is observed that the data obtained with the high-speed logger connected to the shake table was filtered using a low pass (6th order Butterworth filter) with a cut off frequency of 20Hz to reduce external noise.

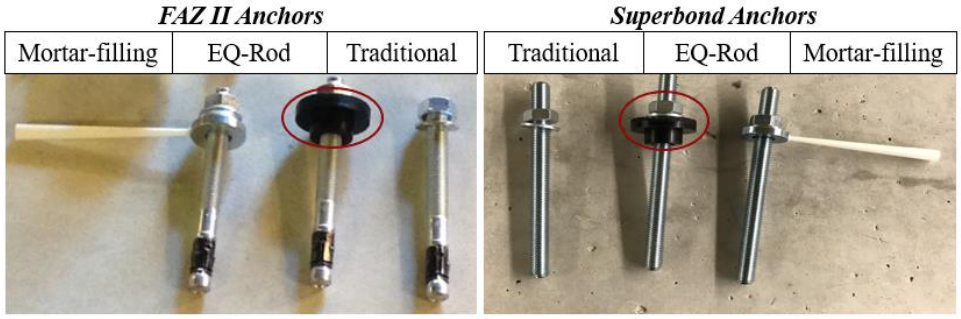

Figure 6: FAZ II and Superbond anchors.

5.1 Sinusoidal input test results

The preliminary experimental results from the sinusoidal input tests on uncracked concrete blocks are initially presented in terms of hysteretic loops for both Traditional anchor and EQ-Rod 2.0 considering either FAZ II or Superbond configurations (Figure 7).

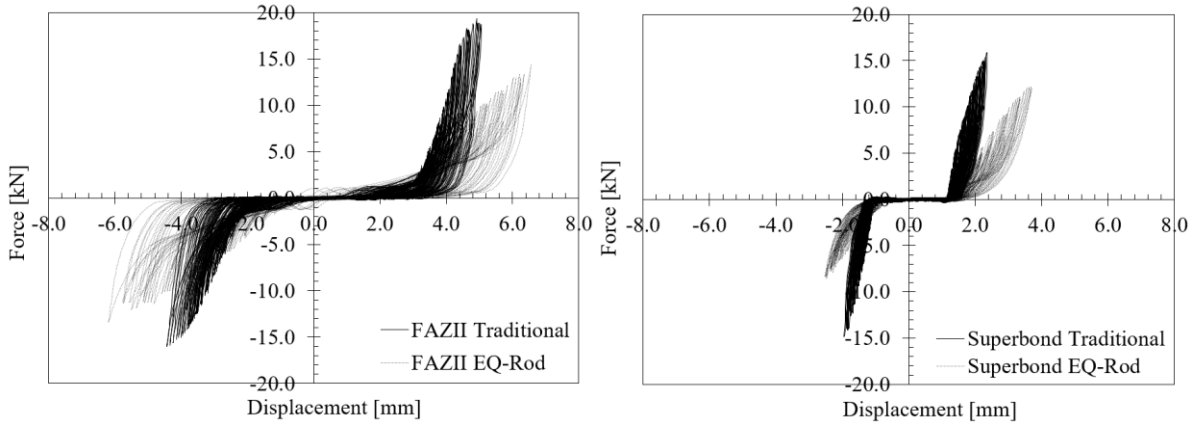

Figure 7: Comparison between FAZ II Traditional and FAZ II EQ-Rod (left) and Superbond Traditional and Superbond EQ-Rod (right) in terms of Hysteretic Loop for uncracked concrete.

The installation of each anchor followed the testing protocol, with the only difference that the application of the torque was reduced to 0 Nm - instead of 30Nm or 20 Nm - in order to simulate the complete loss of tightening torque due to long period.

Analyzing the maximum force values determined on the non-structural system, the results showed a reduction in the range of 15-25% for the EQ-Rod solution when compared to the FAZII traditional one, and 20-35% for EQ-Rod system when compared to the Superbond traditional anchor. These results were associated to the large hysteretic energy of the EQ-Rod system, thus to the greater displacements that it reached during most of the cycles.

5.2 Ground motion input test results

In accordance to the proposed test matrix, the shake table tests were carried out for all the proposed configurations in uncracked and cracked concrete. Test results in terms of force/displacement curves of the driving mass are shown for just one test of an input record (EQ_1) for all the three types of expansion anchors (Figure 8) and chemical anchors (Figure 9).

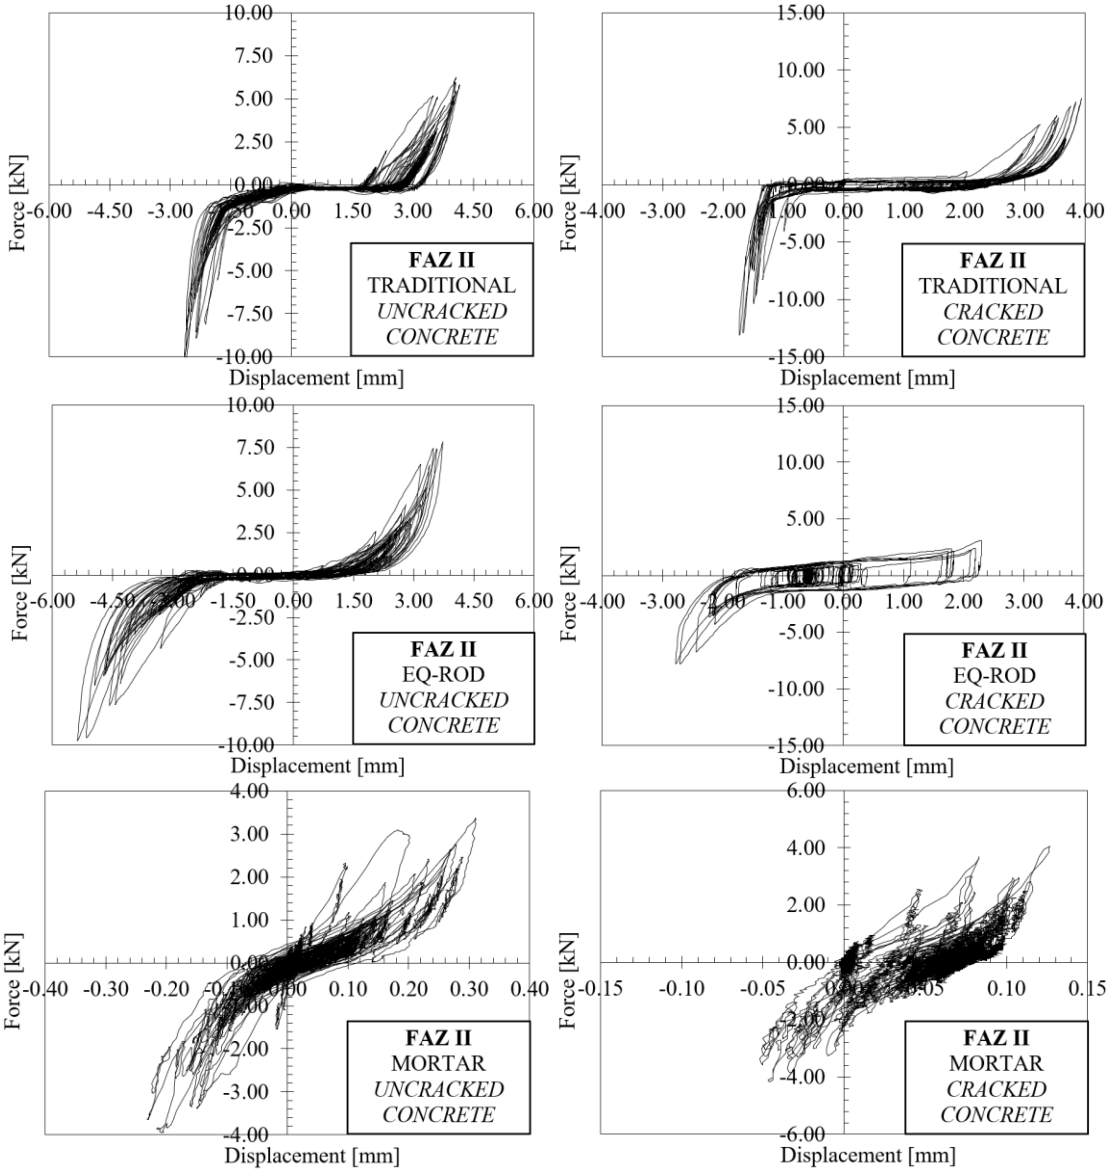

Figure 8: Force-displacement relationships for the FAZII Traditional, FAZII EQ-Rod, FAZII Traditional with Mortar Filling in uncracked and cracked concrete.

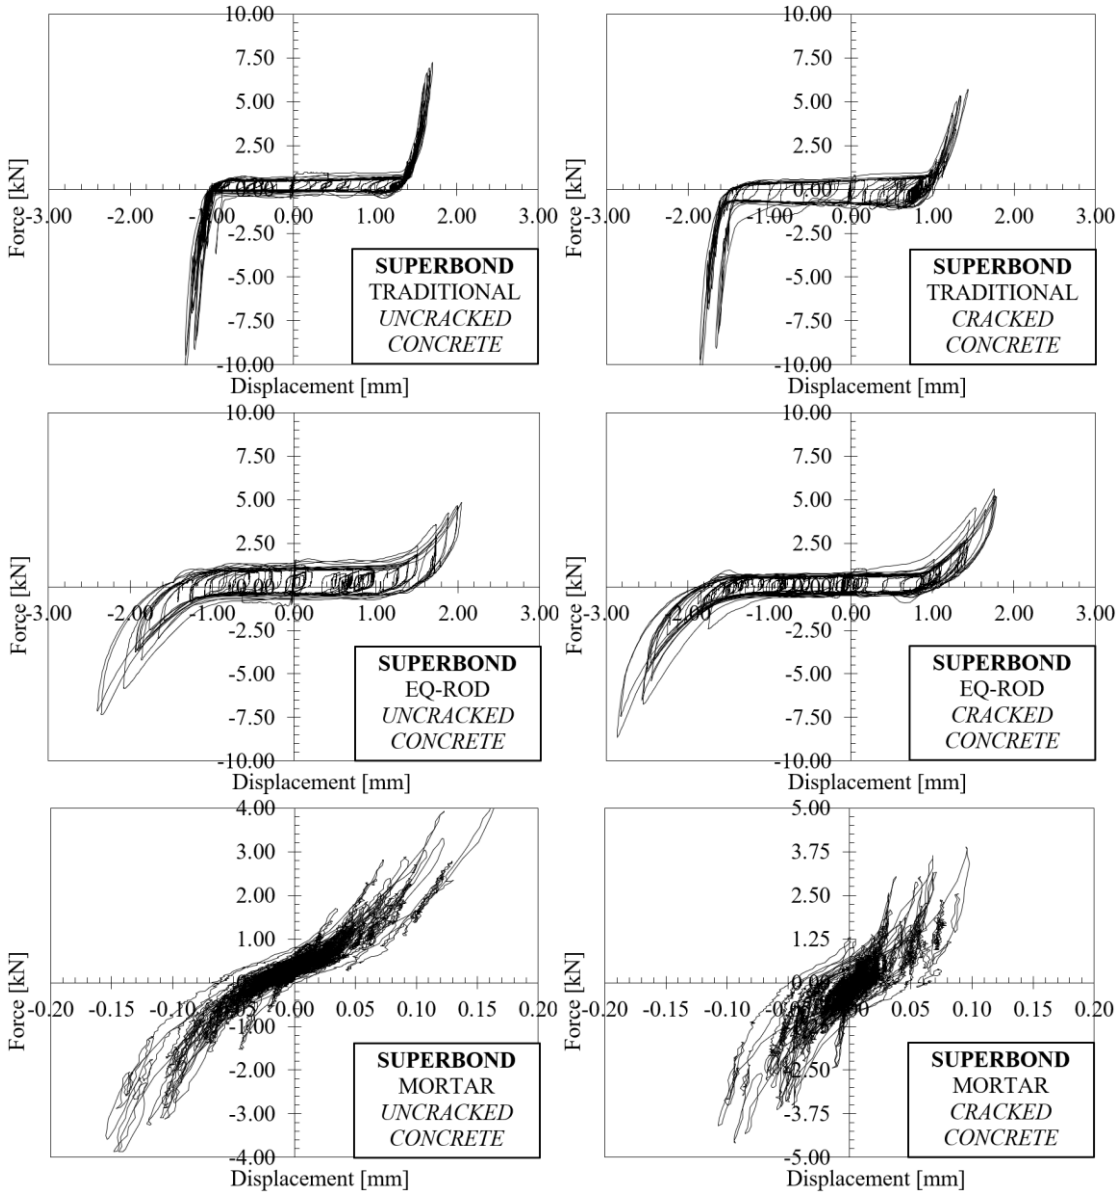

Figure 9: Force-displacement relationships for the Superbond Traditional, Superbond EQ-Rod, Superbond with Mortar Filling in uncracked and cracked concrete.

The experimental tests provided the following main results: 1) for the expansion anchors in uncracked concrete, the EQ-Rod system can provide a reduction in terms of driving mass forces and accelerations in the range of 10-15% for the input signals and of 15-30% for the aftershocks; 2) for the expansion anchors in cracked concrete the EQ-Rod reduction in terms of driving mass forces is in the range of 20-30%, while in terms of accelerations in the range of 25-40% for the input signals and 30-40% for both accelerations and forces considering the aftershocks; 3) for chemical anchors in uncracked concrete the EQ-Rod reduction is 10-25% in terms of forces and 20-30% in terms of accelerations when considering the input signals, while 30-40% for both demands when considering the aftershocks; 4) finally, for chemical anchors in cracked concrete, the EQ-Rod solution provided a reduction in terms of driving mass forces and accelerations in the range of 20-30% for the input signals and of 30-40% for the aftershocks.

The performance and benefits of EQ-Rod in cracked concrete appears in general superior to that in uncracked concrete. It should be noted that, in addition to the inherent isolation-dissipation mechanism, EQ-Rod anchor reaches larger displacements in cracked concrete and the overall system has thus lower frequencies (higher period) and attracts less forces as it moves towards the de-amplification part of the spectra.

Notwithstanding the efficiency of the proposed EQ-Rod configuration, test results also showed that a significant benefit in terms of response can be obtained by applying mortar filling, with a reduction of 40-60% for all the analyzed configurations in uncracked and cracked concrete. This high reduction is due to the lack of dynamic impact (pounding) due to the presence of gaps between steel plate/anchor and concrete/anchor. The anchor with mortar filling thus acts as a more rigid element, while EQ-Rod allows for a combination of isolation and dissipation. It appears that a combination of the two concepts (filling the gap and adding a tight-fit EQ-Rod dissipative system) would be able to provide the best and most reliable benefits.

6 CONCLUSIONS

With the aim of improving the seismic response of non-structural systems anchored to concrete structures a post-installed fastener with supplemental damping has been experimentally proposed and studied. The first prototype of this solution, referred to as EQ-Rod, was developed in 2008, while a new system, named EQ-Rod 2.0, is herein considered, conceived as an easily applicable solution useful for either expansion or chemical fasteners. The seismic performance of this system has been deeply studied through uni-directional shake table tests using specific testing protocols for both uncracked and cracked concrete.

Worth noting that due to the larger geometric tolerances between the EQ-rod and fastener rod (inner tolerance/gap) as well as due to the different material of the new EQ-Rod when compared to the initial prototype, during the tests the bearing stresses on the rubber material led sometimes to the yielding of the rubber damper with permanent deformations and amplifications of the dynamic effects and this in turns reduced the efficiency of the EQ-Rod system as a damping element under cumulative aftershocks.

However, the experimental results confirmed that the concept of adding damping to a fastener can be adopted to improve the seismic performance of the system, reducing both accelerations and forces onto the connected non-structural component. The proposed system can thus be considered as a damage-control solution for such applications.

The shake table test results provided evidence of the efficiency of the dissipative solution, yet further improvements of the system design are needed and recommended to fully exploit the novelty of the dissipative/isolation mechanism of the EQ-Rod and obtain a greater and robust reduction of the driving mass accelerations when compared to the traditional anchor (with or without mortar filling).

7 ACKNOWLEDGEMENTS

The research project has been funded by Fischerwerke Artur Fischer GmbH & Co. KG, whose support is gratefully acknowledged. Acknowledgements are also provided to Dr.-Ing. Quintana-Gallo for his technical support, particularly during the initial phases, based on his personal experimental test experience on EQ-Rod at the University of Canterbury. Special thanks go also to Dr.-Ing. Andreas Pürgstaller, supervised by Prof. Konrad Bergemeister, from the University of Natural Resources and Life Sciences Vienna, Austria for developing FEM analysis and initial quasi-static tests on the anchor prototype.

Abstract

Nonlinear static analysis of reinforced concrete frame structures is useful in pushover analyses for structural capacity computation. A popular method for nonlinear static analysis is by modelling with force-based fiber beam column elements, where equilibrium, compatibility and constitutive relationship are satisfied at structure level, element level and fiber level respectively. The existing formulation of the fiber beam column element consists of an iterative procedure at the element level to satisfy element compatibility, where the residual deformations of the sections are integrated to find the element residual deformation. Then the corrective force corresponding to element residual deformation is applied globally at the element level which is in turn distributed to the section level according to force interpolation functions. However, the existing formulation does not evaluate section level equilibrium directly where the section forces and deformations are calculated by minimizing element level residual deformations. This paper proposes a modification to this existing formulation by transferring equilibrium satisfaction to the section level. This modification allows the minimization of section unbalanced forces at the section level itself, rather than transferring unbalanced forces of the sections displaying high nonlinearity, to element level. This equilibrium satisfaction is done by adjusting the section deformation through an iterative procedure which yields the correct section stiffness and deformation for the corresponding section force increment. Section stiffness can be assembled to find corresponding structure stiffness which can be used to calculate structure resisting force. At structure level, the Newton Raphson iterative procedure is identical to that of the existing formulation. The study focuses on the reinforced concrete frame elements with only material nonlinearity where plane sections remain plane and normal to the longitudinal axis. Furthermore effects of bond slip and shear were not considered in this study. The proposed formulation was experimentally validated and was proved to be well suited to predict the nonlinear static response of rein-forced concrete structures exhibiting highly localized nonlinear behavior.

Keywords: RC frames, nonlinear static analysis, force based fiber beam column element

1 INTRODUCTION

Reinforced concrete structures exposed to severe earthquakes and winds can cause massive destruction of lives and property. Therefore accurate numerical simulation of reinforced concrete structures using nonlinear analysis is vital. The existing nonlinear analysis methods can be categorized in to three groups namely, lumped plasticity method, distributed plasticity method and modelling with three dimensional solid elements. In lumped plasticity method, plasticity is monitored at predetermined locations where nonlinear behavior is expected. This method requires expert knowledge to identify intended plastic hinges. Modelling with three dimensional solid elements can yield an accurate prediction but unfortunately that accuracy comes with a huge computational cost. The best compromise between accuracy of prediction and cost of computation is the line element with distributed plasticity, where plasticity is monitored at several integration points along the element. The line element with distributed plasticity can be modelled using either force based or displacement based finite element approaches. The displacement based finite element formulation is based on satisfying compatibility and constitutive relationship in strong form while satisfying equilibrium in weak form. In addition to that, the relationship between element nodal deformations and section deformations needs to be assumed. Therefore displacement based formulation requires discretization of frame elements, in the cases of material nonlinearity and/ or tapered sections which is computationally expensive. However, force based formulation do not require such refinement as the force interpolation functions which defines the relationship between nodal forces and section forces is exactly known. It is important to note that in force based formulation there are no additional assumptions except compatibility satisfaction in weak form. Accordingly researchers are inclined to use force based finite element formulation to model line elements with distributed plasticity. Reference [2] introduced a force based fiber element which was later improved in [9]. The main problem at that time was determining the element resisting forces corresponding to a given element nodal deformation. Reference [1] introduced an iterative procedure at element level to minimize element residual deformations to obtain element resisting forces corresponding to a given element nodal deformation. Later, [7] improved the method of stated in [1] which resulted in the force based fiber beam column element. This element is capable to predict the axial force – bending moment interaction of reinforced concrete structures and is widely used by structural Engineers [4]. The existing fiber beam column element formulation has two main nested iterative procedures at structure level and element level. When satisfying compatibility at element level, the residual deformation of the element is calculated using section residual deformations. Then the corrective force corresponding to element residual deformation is applied at the element level and is subsequently distributed to the section level according to force interpolation functions. However, if the nonlinear behavior is concentrated to a certain section, the corrective force applied at element level may fail to directly address the section which exhibits highly nonlinear behavior. Therefore in such cases satisfaction of element level compatibility becomes problematic. The novel formulation is proposed with the idea of correcting the section unbalanced forces at the section level itself rather than correcting integrated section residual deformations at element level. In the novel formulation, an iterative procedure is introduced at the section level to minimize section unbalanced forces and achieve section level equilibrium at the section level itself.

2 MODEL ASSUMPTIONS

The proposed formulation focuses on planar reinforced concrete structures which exhibit material nonlinearity. The present study do not account the effects of geometric nonlinearity.

The novel formulation is based on force based line element which has two nodes, each having three degrees of freedoms. Figure 1 illustrates the nodal forces and deformations of the force based frame element referring global (X, Y) coordinate system.

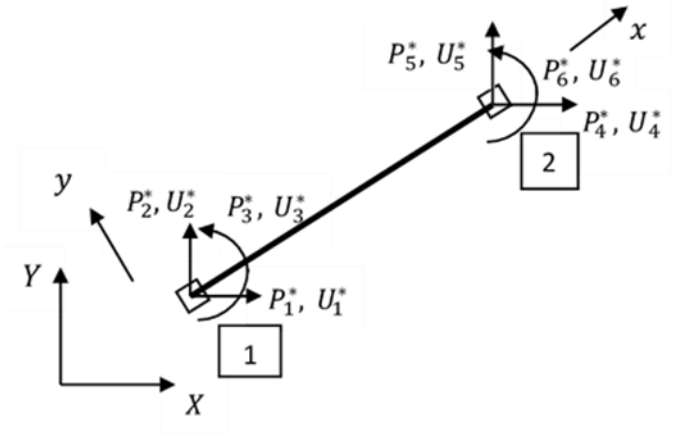

Figure 1: Nodal forces and deformations of the force based frame element referring global (X, Y) coordinate system

The element force vector and the deformation vector can be written as $\{P_1^* \; P_2^* \; P_3^* \; P_4^* \; P_5^* \; P_6^*\}^T$ and $\{U_1^* \; U_2^* \; U_3^* \; U_4^* \; U_5^* \; U_6^*\}^T$ respectively.

The frame element shown in Figure 1 has a singular stiffness matrix. Thus, the nodal forces, deformations and element stiffness are expressed referring local coordinate system (x, y) and the rigid body modes are removed to achieve a nonsingular stiffness matrix. This resulting basic system is illustrated in Figure 2 referring (x, y) local coordinate system.

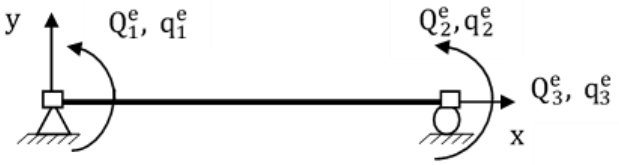

Figure 2: Nodal forces and deformations of the basic system referring local coordinate system (x, y)

Hereafter in this paper, the element force and deformation vectors refer to the force and deformations vectors of the basic system. Accordingly, the element force and deformation vectors can be written as $\{Q_1^e \; Q_2^e \; Q_3^e\}^T$ and $\{q_1^e \; q_2^e \; q_3^e\}^T$ respectively.

The element proposed, is a line element with distributed plasticity where the nonlinearity is monitored at selected number of gauss integration points. Each section at control stations are sufficiently divided in to several number of fibers where uniaxial material models are assigned to each fiber. The control stations and division of a section into fibers is illustrated in Figure 3.

The proposed formulation is based on the assumption that plane section remains plane and perpendicular to the longitudinal axis. This assumption allows to use a uniaxial material model for the relationship between fiber strain (ε_{fib}) and fiber stress (σ_{fib}). Accordingly, the section force vector can be written in terms of axial force ($N(x)$) and bending moment ($M(x)$) while section deformation vector can be written in terms of section curvature ($\kappa(x)$) and axial

strain of the centroid axis (ε_0) as illustrated in Figure 4. Section force and deformation vectors can be written as $\begin{pmatrix} N(x) \\ M(x) \end{pmatrix}$ and $\begin{pmatrix} \varepsilon 0 \\ \kappa(x) \end{pmatrix}$ respectively.

In addition, effect of bond slip and shear was not accounted in this study.

3 PROPOSED FORMULATION

The formulation is based on four hierarchical levels namely, structure level, element level, section level and fiber level where, the law of equilibrium is satisfied at both structure level and section level while constitutive relationship is fed at the fiber level. However, the compatibility of the structure is satisfied indirectly by the computation of the correct section deformation and section stiffness for a given section force increment by entertaining an iterative procedure at section level. In order to facilitate the satisfaction of equilibrium at structure and section levels, two nested iterative procedures are adapted at structure level and section level. It is important to note that there is no iterative procedure at element level as in the existing fiber beam column formulation.

The formulation was written utilizing the displacement control method of structure state determination where, displacement is applied to a specific degree of freedom using a series of steps. At each displacement step, the structure force and deformation increments are calculated by following the aforementioned iterative procedures. Once the calculation of structure

force and deformation vectors are completed for a series of steps, the load – deformation response of the reinforced concrete structure can be generated.

The computations at structure level are performed after applying boundary conditions and rearranging vectors and matrices by shifting the rows and columns representing displacement controlling degree of freedom to the end. Here, P2 and U2 represent the force and displacement at displacement controlling degree of freedom while F1 and U1 represent the forces and deformations of other degrees of freedom excluding the restrained ones. The structure stiffness matrix is condensed accordingly for the computations. O and R represent unbalanced forces and resisting forces while i represent the structure level iteration number.

At the start of a step, a displacement is applied on a certain degree of freedom. Based on this displacement increment, an initial estimate of structure force and deformation increment is computed linearizing around the structure stiffness matrix of the previous iteration as shown in (1).

$$\Delta\lambda^{i=1}\begin{Bmatrix}P_1\\P_2\end{Bmatrix}=\begin{bmatrix}K_{11} & K_{12}\\K_{21} & K_{22}\end{bmatrix}_{i=0}\begin{Bmatrix}\Delta U_1\\\Delta U_2\end{Bmatrix}^{i=1} \tag{1}$$

In the next stage, structure resisting force corresponding to the deformation increment estimate needs to be calculated as shown in (2).

$$\begin{Bmatrix}R_1\\R_2\end{Bmatrix}^{i=1}=\begin{bmatrix}K_{11} & K_{12}\\K_{21} & K_{22}\end{bmatrix}_{i=1}\Delta\begin{Bmatrix}U_1\\U_2\end{Bmatrix}^{i=1} \tag{2}$$

For this purpose, the updated structure stiffness matrix corresponding to the estimated structure force increment is computed using an iterative procedure at section level. Here, the correct section deformation and updated section stiffness matrix is generated corresponding to a section force increment by minimizing the force difference between section force and section resisting force.

Once the structure resisting force corresponding to the estimated displacement increment is computed, the difference between the estimated structure force and resisting force is evaluated using (3).

$$\begin{Bmatrix}O_1\\O_2\end{Bmatrix}^{i=1}=\Delta\lambda^{i=1}\begin{Bmatrix}P_1\\P_2\end{Bmatrix}-\begin{Bmatrix}R_1\\R_2\end{Bmatrix}^{i=1} \tag{3}$$

If the unbalanced force is significant, a corrective force and deformation vectors are calculated linearizing around the freshly calculated structure stiffness matrix as demonstrated in (4).

$$\begin{Bmatrix}\Delta U_1\\\Delta U_2\end{Bmatrix}^{i=2}=\begin{bmatrix}K_{11} & K_{12}\\K_{21} & K_{22}\end{bmatrix}_{i=1}^{-1}\begin{Bmatrix}O_1\\O_2\end{Bmatrix}^{i=1}+\begin{bmatrix}K_{11} & K_{12}\\K_{21} & K_{22}\end{bmatrix}_{i=1}^{-1}\Delta\lambda^{i=2}\begin{Bmatrix}P_1\\P_2\end{Bmatrix} \tag{4}$$

In the next phase, the structure stiffness matrix will be updated again for the calculated displacement correction, by delving to element, section and fiber levels and completing the section state determination process. Subsequently, structure resisting force corresponding to the structure deformation correction is computed as before. Then, structure force and resisting force is evaluated again. These nested iterative procedures are continued until structure unbalanced force comes under a prescribed tolerance value. This process will produce a correct structure force and displacement increment, corresponding to the applied displacement step.

Once this process is repeated for a series of displacement steps, the behavior of the structure can be predicted.

4 EXPERIMENTAL VALIDATION

4.1 Flexural cantilever wall

The experimental validation of the proposed novel formulation was done with the reinforced concrete cantilever wall RW2, experimented in [8] which was designed to behave in flexure mode. Figure 5 and Table 1 depicts the loading arrangement and details of the reinforced cantilever wall RW2. Figure 6 illustrates the cross section with reinforcement arrangement.

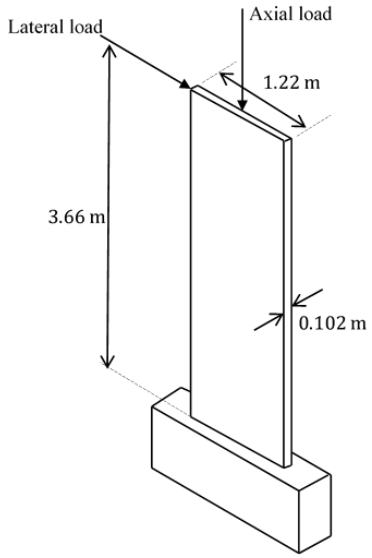

Figure 5: Loading arrangement and dimensions of RW2

Structure level force tolerance (kN or kNm)	10^{-10}	10^{-10}

Table 2: Input parameters for numerical models

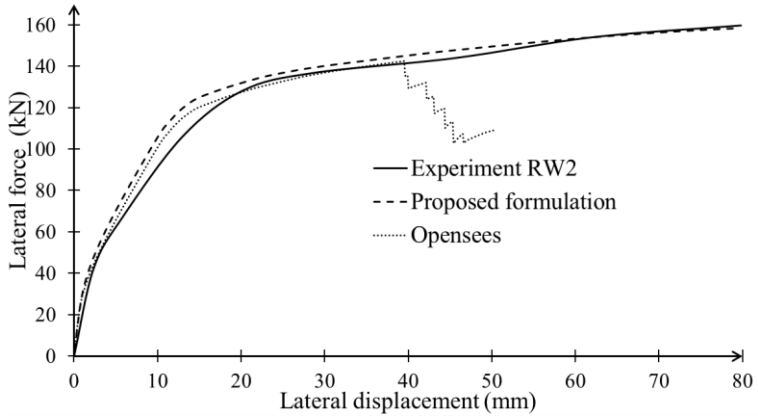

Figure 7: Load deformation responses of the RW2 cantilever wall obtained experimentally, using novel formulation and using OpenSees software

It is evident from Figure 7 that the prediction made by the proposed formulation is very close to the prediction made by experiment and OpenSees. The proposed novel formulation has been able to capture the tensile concrete cracking behavior, tensile steel yielding behavior and the ductility of the reinforced concrete wall.

In the load – deformation response predicted by the novel formulation, the initial slope is approximately constant until the tensile concrete fibers starts to crack around 13 kN load. Due to further cracking of concrete tensile fibers, a considerable drop of slope can be seen around 30 kN load. Due to this concrete tensile fiber cracking, the centroid axis shifts towards the compression zone. With the application of further displacement increments, cracking of concrete tensile fibers reaches a saturated level resulting a constant slope until tensile steel starts to

yield at 98 kN. The drop of tangent stiffness of the concrete constitutive model is reflected by the gradual reduction of slope in the load – deformation response. After yielding of tensile reinforcement, the stiffness of the beam drops to a very lower value and the strength remains approximately constant producing a larger ductility as shown in Figure 7. The comparison shown in Figure 7 also depicts that these nonlinear behaviors can be captured by the proposed novel formulation. Figures 8, 9, 10, 11, 12, 13, 14, 15 present the stress and strain distributions generated by the novel formulation, at different regions of the load - deformation curve. The section numbers referred in the figures correspond to the integration points shown in Figure 3.

4.2 Shear dominant cantilever wall

The load-deformation response of a shear dominant reinforced cantilever wall (SW21), experiment by Lefas [3], was compared with that of numerical prediction from the proposed novel formulation. The loading arrangement, dimensions and reinforcement details of the cantilever wall are given in Figure 16. Table 3 lists out the physical parameters.

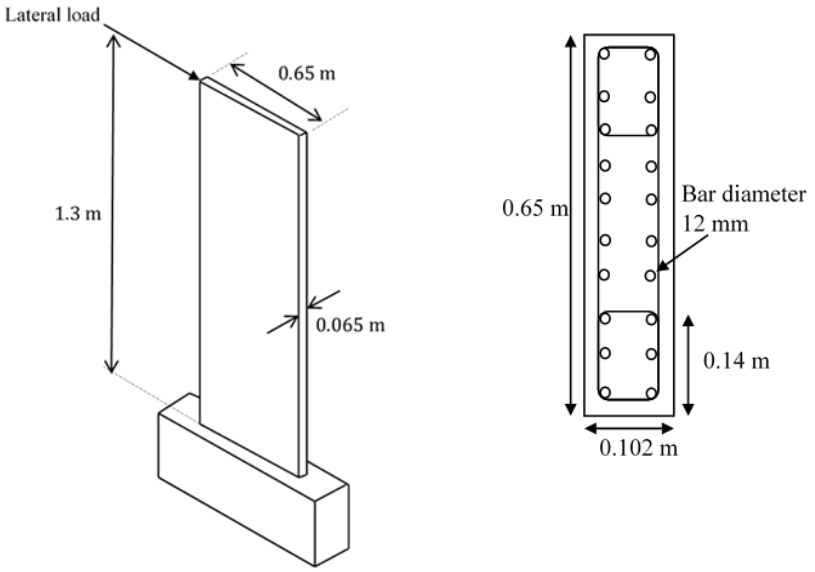

Figure 16: Loading arrangement, dimensions and reinforcement details of SW21

The load – deformation comparison of the experimental and numerical predictions given in Figure 17 displays a considerable deviation. The slope of the load – deformation curve of numerical prediction is quite high compared to that of experimental prediction. This behavior can be explained by the fact that the proposed formulation only accounts axial force – bending moment interaction. In the numerical prediction, a deformation corresponding to a certain force level consists of only flexural deformation component. However, in the real situation, the deformation should include the shear deformation component. Thus, the deformation in the experimental prediction is higher for the same force level. Thus, the proposed formulation cannot be recommended to predict the response of shear dominant reinforced concrete beams and walls. However, the proposed formulation can predict the flexural behavior accurately.

Height (mm)	1300
Outer perimeter Depth x width (mm x mm)	650 x 65
Aspect ratio	2
Compressive axial load (kN)	0
Cube strength (MPa)	42.8
Ratio of main flexural reinforcement to gross concrete area of edge element (%)	3.3
Yield strength of longitudinal reinforcement (MPa)	470
Ultimate strength of longitudinal reinforcement (MPa)	565

Table 3 Details of shear dominant reinforced concrete cantilever wall

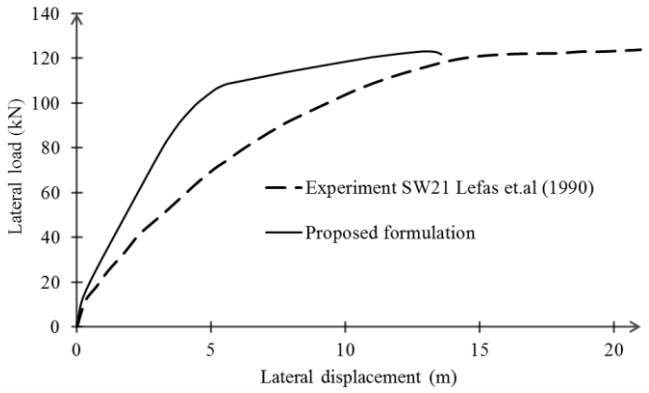

Figure 17: Load deformation response of shear dominant cantilever wall in the experiment and when using proposed formulation

5 SENSITIVITY ANALYSIS

A sensitivity analysis was performed on the proposed element using the reinforced concrete cantilever wall experimented [8]. The load deformation response was examined by changing number of fibers, number of integration points and step size. The force tolerances at structure level and section level was kept at 10^{-10}kN or kNm.

5.1 Number of fibers

Division of a section in to a sufficient number of uniaxial fibers is required to calculate section resisting forces corresponding to a given section deformation. In order to accurately predict the section resisting forces, number of fibers needs to be increased. However, drastic increase of number of fibers may cause an increase in the computational cost. Figure 18 demonstrates the variation of load-deformation curves with number of uniaxial fibers used in sections. In this comparison, number of integration points at each element was kept at six while the displacement step size was maintained at 0.1 mm. The load – deformation responses when the number of fibers 2, 4, 6, 8 shows a considerable deviation from that of having 50 fibers. The section height of RW2 is 1.22 m, thus the analysis should be carried out with higher number of concrete fibers.

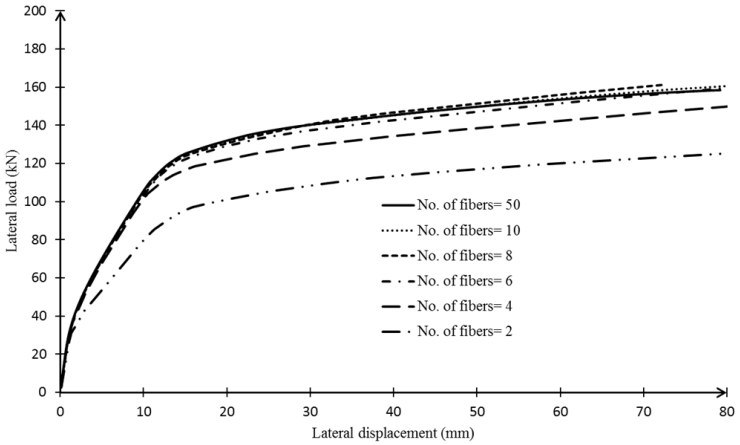

Figure18: Load deformation curves varying the number of fibers

5.2 Number of integration points

The proposed element utilizes Gauss-Lobatto integration scheme to find the element stiffness matrix from section stiffness matrix. Reference [7] describes that Gauss-Lobatto integration scheme is far more superior to the conventional Gauss integration due to the fact that the end sections are not monitored in Gauss integration. Reference [7] further suggest that if Gauss integration to be used, the order of integration needs to be increased. The load – deformation responses varying the number of integration points is plotted in Figure 19. These load – deformation curves were recorded while maintaining number of fibers at 50 and displacement step size at 0.1 mm. Figure 21 demonstrates that, in this problem, using 5 to 7 integration points per element provides a better monitoring of the plasticity along the element.

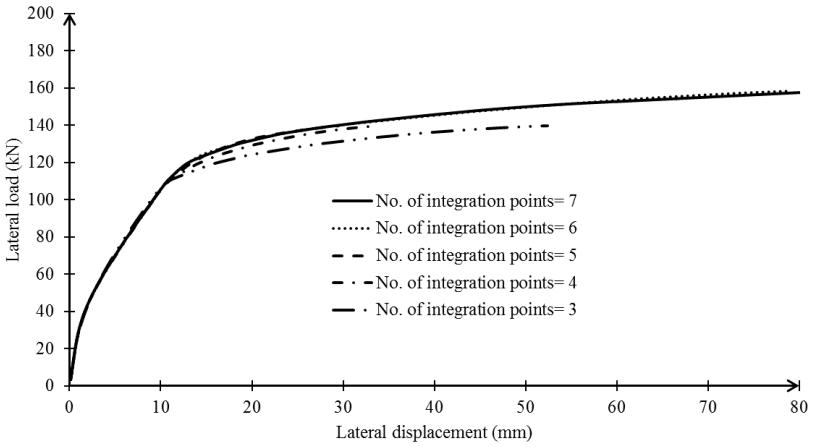

Figure 19: Load deformation curves varying number of integration points

5.3 Displacement step size

The load deformation responses varying the displacement step size is given in Figure 20. These load – deformation curves were obtained, maintaining number of fibers at fifty and number of integration points at six. The deviation of the load deformation curves exhibited in

the case of larger displacement steps, points out that in order to capture all nonlinear behaviors of reinforced concrete structures, the total displacement should be applied to the structure in sufficiently small displacement steps.

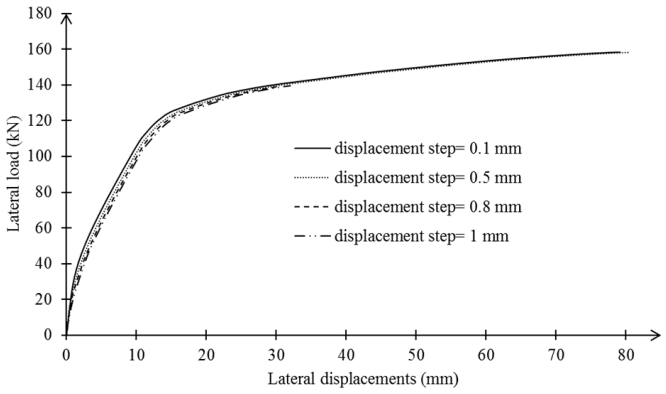

Figure 20: Load deformation curves varying displacement step size

6 CONCLUSIONS

This paper introduces a novel force based frame element with distributed plasticity which can predict the axial force – bending moment interaction. The existing force based fiber beam column element [6], [7] which can predict axial force – bending moment interaction, satisfies the equilibrium, compatibility and constitutive relationships at structure level element level and fiber level. However, section level equilibrium is not evaluated directly. Therefore the proposed formulation omits the compatibility satisfaction at element level and introduce an iterative procedure at section level to satisfy section level equilibrium. The novelties of the proposed formulation are introduction of section level iterative procedure to find correct section deformation and updated section stffness for a given force increment and the use of updated structure stiffness matrix to compute structure resisting force. The formulated element was validated with a well-recognized experimental reinforced cantilever wall RW2 [8]. The comparison of load – deformation response illustrated a very good agreement with the experimental response. The load – deformation response of reinforced cantilever wall was also predicted using OpenSees software, using equal number of elements, integration points, number of concrete fibers per section and tolerance values. The comparison proved that the proposed formulation has the capability to predict the load- deformation curve of RW2 to the level of the experimental curve where as the OpenSees prediction became unstable in the midway. Accordingly, the proposed novel formulation has the capability to predict the flexural response of reinforced concrete structures accurately in a stable manner.

Abstract

This research aims to obtain envelopes of the moment and shear demands in reinforced concrete (RC) wall buildings subjected to ground motions. These envelopes are intended to be used for designing RC buildings. Three research buildings with non-rectangular walls designed according to Eurocode 8 are considered. The seismic performance of the buildings is evaluated from nonlinear response history analysis (NRHA) with increasing levels of ground motion intensity. The RC walls are simulated with a model with distributed inelasticity (MDI), which considers that the nonlinear behaviour can take place at any building level if the demand is larger than the wall yield capacity, while the flexural stiffness is a function of the moment demand of the wall. The design envelopes for moment and shear forces are obtained from the results of the NRHA, where the effects of higher modes are evidenced.

Keywords: Reinforced concrete, Walls, Seismic demands, Seismic behaviour.

1 INTRODUCTION

In high seismicity areas, RC structural walls are largely used as lateral-load resisting systems for mid- and high-rise buildings. RC walls are stiff and strong, easily incorporated into architectural layouts, and, when properly designed and detailed, perform satisfactorily when subjected to severe earthquakes. Structural walls can be configured in numerous ways within a building, with multiple walls resisting the demands in each principal direction. Rectangular sections are relatively easy to be designed, and have been extensively studied in the last years. Intersecting wall segments can be combined to create flanged or non-rectangular walls, including T-, C-, and L-shaped cross sections. RC walls are common in residential buildings and hotels and are usually located around stairs, elevators, corridors, and partitions between residential units [1].

Seismic moment and shear forces demand in walls of RC buildings have been studied mainly using a single wall as a representation of the entire building, where the interaction between different walls within buildings is not considered [2, 3]. Moreover, these studies assume that the nonlinear behaviour takes place at the base of the wall only. Therefore, elements with lumped plasticity and constant stiffness above the critical section have been used. The first problem of this approach is that a constant flexural stiffness is considered along the wall height. However, the flexural stiffness of the wall is a function of the moment demand which varies along the wall height. A second problem of such approach, that assumes an elastic response above the critical section, is that the bending moments in such regions are not bounded, while the bending moment at the base is bounded by the provided moment strength. Because certain design codes specify design envelopes for bending moments in RC wall buildings (e.g. Eurocode 8, NZS 3101, CSA A23.3), the assumption of elastic response and unbounded bending moments above the base of the walls may be an unrealistic situation under severe earthquakes.

The main objective of this research is to provide design recommendations for RC wall buildings. Specifically, design envelopes for moment and shear demands are proposed. The envelopes are obtained from an analytical study of three research buildings with non-rectangular RC walls.

2 RESEARCH BUILDINGS

The plan view of the research buildings is shown in Figure 1, where T-shaped and C-shaped RC walls are considered to resist lateral loads in both directions. The buildings have ten, twenty and thirty storeys and the inter-storey height is 3.0 m. The thickness of the walls of the three buildings varies between 0.3 m and 0.4 m, depending on the number of storeys.

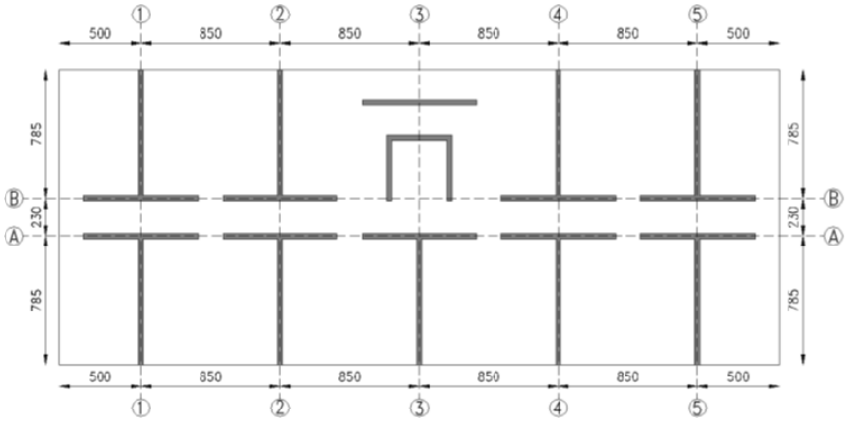

Figure 1: Plan view of the research buildings (dimensions in centimetres).

The buildings were designed according to Eurocode 8 (EC8) [4]. A type C soil (dense sand or gravel, or stiff clay) was used in conjunction with 0.4g design ground acceleration, considering a high seismicity area. The properties of concrete and reinforcement adopted for the seismic design are typical values used in engineering practice. The yield strength of the reinforcement (f_y) and characteristic compressive strength of the concrete (f'_c) are 500 MPa and 30 MPa, respectively.

Table 1 summarises the main design outputs of the three buildings, where T is the fundamental period of the buildings, q is the behaviour factor for uncoupled wall systems of high ductility class [4], W is the seismic weight, V is the design base shear of the building, ρ_L is the longitudinal reinforcement ratio, N_{ed} is the factored axial load in the walls, and A_g is the gross area of the walls. The value of ρ_L for the 30-storey building is lesser than that the 20-storey one because of the lower seismic demand induced by the larger period of the tall building.

N°-Storey	T [sec]	q	W [kN]	V/W	T-shaped wall		C-shaped wall	
					ρ_L [%]	$N_{ed}/A_g f'_c$	ρ_L [%]	$N_{ed}/A_g f'_c$

Table 1: Design outputs.

3 ANALYTICAL MODELS OF BUILDINGS

The seismic performance of the research buildings is estimated from two-dimensional (2D) nonlinear response history analyses (NRHA) using the finite-element software RUAUMOKO 2D [5]. The walls and beams are modelled using beam elements with lumped flexural nonlinear behaviour and elastic shear behaviour.

Figure 2 shows the two-component beam element used to model the walls, where two members in parallel represent the behaviour of the element. The two members are elastic but one of them allows the formation of hinges at ends of the member [5]. The nonlinear behaviour is achieved assigning a hysteretic model to the flexural behaviour of the hinges.

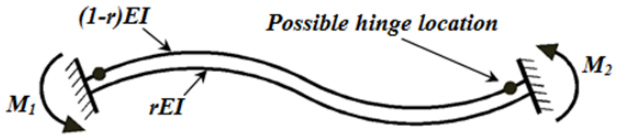

Figure 2: Two-component beam element, adapted from Carr [5].

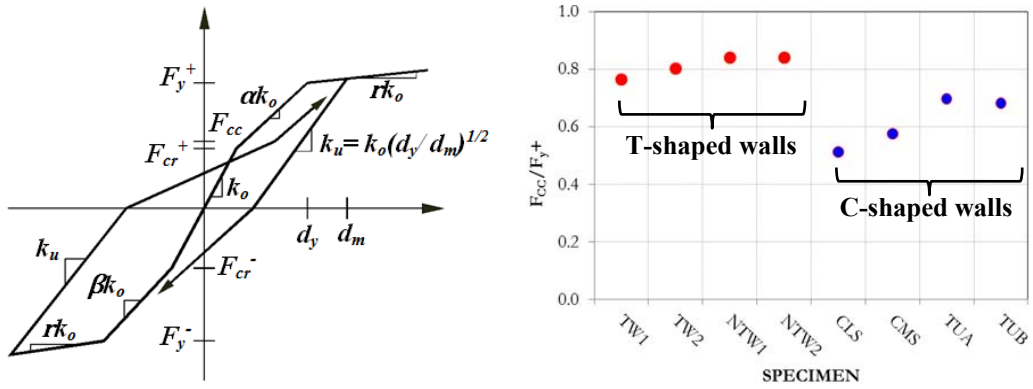
In this study, the nonlinear moment-rotation relationship of the hinges of the two-component beam elements used to represent the RC walls is represented using the tri-linear SINA hysteretic model [6]. This hysteretic model is shown in Figure 3a and consists on a tri-linear backbone with stiffness changes at cracking (F_{cr}^+, F_{cr}^-) and yielding (F_y^+, F_y^-). The SINA hysteresis rule allows different behaviour in the two loading directions, allowing modelling the behaviour of asymmetric RC walls. Additionally, the pinching effect is considered through the definition of the crack closing moment (F_{cc}). The SINA model considers that F_{cc} is the same in both directions.

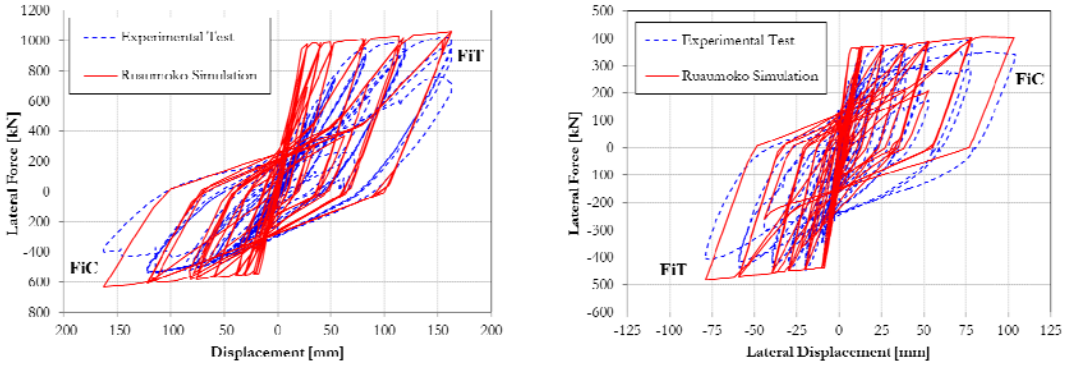
Using available experimental data of non-rectangular RC walls subjected to cyclic loads reported by Thomsen and Wallace [7] (named TW1, TW2), Sittipunt and Wood [8] (CLS, CMS), Beyer et al. [9] (TUA, TUB), and Brueggen [10] (NTW1, NTW2), the RC wall model

was calibrated achieving a good representation of the cyclic behaviour of the tested walls. For each specimen the tri-linear backbone was obtained directly from the moment-curvature relationship while the crack closing moment (F_{cc}) was defined through a trial and error procedure. The values of F_{cc} obtained for the specimens are shown in Figure 3b. The comparison between the experimental behaviour and the predicted response for two specimens is shown in Figure 4, where the proposed model is able to predict the cyclic response adequately in both loading directions.



a) b)

Figure 3: a) Tri-linear SINA hysteretic model, adapted from Carr [5], and b) F_{cc} values used for the studied walls.



a) b)

Figure 4: Comparison between the analytical model and experimental results: a) T-shaped wall (NTW1) after Brueggen [10], and b) C-shaped wall (TUA) after Beyer et al. [9].

Figure 4 shows that the experimental yield displacements, mainly for flange in tension (FiT), are larger than the analytical values due to the gradual yielding of the tension reinforcement within the flanges, whereas the reinforcement closest to the webs yields first, and subsequently progressing out from the web–flange intersection as lateral displacement increases [11]. Even though the simulated values overestimate the elastic stiffness, the proposed model is considered adequate because the response of the studied walls is essentially inelastic.

3.1 Building Model

The two-dimensional model of the building is shown in Figure 5, where all the axes of the building are modelled simultaneously. The walls were modelled with two-components beam elements using the described tri-linear SINA hysteretic constitutive relationship that considers different strength and stiffness in opposite directions. The effective slabs, which connect the

two walls in each axis, were modelled using two-node beam elements considering the Takeda hysteretic rule. End offsets are considered in these elements to account for the wall widths.

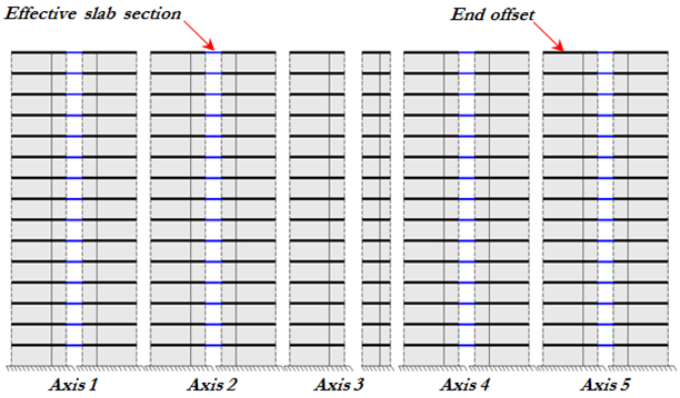


Figure 5: RUAUMOKO 2D structural model of studied buildings.

To model the RC walls, the approach used in this study is a model with distributed inelasticity (MDI), which considers that the nonlinear behaviour can take place anywhere in the wall if the moment demand is larger than the yield moment. The MDI of one wall is shown in Figure 6a, where four two-component beam elements are considered at each storey. This number of elements is considered adequate to represent satisfactorily the lateral displacement profile and flexural lateral stiffness of the walls. Since the inelastic behaviour is lumped in discrete points along the wall height (perfect hinge of two-component beam element), the proposed model in RUAUMOKO 2D was validated with a fibre beam model developed with SeismoStruct [12]. The comparison of a static pushover analysis of the T-shaped wall predicted with the two models in both loading directions is shown in Figure 6b. For the pushover analysis a concentrated load at the top of the wall was considered. The figure shows that the obtained behaviour with both models is similar for the two loading directions (flange in compression (FiC) and flange in tension (FiT)). Therefore, the proposed model with two-component beam elements is able to predict the behaviour of the wall adequately. A further development of the research will be the validation of the proposed MDI model with a fibre beam-column element able to capture the nonlinear shear behaviour of the wall [13, 14] and the multi-axial stress interaction under multi-axial loading conditions [15, 16].

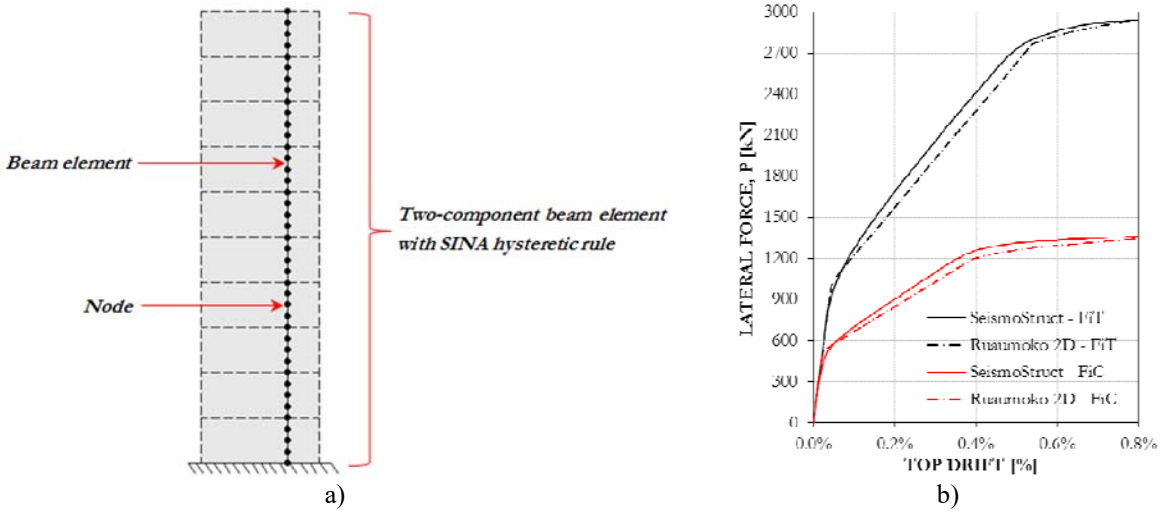

Figure 6: a) MDI and b) comparison of pushover analysis of the T-shaped wall using the proposed model with Ruamoko 2D and a fiber model with SeismoStruct.

4 CONSIDERED GROUND MOTIONS

To carry out the NRHA of the three buildings (Table 1) a set of seven artificial accelerograms were generated to be compatible with the design spectrum of EC8 [4]. Artificial records were selected because they matched the design spectrum for almost the full period range with a comparatively small error. The number of records was selected according to the prescriptions of the design codes (IBC, EC8, among others), which prescribe a minimum of seven spectrum-compatible records in order to obtain representative average results for design verification. The accelerograms were generated with SeismoArtif v2016 program [17]. Figure 7 compares the pseudo-acceleration and displacement spectra for 5% damping for each accelerogram with those of the EC8 design spectrum. Additionally, the figure shows the average response spectrum of the artificial accelerograms.

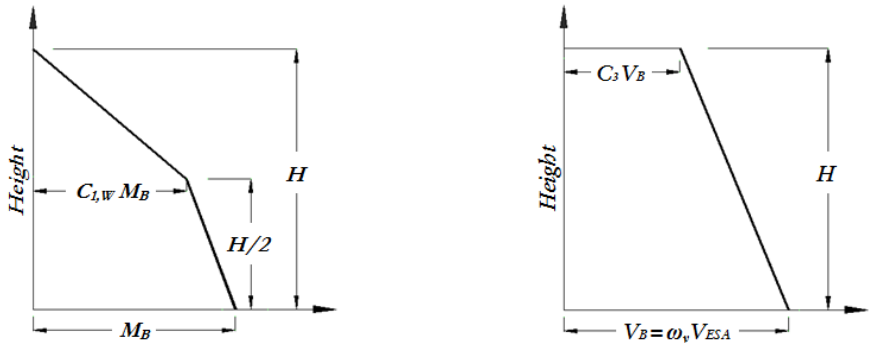
Figure 7: EC8 design and artificial spectra used for NRHA: a) pseudo-acceleration and b) displacement.

5 RESULTS

The results obtained from NRHA are presented in this Section. The NRHAs were performed with RUAUMOKO 2D program using the seven records mentioned in the previous section. The records were scaled to 100% (IR=1.0), 150% (IR=1.5) and 200% (IR=2.0) of the design intensity to analyze the seismic behaviour of the buildings. The use of seven records for each analysis permits to obtain representative average values of the moments and shear forces.

From the nonlinear results of the buildings, moments and shear design envelopes are proposed for the walls of the studied buildings with the non-rectangular walls. Figure 8 shows the shape of the moment and shear envelopes and the parameters that define them (whose definition will be given later).

The proposed envelopes for capacity design are based on the Simplified Capacity Design model for rectangular cantilever RC walls developed by Priestley et al. [18]. This model was also used on T-shaped walls by Smyrou et al. [19]. However, the results obtained in this study present several differences with respect to the previous ones, as it is explained in the following sections.

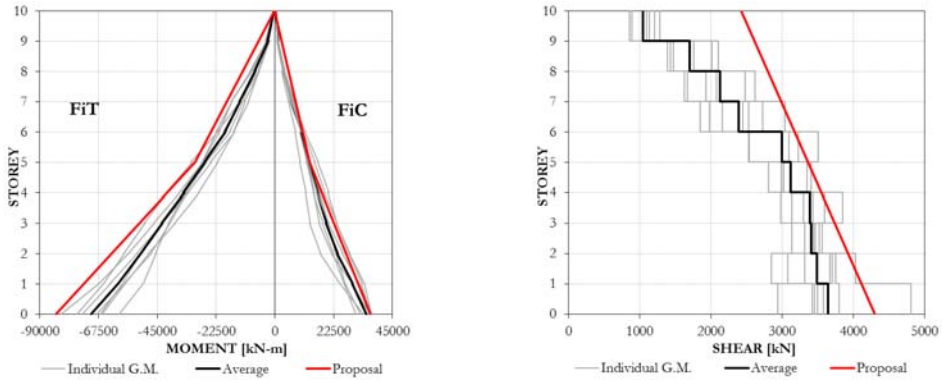


a) b)

Figure 8: Capacity design envelope for cantilever walls: a) moment and b) shear.

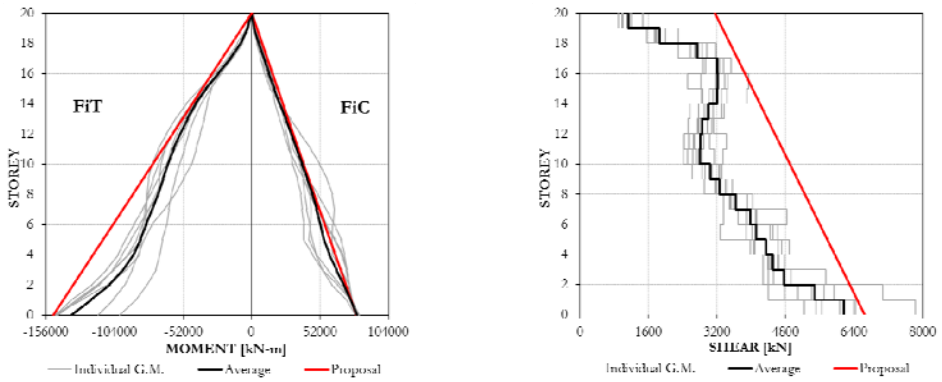
5.1 Superposition of the proposed envelopes and demands from NRHA

Figures 9, 10 and 11 show the maximum moment and shear demands from the NRHA, its average values and the proposed design envelopes (moment and shear forces). Due to the limited space, only some representative results are presented in this paper; however, more information is available elsewhere [20]. As expected, the figures shown different responses of the walls for the flange in tension (FiT) and flange in compression (FiC) directions, which is an important difference with respect to the responses of rectangular walls.



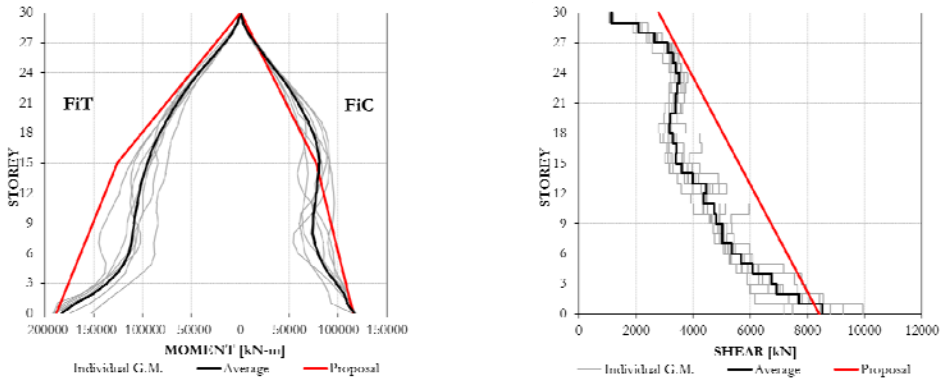
a) b)

Figure 9: T-shaped wall demands and design envelopes for 10-storey building (IR=1.0): a) moment and b) shear force.



a) b)

Figure 10: T-shaped wall demands and design envelopes for 20-storey building (IR=1.5): a) moment and b) shear force.

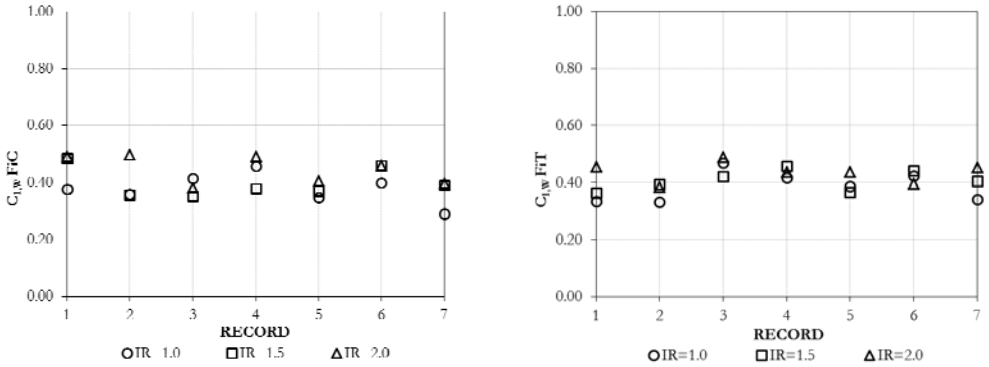


a) b)

Figure 11: T-shaped wall demands and design envelopes for 30-storey building (IR=2.0): a) moment and b) shear force.

5.2 Moment envelope

Figure 12 shows the values of the $C_{1,W}$ coefficient estimated for each record and each seismic intensity for the 10-storey building. This coefficient is the ratio of the mid-height moment to the overstrength base moment M_B (see Figure 8) that considers the overstrength conditions at the base hinge (strain hardening of reinforcement). The $C_{1,W}$ coefficients are similar for FiC and FiT for each intensity level; however, a large number of analyses is necessary to estimate the relationship between the storey numbers (or elastic period), the intensity ratio (IR) and the $C_{1,W}$ coefficient.



a) b)

Figure 12: Ratio of mid-height moment over base moment for T-shaped wall of 10-storey building with different intensity levels: (a) FiC, and (b) FiT.

The $C_{1,W}$ coefficients obtained for the three research buildings and three seismic intensity ratios (IR) are summarized in Table 2. The results obtained in this work show that the dynamic amplification in moment and shear profiles increases for higher intensity. The same tendency has been demonstrated in previous studies of RC wall buildings [3, 18, 19]. Therefore, the moment and shear force envelopes need to be related to the seismic intensity, which is characterized by the curvature ductility demand (μ_Φ) due its direct relationship with the seismic intensity.

N°-Storey	$C_{1,W\ FiC}$			$C_{1,W\ FiT}$		
	IR=1.0	IR=1.5	IR=2.0	IR=1.0	IR=1.5	IR=2.0
10-Storey	0.38	0.40	0.45	0.39	0.41	0.44
20-Storey	0.36	0.48	0.56	0.46	0.46	0.51
30-Storey	0.44	0.58	0.69	0.52	0.50	0.52

Table 2: Summary of $C_{1,W}$ coefficients.

From the $C_{1,W}$ values for FiC the following equation is proposed, which can also be conservatively be used for FiT.

$$C_{1,W} = m\,\mu_\Phi + b \tag{1}$$

where μ_Φ is the curvature ductility demand for FiC at the base of the walls, while the coefficient m and b are given by Equation 2 and Equation 3, respectively. These latter coefficients, estimated with a regression analysis, depend on the elastic periods of the buildings (T_e).

$$m = 0.022\,T_e + 0.006 \tag{2}$$

$$b = 0.03\,T_e + 0.33 \tag{3}$$

For the calibration and definition of previous equations, which define the moment and shear envelopes, the curvature ductility demand for FiC was used, even though the response of the T-shaped walls was different for FiT and FiC. For FiC both stiffness and yield curvature are lesser than for FiT. Therefore, due to the fact that larger nonlinear behaviour (or ductility demand) is expected if the flange acts in compression, the use of the curvature ductility demand for FiC is justified.

5.3 Shear envelope

NRHAs indicate that the shear force demand in the T-shaped walls is larger for the direction with FiT than for that with FiC because the moment strength and the stiffness of the wall is larger for the direction with FiC. Figure 13 shows the coefficient ω_v for the 10-storey building. This coefficient is the ratio of the maximum shear forces from NRHA at the base (V_B) to the shear forces from an equivalent static analysis (V_{ESA}), the capacity design base shear is calculated as the product of V_{ESA} at the base and ω_v (see Figure 8b). To estimate the base shear force of the wall (V_{ESA}) the provided moment strength at the base of the wall should be considered. Table 3 summarizes the maximum shear forces and the amplification factors (ω_v) for the three research buildings and three seismic intensity ratios (IR). The table shows that the values of ω_v depend on the seismic intensity, storey number, and the loading direction (FiC or FiT). Table 3 summarises the maximum average values for base shear forces from NRHA and equivalent static analysis, for T-shaped walls when flange acts in compression (FiC) and tension (FiT). Since the shear is resisted mostly by the web of the walls, identifying the loading direction is not relevant to the definition of the envelope, but the estimation of the ω_v factor should be consistent with the direction of analysis. In this study, the amplification factors ω_v were calculated with the shear forces for FiT. Table 3 shows that ω_v increases with the storey

numbers and with the seismic intensity. Therefore, this amplification factor increases with the elastic period (T_e) and curvature ductility demand (μ_Φ).

	1.5	113071	-167429	1868	2766	5790	-7329	2.65
	2.0	116621	-183336	1927	3029	6824	-8060	2.68

Table 3: Summary of maximum shear forces and amplification factors.

From the ω_v values for FiT, the following equation is proposed.

$$\omega_v = 0.10\mu_\Phi + 0.5T_e + 0.70 \quad (4)$$

The ratio between the base shear and the top shear of the wall is given by:

$$C_3 = -0.08T_e + 0.60 \quad (5)$$

In previous equations, the curvature ductility demand for FiC and the elastic period of the building were used.

5.4 Comparison with previous studies

This section compares the proposed moment and shear design envelopes with those proposed by Priestley et al. [18] and Smyrou et al. [19]. Figure 14 compares the ratio of the mid-height moment over the base moment for the three research buildings. The model of Smyrou et al. is the most conservative for all the research buildings. On the other hand, for the 10-storey building, the ratios of the proposed model are similar to the ones of Priestley et al. approach. However, for taller buildings and larger ductility demands the aforementioned tendency changes and the values obtained from the proposed model are larger than those proposed by Priestley et al.

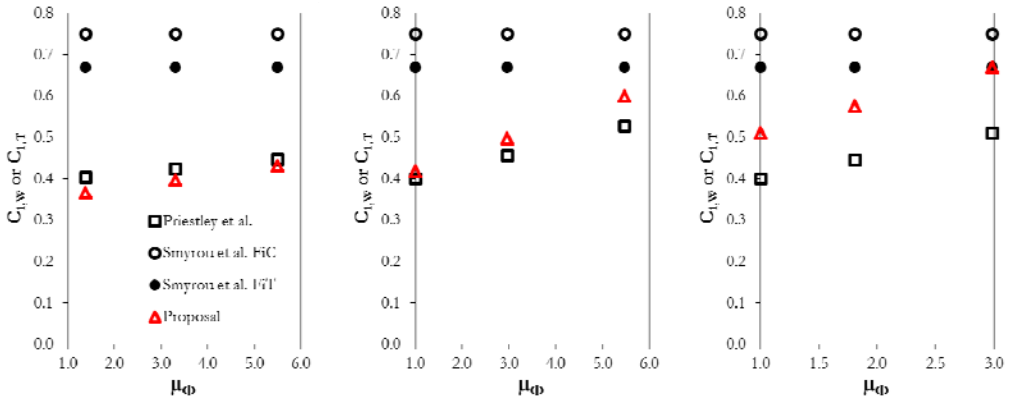

Figure 14: Ratios of mid-height moment over the base moment according to different approaches: a) 10-storey building, b) 20-storey building, and c) 30-storey building.

Figure 15 compares the dynamic amplification factors (ω_v) obtained from the proposed model with those presented by for Smyrou et al. and Priestley et al. for the three buildings. For the 10-storey building, the amplification factors of the proposed model are significantly larger than those of the other two models. For the 20- and 30-storey building, despite the differences between the models are lesser, the proposed approach is more conservative.

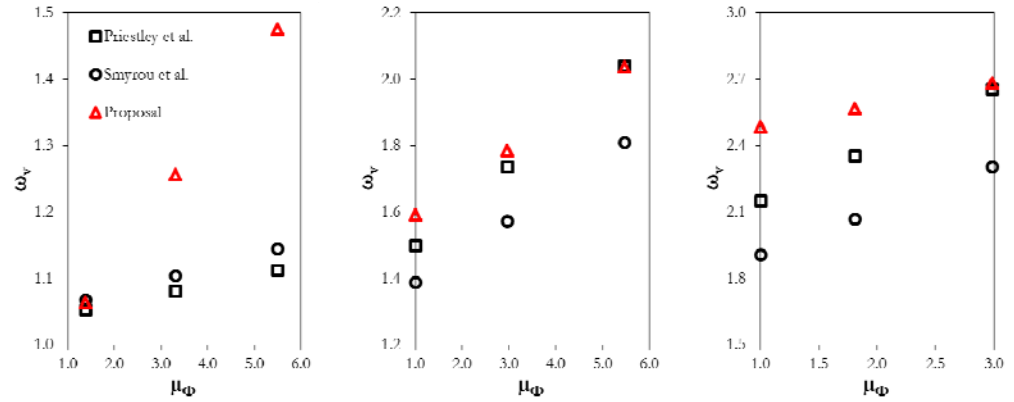

Figure 15: Dynamic amplification factors according to different approaches: a) 10-storey building, b) 20-storey building, and c) 30-storey building.

The discrepancies between the proposed model and the other two studied models can be explained by the different assumptions used in each of the cases. The periods of the studied

buildings are significantly smaller than those of the buildings studied by Priestley et al. and Smyrou et al. The larger periods of the buildings studied by Priestly et al. are related to the use of the direct displacement-based seismic design (DDBD) approach for designing their buildings. In this study, the EC8 design code was used, which resulted in buildings with shorter periods because of the drift limitation of the code. Another difference is that the flexural stiffness considered in this study varies along the height of the buildings due to the variation of the axial load in the walls (or moment strength) and also varies for FiC and FiT, whereas the flexural stiffness considered by Smyrou et al. and Priestley et al. was considered constant above the critical section.

Finally, in this study the whole building was modelled, which is expected to capture the interaction between walls [21].

6 CONCLUSIONS

In this work, three RC buildings with non-rectangular walls were designed according to Eurocode 8 and their seismic performance was assessed from nonlinear response history analysis (NRHA) for three different ground motion intensity levels. Walls were modelled with a model with distributed inelasticity (MDI) and the nonlinear behaviour was represented with a calibrated hysteretic rule. Capacity design envelopes for moment and shear of RC walls are proposed as a function of the building elastic period and the wall curvature ductility demand. These envelopes were defined and calibrated from the results of NRHA on T-shaped walls using a MDI. The proposed design envelopes have differences with respect to previous ones available in the literature. The differences are related to the use of non-rectangular walls in this study where strength and stiffness depend on the direction of loading. Additionally, this study considered the entire building in the analysis model, capturing the interaction and redistribution of strength between the walls within of building. The proposed envelopes are intended to be used for designing RC buildings.

Keywords: Railway, Dynamics, Solver-coupling, Co-Simulation

Abstract. *In the railway domain, studies have been undertaken on the attenuation of vibrations transmitted to the vehicle in order to improve the comfort of the passengers. However, a slight variation in the stiffness and damping characteristics of the train constitutive parts can considerably change the amount of energy transmitted to the soil in terms of vibrations. To predict those ground-borne vibrations generated by the vehicle moving along the track that could affect or disturb the surrounding environment, a relevant option would be to build a numerical model that simulates the passage of a vehicle on a track by coupling a multibody modeling of the train with a finite element modeling of the soil using co-simulation techniques. However the location where the model has to be split remains uncertain and then the border between the multibody and the finite element parts must be determined. The aim of this paper is to emphasize the possibility to perform co-simulation between two or more subsystems using an in-house C++ library package called EasyDyn. Using its co-simulation capabilities, the recoupling of a vehicle, that can be modeled using the minimal coordinates approach in multibody systems and a track modeled using a finite element representation of the rail and sleepers, will be discussed.*

1 INTRODUCTION

Nowadays virtual prototyping constitutes a truly useful tool that can provide decisive information about a specific problem. Indeed, in the railway domain, a modeling of a train passing over a soil can be used in order to estimate the ground-borne vibrations generated. Although single simulation were firstly adopted to predict the effect of a running train on the generated ground wave propagation [1, 2], recent research suggested to split the problem in order to take into account specific complex phenomena [3]. Theferore, Kouroussis et al. designed and validated a two-step model [4, 5, 6] that furnishes a sufficiently accurate prediction of the vibrations generated on the ground for different types of soil. This model uses a first step to estimate the forces applied on the soil through a fully coupled model of the vehicle, the track and a reduced coupled lumped masses (CLM) model of the soil [7]. While the first step uses a multibody representation of the vehicle and a finite element definition of the track, both two-dimensional, the second step involves a three-dimensional modeling of the soil including different layers if required. This soil modeling is performed into a dedicated finite element software which provides the different levels of vibrations for different distances from the track and also for different soil configurations.

In order to go further in the modeling of this vehicle/track/soil problem, it is interesting to investigate the possibilities offered by the co-simulation techniques that couple the problem during the time integration process. However this re-coupling involves a discussion on two different issues: the way the time integration of both subsystems is performed (co-simulation scheme) and the type of data (force or displacement) that are exchanged between each subsystem (co-simulation type). In order to compare efficiently the different co-simulated models, different types of tracks including a fixed soil will be studied. Indeed, depending on the split location and the co-simulation scheme chosen, the simulations can lead to drastically different results. Furthermore, depending on the split location, the number of coupling points and the stiffness and damping characteristics of the coupling link between both subsystems can significantly change the results obtained.

The aim of this work is to investigate the benefits and also the drawbacks of co-simulation techniques through a railway example using an in-house C++ library package called EasyDyn. After a brief description of the model used, the different split locations and coupling approaches will be discussed through the rail deflection results obtained.

2 EASYDYN FRAMEWORK

The EasyDyn framework [8] is an in-house set of tools initially dedicated to the time-integration of differential equations for teaching and research purposes. The framework programmed in C++ evolved in a library package able to simulate the behavior of multibody systems through the minimal coordinates approach. The workflow of the framework, illustrated in Figure 1, consists in:

- Defining the kinematics of bodies of the multibody system through their homogeneous transformation matrices $\mathbf{T_{0,i}}$ and their mass and inertial properties. This step is performed in a python environment that will, thanks to a python library called CaGEM (Computer Aided Generation of Motion), compute the different equations of motion symbolically. At the end of this step, a C++ file containing the kinematics is written.

- Defining applied forces and torques, through their wrench form $\mathbf{R_i}$ and $\mathbf{M_{G_i}}$, into the C++ file such that the multibody library (mbs) of EasyDyn can compute the equations of

motion into their residual form $\vec{\mathbf{f}}$.

- Time-integrating the equations of motion using the simulation (sim) library of EasyDyn.

Recently, co-simulation features were added to EasyDyn to allow it to communicate with other subsystems included in the same program or even with subsystems implemented in other software packages.

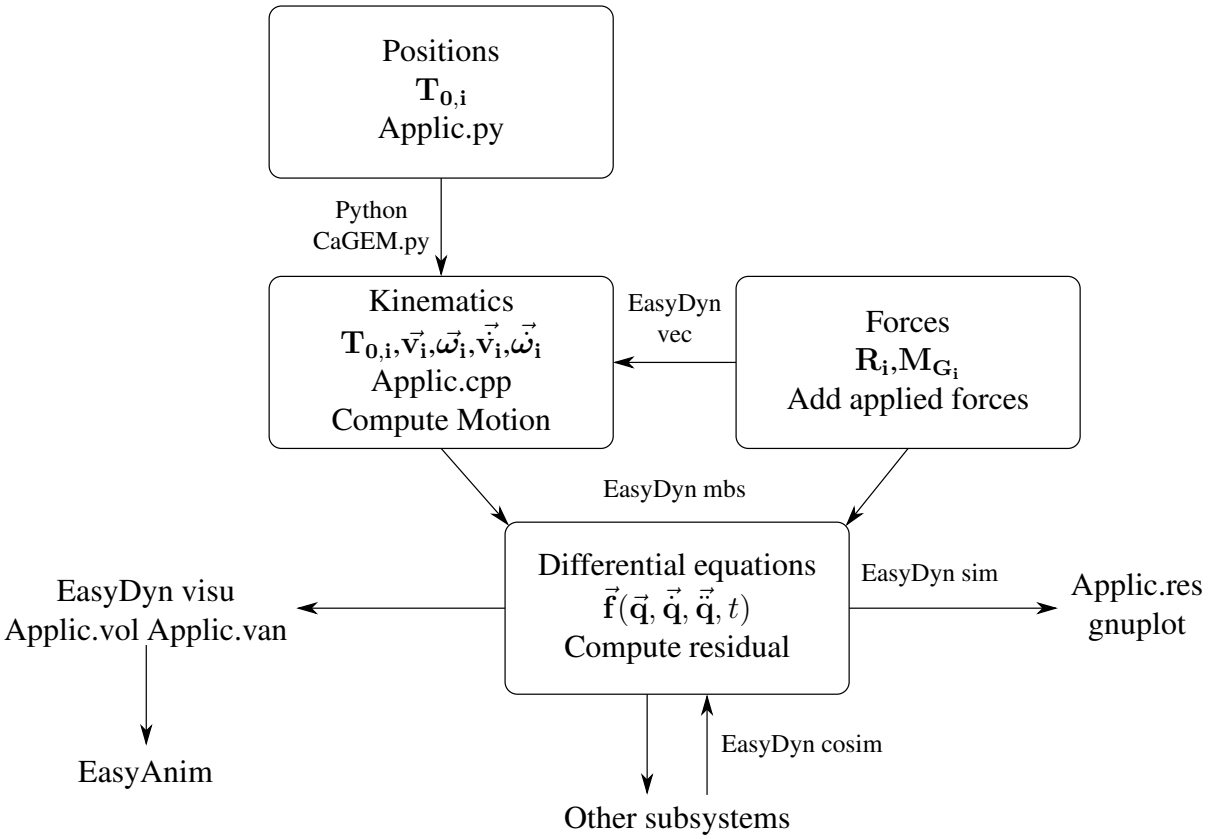

Figure 1: EasyDyn workflow

3 MODEL COMPOSITION

The model studied here (inspired by [9]) to test the co-simulation possibilities offered by EasyDyn is illustrated in Figure 2. It consists of a two-dimensional monolithic modeling of a wheel, on which a constant force $m_{tot}g$, equivalent to the static force applied by the whole vehicle, is applied. The wheel mass is tuned such that the maximal mass per wheelset is reached. The wheel is moving on a track at a v_0 speed and has a vertical degree of freedom q_0. Its contact with the rail is defined by a purely stiff and non-linear Hertz contact of stiffness K_{Hz}.

The track is composed of the rail which is described by its degrees of freedom $q_{r,j}$ related to the motions allowed by the Euler-Bernoulli definition of the rail beam elements. Each rail element possesses two nodes with two degrees of freedom each: one for the vertical translation and one for the rotation about the axis perpendicular to the plane containing the model.

The sleepers are described by their degrees of freedom $q_{s,i}$ that are only vertical. The soil is considered as a fixed reference.

The three parts that forms the monolithic model (vehicle, track and soil) are linked by different elastic elements. Besides the Hertz contact that links the vehicle and the rail, the railpads

(denoted by the subscript p) provides an elastic and damped link between the rail and the sleepers while the ballast (defined by subscript b) links the sleepers with the fixed soil.

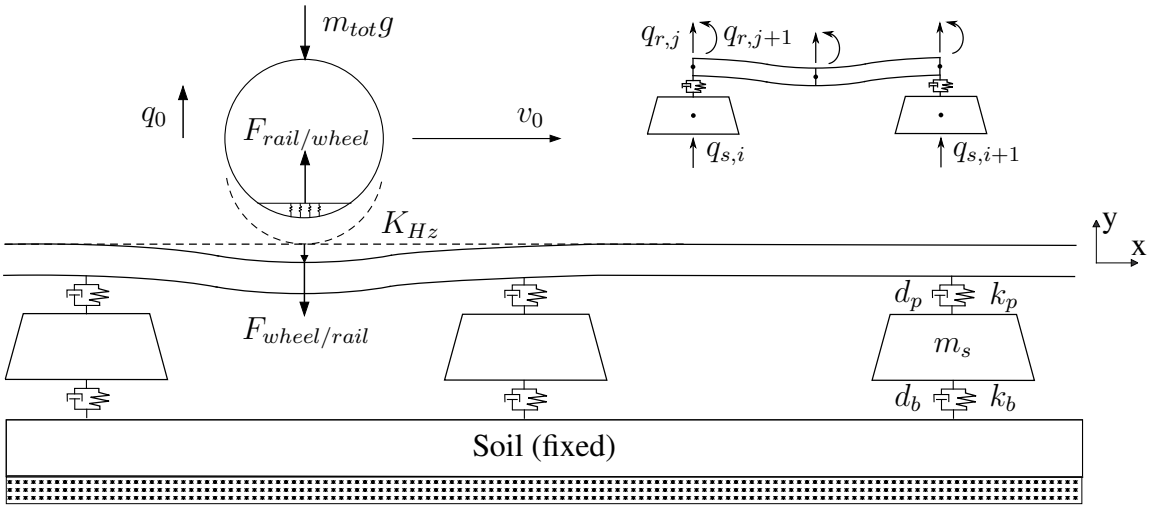

Figure 2: Monolithic modeling of a wheel passing over a flexible track.

The aforementioned monolithic modeling will be taken as a reference to compare the co-simulated results with. Furthermore, the co-simulated models will be very similar to the monolithic one since the only variable element will be the place in which the model will be split, all other parameters remaining identical.

4 SUBSYSTEMS DEFINITION AND INTERACTION

To define the subsystems from the monolithic reference, the only point that requires to be discussed is the split location. Once the subsystems are defined, it has to be decided the type of the data that each subsystem will send to the other one. Moreover, the order in which both subsystems are integrated must be defined.

4.1 Split locations

The co-simulation technique studied in this work consists of an applied-force coupling (see [10, 11]) of both subsystems. This means that the coupling will involve a force (computed or not in each subsystem) applied on both subsystems. Other co-simulation schemes exists such as the constraints coupling [12, 13, 14] but they involve algebraic equations that require specific time-integration schemes. Similar applied-force studies have been undertaken by Antunes et al. [15]. Nevertheless, the present work investigates the case of a flexible track and studies also different split locations and different types of data exchange.

Considering the applied-force methodology, the only way to split the monolithic modeling is through an elastic element that can be used to compute the applied force. The two possible locations are, for this example:

- **The wheel/rail contact:** it involves a relative asymmetry in the degrees of freedom distribution between the subsystems. Moreover, the contact is unique and purely stiff. The contact point is also moving horizontally when observed by the rail.
- **The rail/sleepers:** the asymmetry in the degrees of freedom distribution is minimized with respect to the previous case. Moreover, there exist as many exchange points as the

number of sleepers but in opposition to the wheel/rail case, those points do not move horizontally. Finally, the rail pads are stiff and also damped elements while the Hertz contact is only stiff.

Figure 3 and 4 show the wheel/rail split and rail/sleepers split respectively. The main variables are not changed between those Figures and Figure 2. In both Figures, the subsystem that contains the vehicle is always called Subsystem 1 (S_1) and the one that contains the sleepers, Subsystem 2 (S_2).

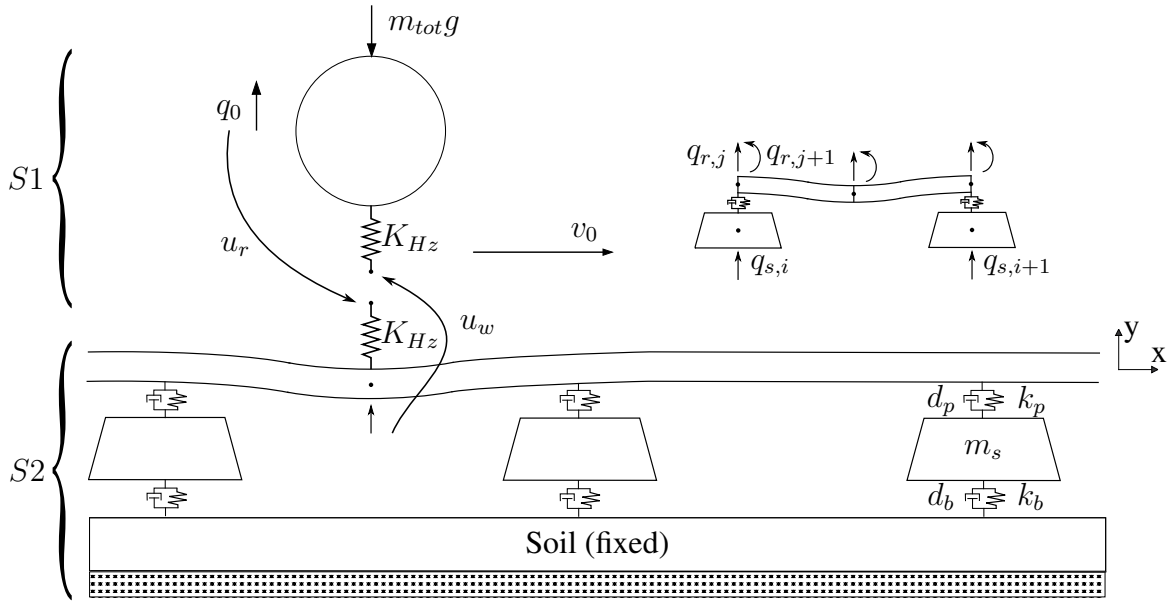

Figure 3: Coupling of wheel and track subsystems through a displacement/displacement method.

4.2 Type of data exchanged

Besides the cutting location, the type of data received by each subsystem (inputs u) must be defined. Indeed, the information going from one subsystem to the other one can take two forms: the displacement of the coupling point or a force applied on the coupling point. In the case of a displacement receiving, the velocity is also required if the element at which the cut is realized presents damping.

In the present work, two different cases will be investigated:

- Both subsystems S_1 and S_2 receive a displacement (called X-X case). Specifically in the case of the Rail/Sleepers cut, the velocity of the coupling points has also to be exchanged since the rail pads present damping characteristics. The X-X Wheel/Rail situation is illustrated in Figure 3.

- Subsystem S_1 receives a displacement and Subsystem S_2 receives a force (called X-T case). Again, a velocity must be sent by S_2 to S_1 in the case of the Rail/Sleepers cut due to the damping properties of the rail pads. The X-T coupling type for a Rail/Sleepers cut is illustrated in Figure 4.

It must be specified that, in the end, a force is always used (being re-computed or not) in the each subsystem. The major difference between the displacement and the force exchange is that

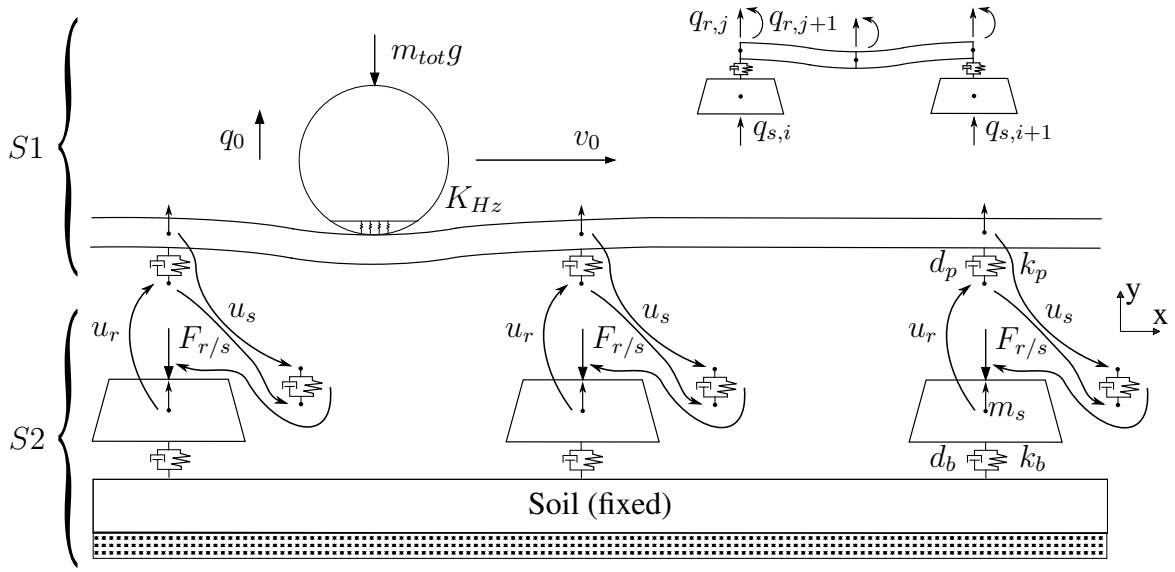

Figure 4: Coupling of wheel-rail and sleepers subsystems through a displacement/force method.

in the force case, the force is a constant until the next time step while this force is a function of the state variables of the subsystem in the displacement exchange.

4.3 Co-simulation schemes used

The co-simulation scheme defines the order in which both subsystems are time-integrated and then how the data are exchanged between them. There exist several types of co-simulation schemes such as explicit, semi-implicit and implicit schemes [10] but this work will focus on two explicit schemes [11]:

- A parallel scheme for which the inputs (coupling variables coming from the other subsystem) of each subsystem are extracted from the state variables of the other subsystem at the beginning of the time step. This means that each subsystem can be time-integrated without waiting for the other one to be integrated. This is called Jacobi scheme.

- A sequential scheme for which both subsystems are integrated sequentially since the inputs of the second subsystem will be computed using the states variables of the first subsystem integration. As for the Jacobi scheme, the inputs for first subsystem integration are computed from the state variables of the other subsystem but at the beginning of the timestep (then the values obtained at the previous time step integration). This is called the Gauß-Seidel scheme.

It has to be mentioned that the data are exchanged following a specific timestep called the macrotimestep while each subsystem can have its own timestep for its time-integration during a macrotimestep. Furthermore, this microtimestep can be different between both subsystems as far as the macrotimestep is common for both of them in order to have a consistent data exchange.

5 RESULTS

In order to demonstrate the co-simulation capabilities of EasyDyn and also the effect of co-simulation techniques on a railway problem, the different aforementioned methods were im-

plemented including the monolithic modeling. The different parameters, whose values are not changed between all the model representations, are expressed in Table 1. It must be mentioned that if the macrotimestep is specified in this table, the microtimestep of each subsystem is not given. This comes from the time integration scheme used that possesses an adaptive time-step. This scheme is identical for both subsystems and is a Newmark-β scheme tuned such that it does not produces numerical damping on the results ($\beta = 0.25$ and $\gamma = 0.5$).

Parameter	Symbol	Value	Unit
Total mass of the wheel	m_{tot}	11250	kg
Hertz contact stiffness	K_{Hz}	92.86	GN/m$^{\frac{3}{2}}$
Rail Young modulus	E	210	GPa
Rail geometrical moment of inertia	I	1987	cm^4
Mass of a sleeper	m_s	90.84	kg
Spacing between two sleepers	l	0.6	m
Area of rail cross section	A_r	63.8	cm^2
Rail density	ρ	7850	kg/m^3
Stiffness of rail pads	k_p	180	MN/m
Stiffness of the ballast	k_b	25.5	MN/m
Damping of rail pads	d_p	28	kNs/m
Damping of the ballast	d_b	40	kNs/m
Number of sleepers	N	50	-
Number of rail elements between sleepers	N_r	2	-
Vehicle speed	v_0	300	km/h
Vehicle initial position	x_0	2	m
Simulation macrotimestep	H	10^{-4}	s

Table 1: Values of the parameters involved in the model simulated.

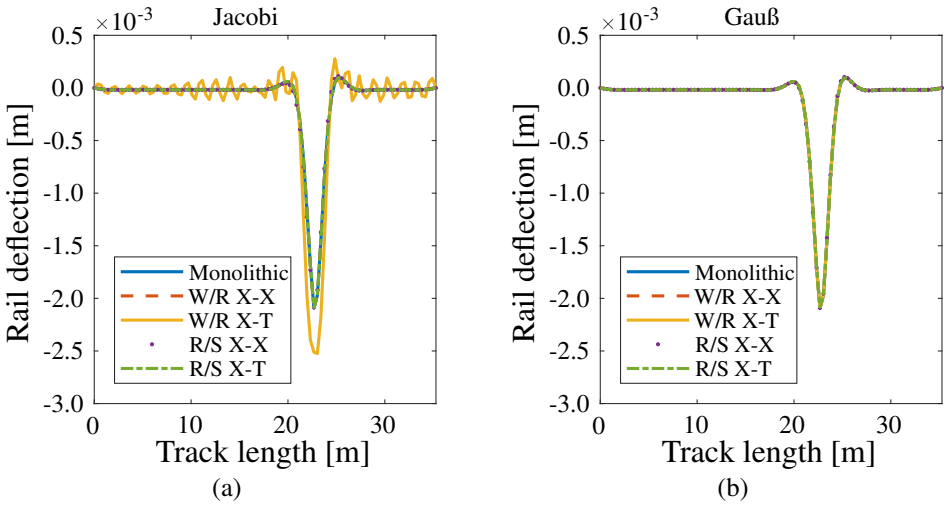

Figure 5: Rail deflexion at $t = 0.25$ s for Wheel/Rail and Rail/Sleepers coupling locations.

Generally speaking, the results obtained are compared through the rail deflection. Figures 5a and 5b illustrates the results obtained for the different coupling locations (W/R and R/S)

and also the different coupling types (X-X and X-T). It can be remarked that a large part of the solutions are slightly different from the monolithic reference. However, one solution involves an abnormal amplification of some specific modes: the Jacobi scheme with an X-T coupling at the wheel/rail contact level.

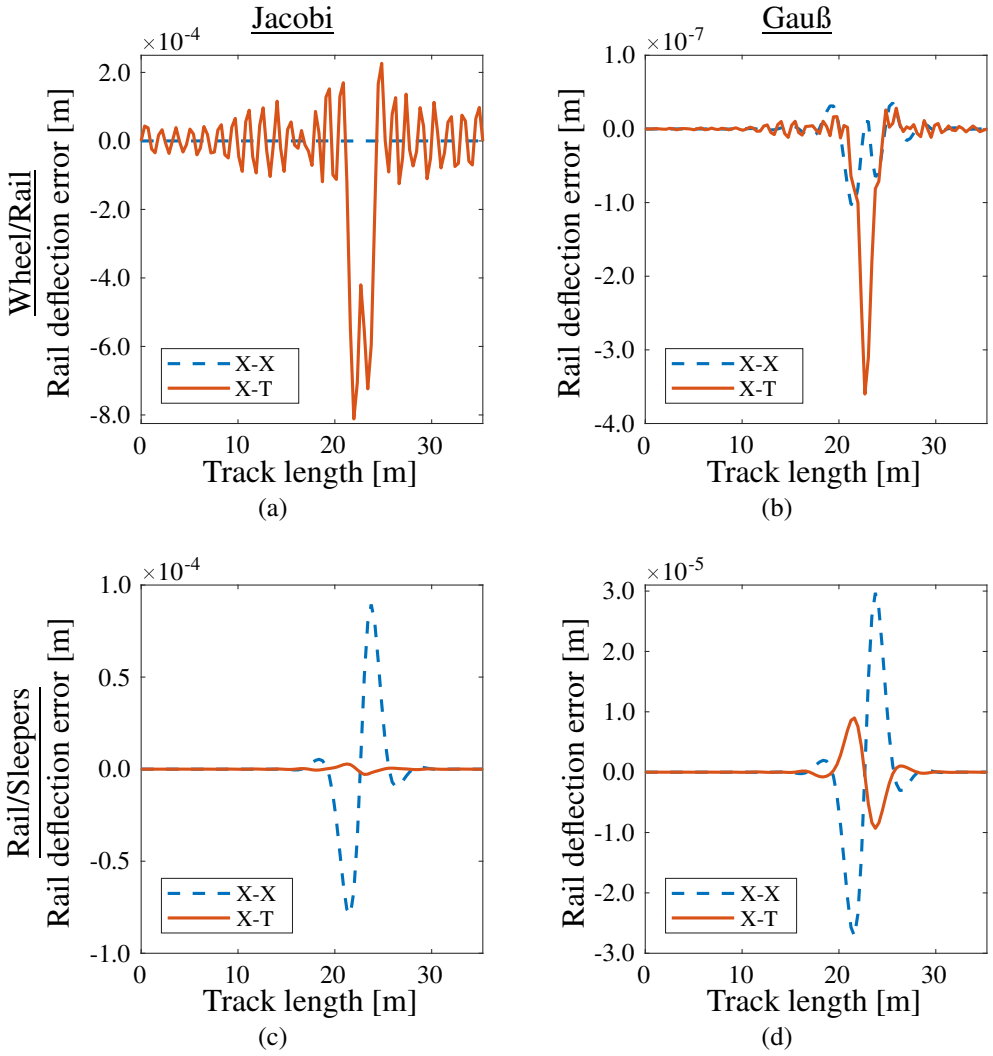

Figure 6: Rail deflexion error at $t = 0.25$ s for Wheel/Rail (top) and Rail/Sleepers (bottom) coupling locations, for Jacobi (left) and Gauß-Seidel (right) coupling approaches and X-X and X-T coupling types.

In order to distinguish the more accurate methods, Figure 6 proposes the rail deflection error defined as the subtraction of the rail deflection given by the monolithic modeling to the considered co-simulated solution. While the instability of the Jacobi X-T W/R is again clearly visible in Figure 6a, a similar but less amplified tendency is present in the corresponding Gauß-Seidel deflection curve in Figure 6b.

Furthermore, due to the classification between the different cases, the error encountered using a specific scheme can easily be observed between different cases. For example, since the Jacobi X-T W/R presents a huge amplification, the generated error remains the biggest found in all the cases. Also, it seems that changing to Gauß-Seidel from Jacobi in the X-X R/S case divides the error by almost 10.

6 CONCLUSIONS

Through a two-dimensional railway example, the capabilities of EasyDyn in co-simulation was highlighted and the effect of co-simulation techniques was studied and compared to the corresponding monolithic modeling. Several cases were developed in terms of coupling location (wheel/rail contact cut and rail pads cut), coupling type (displacement/displacement and displacement/force) and coupling approach (Jacobi and Gauß-Seidel).

Generally speaking, the parallel scheme (Jacobi) provides a less accurate rail deflection than the sequential Gauß-Seidel scheme for this specific railway example. This can be explained by the loss of accuracy in the parallel integration of both subsystems during a macrotimestep while the time-integration of the second subsystem in Gauß-Seidel scheme uses a more accurate version of its input variables thanks to the already performed integration of the first subsystem.

Furthermore, if the displacement/displacement coupling type seems to be more accurate in the wheel/rail coupling location case, the tendency is reversed in the rail/sleepers case. Meanwhile, even if the rail deflection seems more accurate in the wheel/rail coupling case (except for the Jacobi X-T case), the rail/sleepers case remains more stable. Additional studies could be carried out in order to detect if it comes from the lack of physical damping in the coupling element or if it comes from the fact that the coupling point is moving in the wheel/rail case.

Finally, this example was developed in order to determine the best coupling method that could be used to perform co-simulation on a more comprehensive model in order to evaluate the ground-borne vibrations in a 3D modeling of a soil. Indeed, it is currently possible to perform co-simulation between EasyDyn an another software containing a three-dimensional modeling of a soil. Based on the results obtained with the model treated in this work and thanks to the EasyDyn capabilities of co-simulation through network, actual co-simulation between a multibody modeling of a full vehicle and a finite element modeling of a soil will be investigated in further research.

Abstract

The safety evaluation of concrete arch dams requires validated numerical procedures capable of representing the dynamic interaction between the dam and the reservoir during a seismic event. The proposed numerical model employs a discrete element formulation, which is ultimately intended to represent the potential dynamic slip of discontinuities in the rock mass foundation. The present paper focuses on the dam-water interaction modelling, which is a key component of the dynamic response of concrete arch dams. A fluid element discretization of the reservoir domain was adopted, based on Cundall's mixed discretization technique, which provides a displacement formulation for time domain analysis. Simple validation tests confirmed the accuracy of the solution. The model was also applied to a case study involving a recently built arch dam in Northern Portugal. In situ measurements of the dam dynamic response were made by two methods: forced vibration tests, performed before and after filling the reservoir, and a continuous monitoring systems installed in the structure. These measurements provided extensive data that allowed the dynamic characterization of the concrete arch structure and the validation of the numerical model.

Keywords: Concrete dams, Dam-water interaction, Discrete elements.

1 INTRODUCTION

The safety evaluation of concrete arch dams built in regions of significant seismic hazard requires the simulation of their response under various levels of seismic action. The numerical models employed in those analyses have to be validated with experimental data, which is becoming more extensively available nowadays. There is a long experience in the development and application of finite element representations of dam-foundation-reservoir systems [1]. Direct finite element procedures involving nonlinear response history analysis have gained more attention recently, proving to be a highly performing tool [2].

Discrete element models are widely used in rock mechanics, namely in dam foundation analysis [3], given their ability to address the role of discontinuities and their complex nonlinear behavior. Some studies of dynamic slip on rock joints during earthquakes have been performed for arch dam foundations [4], in which the reservoir effect was modelled by the classical Westergaard's added mass technique. A more elaborate representation of the hydrodynamic interaction, involving the discretization of the water domain, is proposed in the present paper. The fluid elements are based on Cundall's mixed discretization technique [5], which is available in the discrete element code 3DEC [6]. The tests performed show that this formulation is capable of addressing the hydrodynamic interaction problem.

A research project involving a recently built arch dam in Northern Portugal is providing extensive data on the dynamic behavior of the structure. In situ measurements of the dam dynamic response were made by two methods: forced vibration tests, performed before and after filling the reservoir, and a continuous monitoring system that has been installed in the structure [7,8]. In the present paper, the results obtained with the proposed numerical model are compared with these field measurements, providing a test of its practical performance under essentially linear conditions, given the relatively low levels of vibration induced.

2 CUNDALL'S MIXED DISCRETIZATION TECHNIQUE

2.1 Fluid elements

The representation of the reservoir in the 3DEC model was achieved with a displacement formulation of fluid elements, as this approach provides a straightforward mechanical interaction with the dam upstream face and the foundation, using the standard contact logic.

The mixed discretization formulation was initially proposed by Marti & Cundall [5] for the accurate solution of plasticity problems with low order elements (or zones). The principle of the mixed discretization technique is to give the element more volumetric flexibility by proper adjustment of the first invariant of the element strain tensor. In the plane case, a 4-node plane element is formed by 2 overlays of 2 uniform-strain triangles. The volumetric strains and stresses are averaged in each overlay. A three-dimensional version of this formulation was subsequently implemented in the 8-node brick element available in the codes FLAC-3D [9] and 3DEC [6]. In this case, the 8-node brick element (or zone) is built by assembling 2 overlays of 5 uniform-strain tetrahedral elements each, as shown in Figure 1. The first invariant of the strain tensor of a particular tetrahedron is evaluated as the volumetric-average value over all tetrahedra in the brick element.

This formulation also allows the representation of the fluid behavior, so it can be used to derive fluid elements. Using the elastic bulk modulus, the same pressure results in the 5 tetrahedra of each overlay. The reduction of the number of deformation modes that this constraint enforces allows a stable numerical response even in the case of zero shear modulus, as it occurs in perfectly-plastic yielding or in a fluid. The main computational advantage of this ap-

proach is that it can be implemented in codes using explicit time stepping algorithms, such as FLAC-3D or 3DEC.

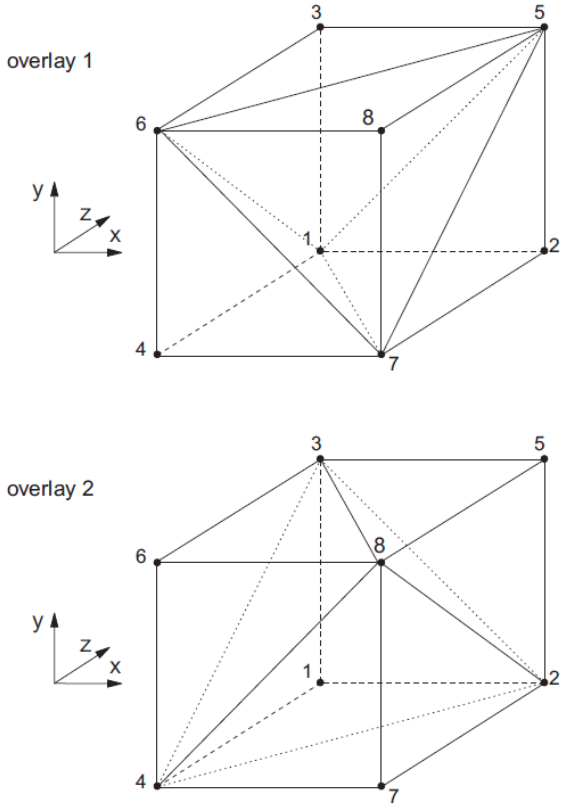

Figure 1: An 8-node element with 2 overlays of 5 tetrahedra in each overlay.

2.2 Application to dam-reservoir interaction problems

Tests of the 3DEC fluid elements based on the mixed discretization technique were performed by comparison with the classical Westergaard solution for a rigid dam with a vertical face. Figure 2 shows the numerical model of the reservoir, for the case of a 100 m high dam. The extension of the reservoir is 200 m, with absorbing boundaries based on a viscous formulation placed at the far end to allow energy radiation [6]. The acceleration was prescribed at the near end, and out of plane displacements were prevented along the two lateral boundaries. A time domain analysis was performed, which converged towards a steady-state solution. Figure 3 shows the pressure diagram along the height, comparing the analytical solution with the results of two fluid element models with different mesh sizes. The numerical results approach the analytical solution, as the element mesh is refined. A fair agreement is obtained with mesh A corresponding to elements with 10 m of dimension (shown in Figure 2), which improves as the element size is reduced to 2.5 m, in mesh B.

A series of tests of this type of fluid elements in transient conditions are presented by Andrian and Agresti [10], using a FLAC-3D model. These authors also performed an application of this model to the case of a gravity dam in Japan, for which field records of earthquake response are available.

3 CASE STUDY

3.1 Description of the dam

The Baixo Sabor hydroelectric project, owned by EDP, is located in Torre de Moncorvo, in the North of Portugal, over the lower reach of river Sabor, a right bank tributary of river Douro. The project includes an arch dam, upstream, and a gravity dam, downstream, to create the pool required for pumping. The main dam is a double curvature arch, with a maximum height of 123 m above the foundation (Figure 4). The crest, at elevation 236.00 m, has a 6.00 m thickness and a total length of 505 m. The arch is formed by 32 blocks, separated by vertical

contraction joints. At the upper central zone of the dam, a crest spillway is installed with 4 openings, equipped with radial gates.

Figure 4: View of Baixo Sabor arch dam and cross-section through the central cantilever

Forced vibration tests were performed for the dynamic characterization of the dam, before the reservoir filling [7], and with full reservoir. The dam is equipped with a seismic monitoring system to evaluate the behavior of the structure when subjected to seismic actions. In addition, a dynamic monitoring system, comprising 20 uniaxial accelerometers, has been installed to continuously characterize its dynamic response. Results obtained during the first six months of operation, which includes the reservoir-filling phase, have clearly shown the effect of the water level on the natural frequencies [8].

3.2 Numerical model

For interpreting the experimental results, a numerical representation of the dam was built with 3DEC [6], a discrete element code widely used in the field of rock mechanics. This code has been applied to the safety assessment of dams, considering the failure modes through the rock foundation, under static or dynamic loads, namely for Baixo Sabor dam [4]. The code allows the consideration of deformable blocks, which are discretized into an internal finite element mesh. For polyhedral rock blocks, tetrahedral elements are preferred, while to represent the concrete arch, 20-node brick elements can be employed. 3DEC has been employed in previous seismic analysis of arch dams considering the nonlinear behavior of the joints, but adopting added-masses to simulate the reservoir effect [11].

The dam model has 32 cantilever blocks separated by vertical contraction joints (Figure 5, where all element faces are approximated by triangular facets). The blocks of the dam cantilevers were discretized into 20-node brick elements, with 3 elements across the thickness. In the present study, focused on the hydrodynamic interaction, a simplified representation of the foundation rock mass was used. An elastic dam-rock interface was adopted, with a joint stiffness calculated to provide an approximate value of the rock mass deformability. Given the low intensity of the dynamic input, the dam contraction joints were assumed elastic. The dam-water and water-foundation interfaces were assigned a null shear stiffness, reproducing a frictionless behavior. At the far end of the reservoir a viscous boundary condition was applied to provide the energy radiation.

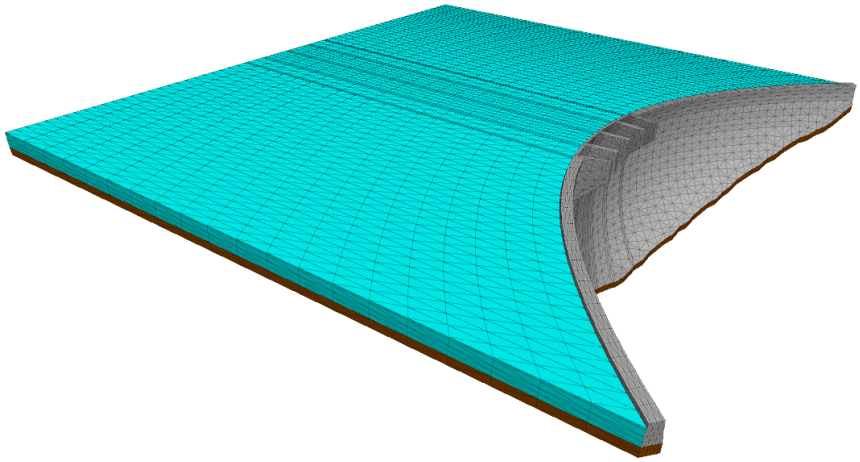

Figure 5: Numerical model of dam and reservoir.

The dam concrete Young's modulus was 36 GPa and the Poisson's ratio was 0.20, values consistent with in situ material tests. A joint normal stiffness of 50 GPa/m was assigned to the dam contraction joints, while a value of 12.5 GPa/m was used for the dam-rock interface. In both cases, the joint shear stiffness was taken as 0.42 of the normal stiffness. The water was assigned a bulk modulus of 2 GPa, and zero shear modulus; the water-dam and water-rock interfaces had a normal stiffness of 2 GPa/m, and zero shear stiffness.

3.3 Comparison of results

In order to determine the natural frequencies in the numerical model, time domain analyses were performed by applying a random excitation to the model, which was simulated by means of horizontal tractions distributed along the dam crest. The frequencies and modal shapes were then identified by standard software, from the response obtained at the locations in the dam that were also used in the experimental measurements.

A comparison of the numerical results with the experimental values is shown in Figure 6. The four lower modal frequencies and configurations, for a condition of full reservoir, are displayed. Regarding the experimental results, a good match had already been found between the forced vibration tests and the continuous monitoring data under ambient vibration conditions [8]. The measurements also agree quite well with the present numerical model using fluid elements, both in terms of frequency values and modal shapes. For this particular wide arch dam, the first mode is the symmetric configuration, while the second mode is anti-symmetric.

The classical Westergaard's added-mass approach is still often used in dam engineering, as it provides a relatively accurate solution with a low computational cost. Various authors have compared it with more elaborate models (e.g. [12]). In general, to have a better approximation, the values of the masses given by the analytical formula need to be scaled, with different scaling factors having been proposed for dams of various heights. In many cases, the full value overestimates the hydrodynamic interaction. The scaling procedure obviously implies the existence of field measurements, which are not available at design stage.

Forced vibration tests		Numerical model	
Freq, (Hz)	Modal configuration	Freq, (Hz)	Modal configuration
2.44		2.44	2.57		2.58	3.34		3.35	3.93		3.82	
Figure 6: Comparison of experimental and numerical modal frequencies and configurations.

In the present study, the results of the fluid element model were also compared with the added-mass representation, using the same dam mesh. In order to match the first frequency, a scaling factor of 0.525 had to be applied to the added-masses. The comparison of frequencies is presented in Table 1. It may be seen that the fluid element results approximate better the measured field data. For example, the difference between the first two frequencies is overestimated with the added-mass solution. However, in many practical situations, the simpler added-mass model can still perform reasonably well in seismic analysis, provided a scaling factor can be determined by either experimental tests or by running a more elaborate numerical model of the reservoir.

Mode	Measured	Fluid elements	Added masses
1	2.44	2.44	2.44
2	2.57	2.58	2.67
3	3.34	3.35	3.56
4	3.93	3.82	4.03

Table 1: Natural frequencies measured in forced vibration tests and results of numerical models with fluid elements and scaled added masses.

4 CONCLUDING REMARKS

Various types of numerical representations have been proposed over the years for the dam-reservoir interaction under dynamic loads. The choice is often dictated by the particular aim of the study and by the formulations available in the code selected for the analysis. The present paper is framed within a discrete element environment, which provides appropriate representation of media with discontinuities. The particular model of the arch dam was focused on the assessment of the dam-water dynamic interaction. The only discontinuities were the dam contraction joints and the interfaces between dam, water and foundation, all of which could be assumed elastic for the low intensity of vibration that was measured in the field experiments. The fluid elements based on Cundall's mixed discretization technique showed a good performance in comparison with the measured data. In the future, this type of model is mainly intended for earthquake analysis, including the evaluation of potential movements in rock joints that may be induced by the seismic event.

Abstract

The paper addresses the significance of soil-structure interaction on the dynamic behaviour of the "Chiaravalle viaduct", based on ambient vibration measurements and numerical simulations. The viaduct is located in Central Italy and is founded on piles in an eluvial-colluvial soil deposit. Experimental modal properties are evaluated by means of the operational modal analysis on accelerometric data from ambient excitation and the role of soil-structure interaction in the interpretation of tests is investigated by means of a refined finite element model of the viaduct. In the soil-structure interaction models the local site condition in correspondence of each bridge piers (resulting from geotechnical and geophysical investigations) are considered in the definition of the soil-foundations compliance. Comparison between the experimental and numerical results highlight the role of the pile-soil-pile interaction, the radiation problem, the pile cap embedment and the variability of the soil stratigraphy along the longitudinal direction of the viaduct in the interpretation of the experimental data.

Keywords: reinforced concrete viaduct; Soil-Structure Interaction; site response; dynamic identification; Operational Modal Analysis; finite element model.

1 INTRODUCTION

The high Italian seismicity in conjunction with the existing dense transport infrastructures require the seismic verification and upgrading of bridges to improve the overall earthquake resilience of communities. In this framework, system identification and structural health monitoring of structures have recently drawn attention for developing assessment tools and reducing uncertainties in the risk assessment procedures. Estimation of the dynamic properties of bridges using recorded vibration data allows the calibration of numerical models for the assessment of the structural safety and for the design of a seismic retrofit (e.g. [1-2]). The Ambient Vibration Test (AVT) is one of the most attractive methods for the evaluation of the dynamic properties of existing constructions in elastic range since it uses natural vibrations as input and foresee the use of small and portable instrumentation. It is generally common practice to perform AVTs, to get modal parameters through the Operational Modal Analysis (OMA) [3-4] and then to calibrate finite element models by changing the mechanical properties of materials, achieving the best fit of the model results with the experimental data. On the contrary, geometry of structural components is assumed in a deterministic way and the structure is assumed to be fixed at the base. However, it is well-known in the literature, from both numerical (e.g. [5-10]) and experimental studies (e.g. [11-12]), that Soil-Structure Interaction (SSI) may play an important role in the dynamic structural response, especially for medium or soft soil conditions and for existing bridges. Thus, numerical models developed to interpret results of vibrational measurements should include the soil-foundation compliance [13].

The objective of this work is to address the significance of soil-structure interaction in the interpretation of the vibrational tests performed on the Chiaravalle viaduct, for which detailed experimental campaigns and surveys on both the soil deposit and the superstructure were available. A 3D finite element model of the bridge is developed accounting for the soil-foundation compliance through Lumped Parameter Models (LPMs) [14], reproducing the dynamic impedances of soil-foundation systems. The latter are obtained with a refined 3D solid model accounting for the pile-soil-pile interaction, the radiation problem and the pile cap embedment. Modal parameters obtained from the OMA are compared with those derived from the numerical models of the bridge.

2 THE CHIARAVALLE VIADUCT

The Chiaravalle Viaduct in Central Italy connects the SS76 road to the Raffaello Sanzio airport (Figure 1a). The viaduct has a total length of 875 m and is constituted by 4 Kinematic Chains (KC#), separated by structural joints. The KCs are constituted by 27.5 m long simply supported girders connected over the piers through post-tensioned cables at the level of the concrete slab. The deck is 12.10 m wide and is constituted by three simply supported V-shaped r.c. beams underlying a 0.25 m thick concrete slab. The column bent piers are constituted by 2 circular columns with diameter of 1.4 m, with heights ranging between about 6÷12 m. Only one pier (P17 of KC2) is different, characterized by a single column with a rounded rectangular cross section (Figure 1a). The foundation of each pier is constituted by 6 r.c. piles of length 30 m and diameter 1 m, connected at the head by a rigid cap of dimensions 5 x 9 x 1.70 m (Figure 1b). During construction, 240 concrete samples were tested, so that results of samples, in conjunction with tests performed specifically for the retrofit design, allow to assume the mechanical parameters (mean compressive strength f_{cm} and elastic mean modulus E_{cm}) reported in Table 1.

From the geomorphological point of view, the viaduct is located in a wide almost flat area with low altitudes set at almost 17-20 m above the mean sea level. With reference to Figure 2a, the geological configuration of the site is constituted by three main formations: a Plio-

Pleistocene marine deposit, prevalently composed of Pleistocene marly, silty clays (AD4) underlying a recent continental covering soil that mainly consists of Quaternary (Pleistocene-Holocene) eluvial-colluvial (sandy and clayey silts, AD1) and Plio-Pleistocene alluvial (mainly sandy gravels with clayey silts lenses, AD2) deposits. Locally, above the Plio-Pleistocene clayey substratum, lenses of sands in clayey-silty matrix can be found (AD3). The area was investigated by means of Boreholes (B), laboratory tests (e.g. triaxial tests, oedometer test) and in-situ Standard Penetration Test (SPT) conducted up to a maximum depth of about 24 m. The geophysical characterization was performed through a Multichannel Analysis of Surface Waves (MASW) and Down Holes (DH). Locations of tests are shown in Figure 2a, b. Furthermore, two Piezometers (PZ) were used to monitor the ground-water level along the viaduct. Results of geotechnical and geophysical surveys leads to the mechanical and dynamic parameters reported in Table 2 for each lithotype.

3 AMBIENT VIBRATION TESTS

Ambient vibration measurements were performed to evaluate modal parameters of the viaduct in order to develop and validate a finite element model for the design of the bridge seismic upgrading.

Table 2. Mechanical and dynamic parameters

AVTs are carried out with low noise unidirectional piezoelectric accelerometers connected to a 24-bit data acquisition system by means of coaxial cables and a portable PC for data storage. Each KC is monitored separately, and different sensor configurations are scheduled where necessary; KC3 was not investigated due to logistic problems. Tests for each KC were performed in different days during the same week of July 2014 in the same timeslot so that ambient effects on the estimated modal parameters can be considered negligible (e.g. [15-17]).

To capture the transverse dynamic behaviour of the bridge, unidirectional accelerometers are placed at each span support and oriented in the transverse direction. For each configuration, 1800 seconds long records sampled at a rate of 2048 Hz are acquired. All the recorded data are processed with standard signal processing techniques before performing the modal analyses. Finally, signals are down-sampled at 51.2 Hz to decrease the number of data and the SSI-Cov technique was used to identify the dynamic properties of the viaduct [3].

4 NUMERICAL MODELLING STRATEGY FOR THE AVTS INTERPRETATION

A refined 3D finite element model of the viaduct is developed to interpret results of AVTs. As for the superstructure, both deck and column bent piers are modelled with elastic frame elements considering the real position of the centroids through rigid links. Mechanical properties of the concrete are based on experimental results presented in Table 1. The deck bearings are modelled with elastic links of suitable stiffnesses. A Fixed Base model (FB) as well as a Compliant Base model (CB) of the viaduct, accounting for the soil-foundation dynamic stiffnesses are developed. In Figure 3a some pictorial views of the FB model are reported.

The CB model, addressing the SSI problem, is developed in the framework of the substructure approach, which allows analysing separately the soil-foundation and the superstructure systems. The analysis of the soil-foundation subdomain furnishes the frequency-dependent complex dynamic impedance matrix of the system that represents the behaviour of the superstructure restraints. Since software dedicated to structural modelling generally performs time domain analyses, the frequency dependent behaviour of the soil-foundation system is generally included through the use of LPMs constituted by assemblages of frequency independent springs, dashpots and masses. Parameters of the lumped system are calibrated to as-

sure the best match between its dynamic stiffness matrix and that of the actual soil-foundation system in a selected frequency range. The LPM presented by Carbonari et al. [14] is adopted to simulate the soil-foundation dynamic behaviour of each pier in the CB model (Figure 3b). Each LPM is characterized by 24 parameters and is able to reproduce the frequency dependent translational, rotational and coupled roto-translational dynamic behaviour of the pile foundations characterised by a double symmetric layout. The external node, representing the interface between the soil-foundation system and the superstructure, is located at the intersection of the two symmetry axes.

4.1 Soil-foundation modelling

The analysis of the soil-foundation system necessary to determine the relevant frequency-dependent impedance matrix is performed adopting a refined 3D solid model. Considering the 2D stratigraphic profile, characterised by an almost constant thicknesses of soil layers for the first 20 m, only one soil-foundation system, assumed to be representative for all the bridge, is modelled within the computer software ANSYS. 8-node brick elements are used to model a cylindrical soil portion with diameter D and height T satisfying conditions $D/d = 50$ and $T/d = 45$ (Figure 4) where d is the pile diameter. The soil is assumed to be a viscoelastic material and infinite elements are provided at boundaries to absorb the outgoing waves and satisfy the radiation condition. Piles are modelled with 2-node beam elements and their physical dimensions are considered by removing cylinders of soils. The beam-solid coupling is assured exploiting potentials of the software. The pile cap, which is assumed to be rigid, is simulated through the soil excavation and the introduction of a rigid constraint, with master node M, between soil-cap interfaces and the piles head. Meshing criteria aim at obtaining an as much as possible structured mesh and assuring a sufficient number of nodes per wavelength.

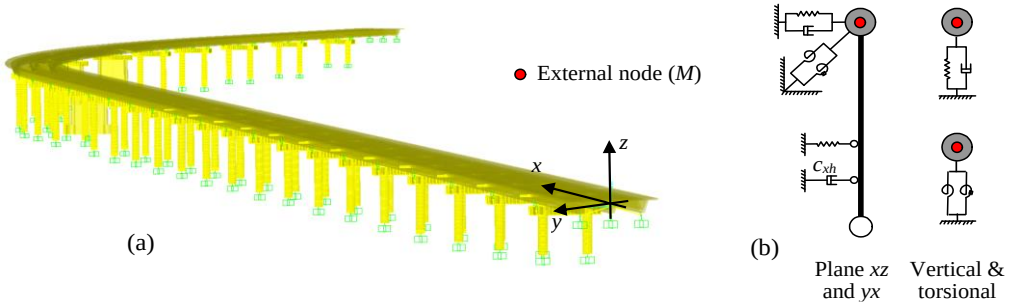

Figure 3. (a) Fixed base model (FB), (b) adopted LPM.

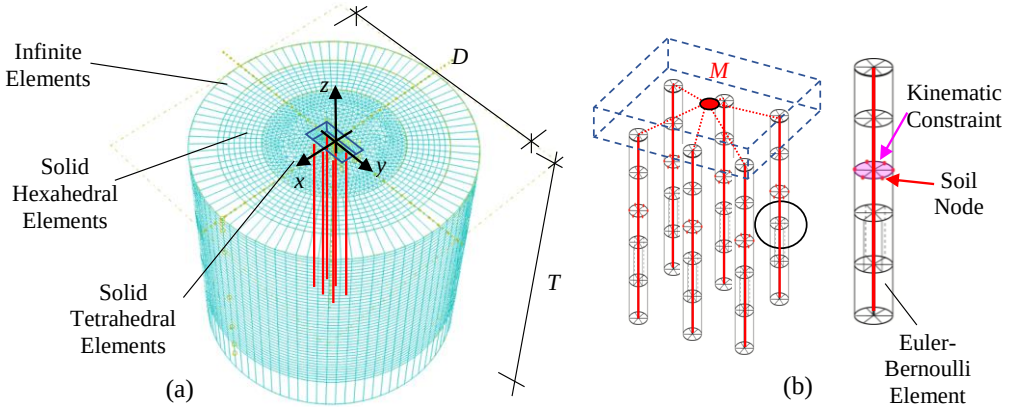

Figure 4. 3D solid finite element model of the soil-foundation system.

Some validation studies are preliminarily performed to define the mesh dimension, balancing results reliability with computational efforts; in particular, the mesh dimension is selected so as the propagation of waves with frequency up to 10 Hz are well captured. Components of the impedance matrix are obtained by imposing unit steady harmonic displacements at the fully restrained master node and evaluating the relevant reaction forces.

Figure 5 shows impedances obtained from the 3D solid model from which a change of the impedance functions slopes at 9.2 Hz is evident. The latter is due to the cut-off frequency of the deposit associated to the fundamental vibration mode of the first soil layer (lithotype DA1). However, as will be shown later, results of experimental tests (AVTs) revealed that the first three structural fundamental frequencies, which are expected to dominate the transverse dynamic response of the bridge, fall below 5 Hz. For this reason, parameters of LPMs are calibrated to reproduce the soil-foundation impedances in the frequency range 0-8 Hz. Impedances of the LPM are reported in Figure 5 with dotted lines. The lumped model is able to capture the dynamic behaviour of the comprehensive 3D solid model very well.

4.2 Experimental data and comparisons with numerical results

In this section results of AVTs are presented in terms of fundamental structural frequencies, modal damping ratios and mode shapes, providing comparisons with those obtained from the developed numerical models (FB and CB).

Figure 6a shows for each KC the normalised mean amplitude of transverse displacements measured above piers at the deck level, obtained from steady-state analysis of the CB model considering unit amplitude forces applied at the master node *M* of the LPMs implemented a the piers base to simulate the soil-foundation compliance. For each KC, the highest amplitude peaks are evident in correspondence of the relevant chain fundamental frequencies; in addition, the interaction of the *i*-th KC is revealed by the presence of lower response peaks also in the response of the other KCs. Three fundamental frequencies are highlighted in Figure 6a for each KC; these will be used to compare experimental and numerical mode shapes.

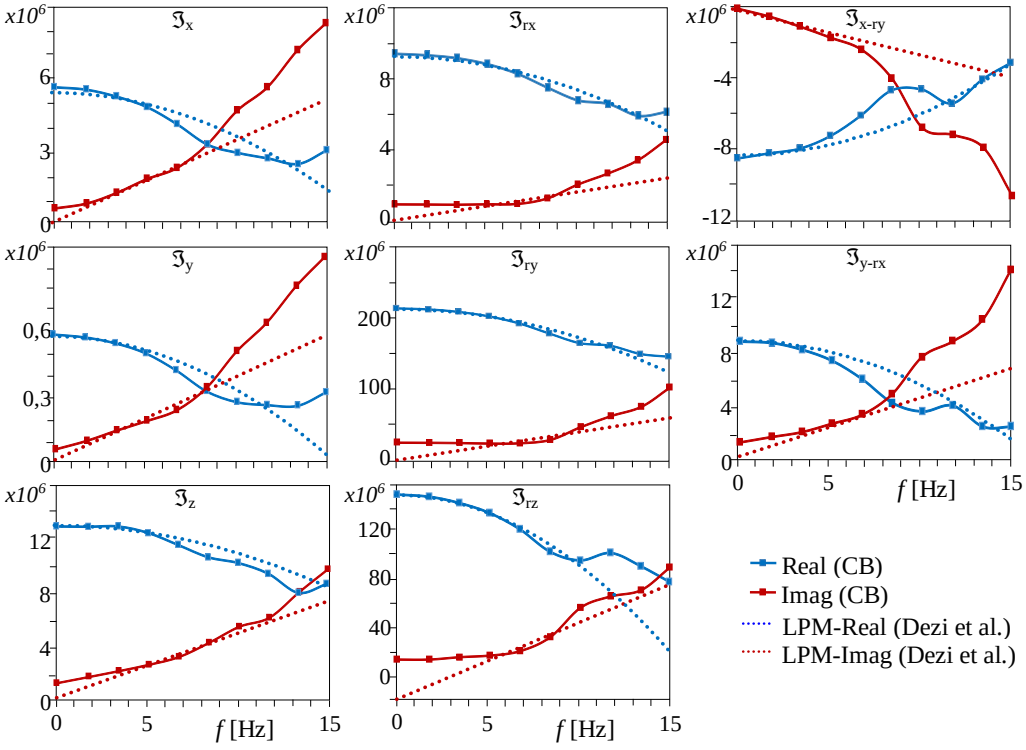

Figure 5. (a) Soil geological profile, (b) position of the test site and geotechnical surveys.

Figure 6b shows the stabilization diagrams obtained from the OMA (continuous lines are the average of PSD of sensors positioned on the KCs), used to identify the viaduct fundamental frequencies. It can be observed that the experimental response is consistent with the numerical one: peaks in the stabilization diagrams are almost aligned with the numerical ones for each KC, as highlighted by vertical dotted lines. Furthermore, also the measured relative amplitude of peaks at different frequencies is almost reproduced by the numerical model for all the KCs, with minor differences for the first peaks of KC1. Results from the FB model is not reported in Figure 6a since its response is sensibly different from the measured one. Results from this model is presented in terms of frequencies and mode shapes, obtained with a classical modal analysis.

Table 3 compares the selected three fundamental structural frequencies obtained from the AVTs and from the numerical models. With reference to experimental results, values of damping ratios are also reported for completeness. Frequencies resulting from the FB model are sensibly higher than the experimental ones; thus, the model appear not able to capture the actual viaduct dynamic behaviour. The CB model better reproduces the experimental data with relative errors always below 1% (excepting mode 3 of KC2).

Figure 7 compares the three transverse mode shapes previously selected for KC1, KC2 and KC4, obtained from the experimental tests and the numerical models, normalized with respect to its relevant maximum transverse displacement.

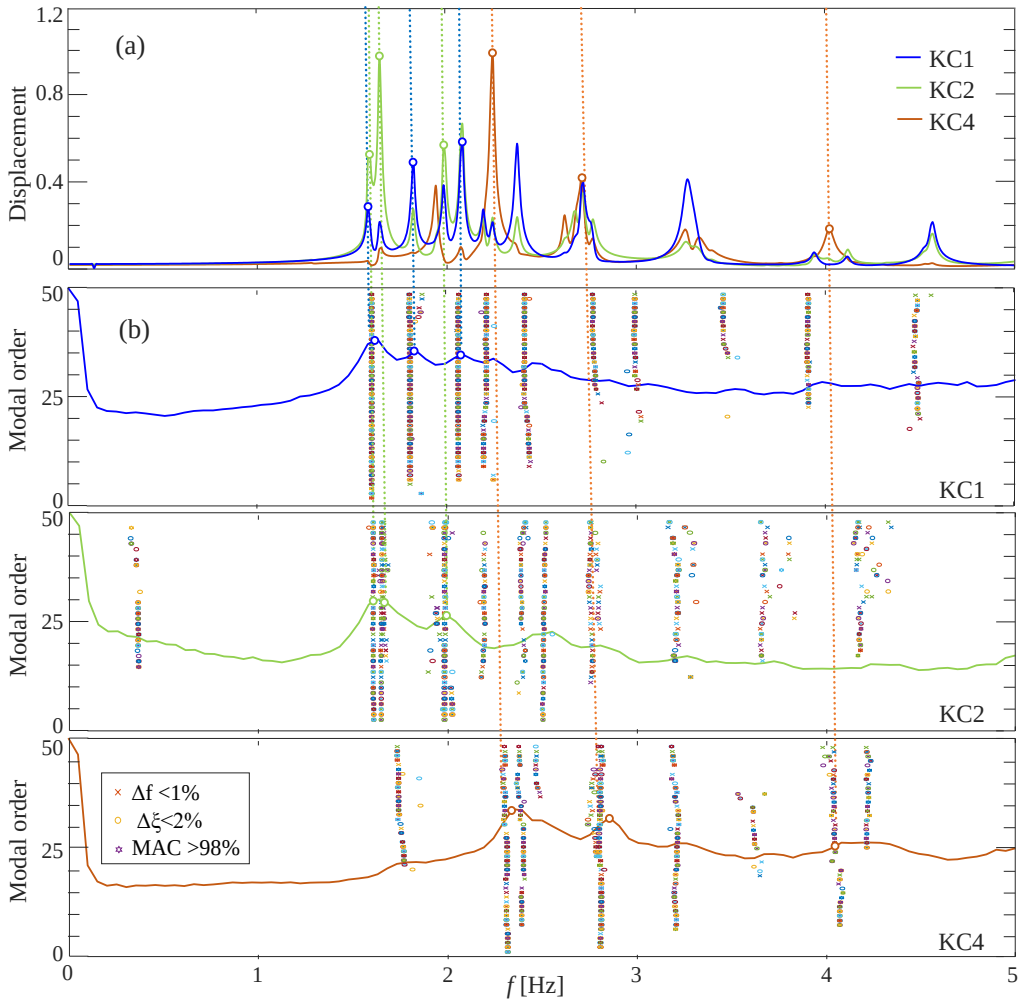

Figure 6. (a) Mean displacement amplitudes from the CB model, (b) stabilization diagrams.

KC#	Mode	OMA		CB		FB	
		f [Hz]	ξ (-)	*f* [Hz]	Δ*f* (%)	*f* [Hz]	Δ*f* (%)
1	1	**1.61**	0.57	1.60	-0.6	1.71	5.8
	2	**1.81**	1.91	1.83	1.1	1.87	3.2
	3	**2.05**	1.78	2.08	1.4	2.14	4.2

Table 3. Comparison of experimental and numerical fundamental frequencies.

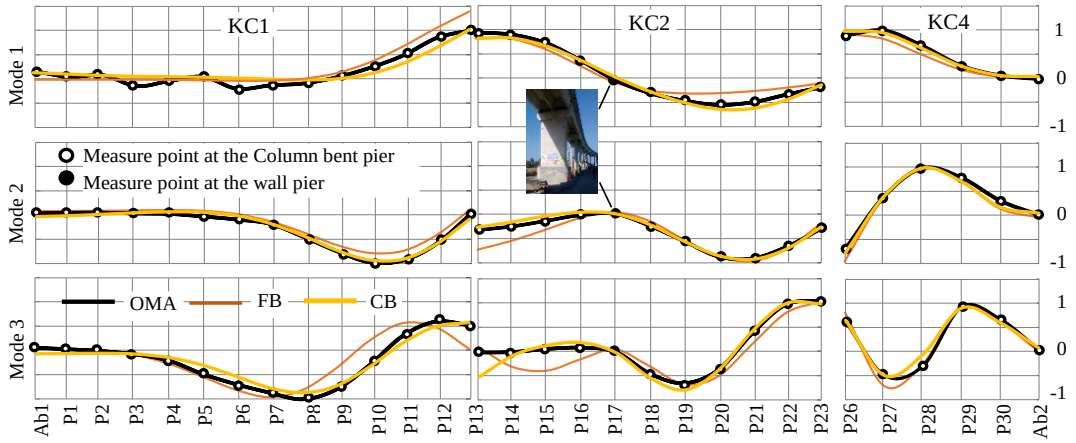

Figure 7. Comparison of numerical and experimental mode shapes.

Experimental data are reported with black lines while continuous lines are used for the numerical results. Experimental and numerical mode shapes from the CB model are practically superimposed while the FB model is not able to well interpret the experimental data.

5 CONCLUSIONS

The significance of soil-structure interaction in the interpretation of vibrational tests performed on bridges has been discussed in this work, with reference to a multi-span r.c. viaduct in Central Italy. A conventional fixed base, as well as a numerical model accounting for the soil-foundation compliance, are developed to interpret the experimental data. The soil-structure interaction is included through the sub-structure approach, simulating the frequency-dependent soil-foundation impedances through lumped parameter models. Models accuracy in reproducing the experimental modal parameters is evaluated on the basis of both fundamental frequencies and mode shapes. It is found that only a numerical model addressing the soil-structure interaction problem in a comprehensive way, i.e. including both the pile-soil-pile and pile-cap interactions, is able to interpret the experimental data.

The presented case study demonstrates that the common practice of calibrating and updating fixed base finite element models to fit experimental results from ambient vibration tests by only changing mechanical properties of materials should be prudently evaluated in the case of bridges, for which soil-structure interaction effects may significantly affects the structure dynamics, especially in the case of soft or medium soil deposits.

Abstract

In the soil-structure interaction framework, among the results of the soil-foundation system analysis (kinematic analysis) the dynamic impedance functions represent the force-displacement relationships of the compliant restraint for the superstructure. The intrinsic variability of soil parameters and of design materials represents an uncertainty source which is necessary to include in the definition of the soil-foundation model, in order to predict the superstructure response adequately. The aim of this work is to evaluate effects of uncertainties on soil dynamic and mechanical properties on the impedance matrix of single piles in homogeneous soils, focusing on the sensitivity of the parameters. A Quasi Monte Carlo (QMC) simulation with sampling based on Sobol' sequence is performed starting from the probabilistic distribution of three main parameters characterizing the soil-piles response, i.e. the soil density, the shear waves velocity and the concrete elastic modulus of piles, available from the literature. The analyses are carried out through the numerical model developed by the Authors and a sensitivity study on the optimal number of simulations is performed, comparing the use of Quasi-random sampling with the classical Monte Carlo simulation technique. Moreover, results of sensitivity studies show the influence of variability of each considered mechanical parameter on the global response of the soil-foundation system.

Keywords: Probabilistic Analysis, Pile foundations, Soil-foundation impedance matrix, Soil-Structure Interaction Analysis, Quasi-random Simulation.

1 INTRODUCTION

It is known from the literature that Soil-Structure Interaction (SSI) has a not negligible impact on the structural response [1, 2]. To properly account for SSI in the structural design, the sub-structure approach can be employed under the assumption of a linear soil-foundation behaviour [3]. The method provides for the analysis of the structural system in two steps. The first one (kinematic interaction analysis) studies the soil-foundation system subjected to the Free-Field Motion (FFM) and provides (i) the dynamic impedance functions, which represent the force-displacement relationships of the compliant restraint for the superstructure, and (ii) the Foundation Input Motion (FIM), i.e. the actual motion experienced by the foundation because of the seismic waves propagating in the soil. The second step (inertial interaction analysis), allows to evaluate the actual superstructure response under the FIM with a compliant base characterized by the soil-foundation impedance matrix.

The soil-foundation geometrical and mechanical parameters largely affect results of the kinematic interaction analysis. Classically, deterministic values are adopted for the main quantities governing the kinematic interaction, basing on design statements, design drawings, field tests or expert engineering judgement. Even if the intrinsic variability of natural and construction materials has been widely studied in the literature, with both focus on the statistical characterization of soil mechanical properties [4, 5] and structural materials [6, 7], few works dealing with probabilistic approach for SSI are available [8-10] and, to the authors' knowledge, none of them address the problem of deep foundations. Since the kinematic interaction may produce not negligible effects on pile foundations [11, 12], a particular interest on the probabilistic characterization of such substructure behaviour arises.

This paper deals with the study of the impedance matrix of a single pile in homogenous soil with a probabilistic approach, suitably accounting for uncertainties related to the mechanical parameters of the soil-foundation system through statistic distributions available in the literature. The effects of the variability of the soil density, the shear wave velocity and the concrete elastic modulus on the dynamic impedance functions are investigated through the analytical model developed by the Authors [13], assuming no correlation between the aleatoric variables. Firstly, sensitivity analyses are performed to validate the sampling method: a comparison between Monte Carlo Simulations (MCSs) [14] and the adopted Sobol' Quasi Random Sampling (QRS) [15], which allows for a significant reduction of the number of samples and consequently of the computational effort, is shown. Then, trends of impedance functions in the frequency range of practical interest for seismic engineering is discussed. Finally, a second sensitivity analysis on the variable parameters highlights the different role of each one on the final output.

2 VARIABILITY OF SOIL AND FOUNDATION MECHANICAL PARAMETERS

In the sub-structure method, the impedance matrix defines the relationship between forces and displacements of the soil-foundation system that can be used in the inertial interaction analysis to simulate the foundation compliance. For a single pile of circular cross-section, the impedance matrix assumes the form

$$\mathfrak{I}(\omega)=\begin{bmatrix} \mathfrak{I}_x & 0 & 0 & 0 & \mathfrak{I}_{x-ry} & 0 \\ & \mathfrak{I}_y & 0 & \mathfrak{I}_{y-rx} & 0 & 0 \\ & & \mathfrak{I}_z & 0 & 0 & 0 \\ & & & \mathfrak{I}_{rx} & 0 & 0 \\ & sym & & & \mathfrak{I}_{ry} & 0 \\ & & & & & \mathfrak{I}_{rz} \end{bmatrix} \tag{1}$$

whose terms are complex-valued and express the harmonic forces to be applied at the pile head, where the degrees of freedom of the system are condensed according to the sub-structuring approach, to produce its uncoupled vibration.

Each term of the matrix depends on the mechanical and geometrical characteristics of the entire system. To investigate the effects of the variability of mechanical parameters on the impedance functions, three fundamental quantities are considered as independent aleatoric variables: the soil density ρ_s, the shear wave velocity V_s and the concrete elastic modulus E_p. The latter is evaluated basing on the variability of the concrete cylindrical compressive strength f_c. Mean values (μ), standard deviations (σ) and Coefficients of Variation (COV) of the variable parameters are chosen to represent a reinforced concrete foundation in homogeneous sand soil [5, 16] starting from values available in the literature [4, 7]. Regarding the other parameters affecting the definition of the impedance functions (i.e. soil and concrete Poisson's modulus, soil damping, concrete density), deterministic values are assumed since available works in the literature [8, 17] reveal that their variability is negligible as much as their effect on the impedance functions. Table 1 shows the statistical distributions and their relevant parameters for the three examined parameters, while Table 2 lists the deterministic values adopted for soil and concrete Poisson's modulus, soil and concrete damping and concrete density.

Uncertainties	Statistical Distribution	μ	σ	COV
Soil density ρ_s [t/m^3]	Normal	17.5	-	10
Shear wave velocity V_s [m/s]	Lognormal	400	σ_{ln} =0.39	-
Concrete elastic modulus E_p [MPa]	Lognormal	3E4	$\sigma_{ln\,(f_c)}$ =0.20	-

Table 1: Statistical distributions for ρ_s, V_s, f_c.

Mechanical parameters	value
Soil Poisson's Modulus v_s [-]	0.4
Concrete Poisson's Modulus v_p [-]	0.2
Soil Damping ξ_s [-]	0.05
Concrete Density ρ_p [t/m^3]	2.5

Table 2: Deterministic parameters.

3 CASE STUDY

In this paper, a single floating pile in a homogeneous deposit is considered, with L/d = 16, where L is the total length of the pile and d is its diameter. The analyses are performed through the analytical model proposed by the Authors in [13], in which the problem is formulated in the frequency domain, the pile is assumed to be a linear elastic Euler-Bernoulli beam, the soil is constituted by infinite independent horizontal layers, and the soil-pile interaction is included through Elastodynamic Greens' functions available in the literature. Figure 1 illustrates the case study and summarizes its geometrical and mechanical characteristics.

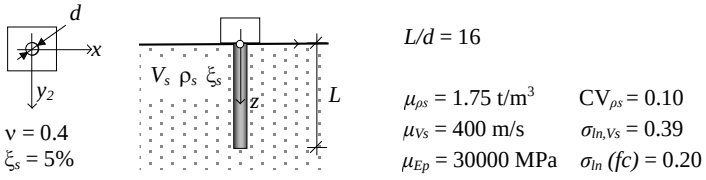

Figure 1: Case study.

4 GENERATION OF SAMPLES

The propagation of the uncertainties through the analytical model starts with a sampling procedure on the independent aleatoric variables according to their probability distributions. It is known that simple Monte Carlo sampling has a low efficiency since it requires a huge number of simulations to achieve a high precision in the results. Many different probabilistic approaches capable of reducing the required number of analyses without a loss in the accuracy of the final output are available in the literature, with many structural and seismic engineering applications (see the use of Latin Hypercube Sampling in [18], Importance Sampling [19] or Subset Simulation in [20, 21]). Among them, Quasi-Random Sampling (QRS) based on Sobol' sequence [15] is adopted in this paper. In the following sections, a brief recall on the QRS is provided, then a sensitivity analysis on the optimal number of simulations required is shown and commented to validate the adopted procedure in comparison with the standard Monte Carlo Simulation (MCS).

4.1 Quasi-Random Sampling (QRS)

Differently from the MCS, where samples are generated from a pseudo-random number source and result randomly distributed, in sense of being completely unpredictable, quasi-random samples derive from a particular algorithm in which the choice of the samples is steered to ensure a uniform cover of the sample space. Hence, quasi-random sampling techniques provide good results, since typical gaps or clusters of the MCS are avoided. Among the various quasi-random sequences available in the literature, Sobol' sequence can be used in sensitivity analysis [22], also for engineering applications [23]. More details about the efficiency of Sobol' sequence can be found in [24].

4.2 Comparison of Sobol' QRS and MCS

A preliminary study on the optimal number of required analyses is developed to validate the adopted sampling procedure, assuming results from the standard MCS as benchmark. The comparison is made on the basis of results of the sensitivity analyses.

Variance-based methods for sensitivity analysis [22] allow to study the influence of the input parameter uncertainties on the uncertainty of the final output, adopting variance as a measure of uncertainty. The first-order index, also called 'importance measure', represents the main effect contribution of each input factor to the variance of the output. Calling X_i the sample vector of the i-th input variable and Y_ω the output vector (one for each ω), the conditional expectation $E(Y_\omega | X_i)$ can be calculated by cutting the entire input variable domain into i slices and averaging the values of $(Y_\omega | X_i)$ within the same slice X_i. Thus, if the conditional expectation $E(Y_\omega | X_i)$ has a large variation across X_i, i.e. the variance of $E(Y_\omega | X_i)$, $V[E(Y_\omega | X_i)]$, is high, X_i is revealed to be important. The first-order sensitivity index $S_{i,\omega}$ for X_i is obtained dividing $V[E(Y_\omega | X_i)]$ for the unconditional variance $V(X_i)$:

$$S_{i,\omega} = \frac{V\left[E\left(Y_\omega \mid X_i\right)\right]}{V\left(X_i\right)} \tag{2}$$

Since the considered variable parameters have been assumed independent, the following condition holds

$$S_\omega = \sum_i S_{i,\omega} = 1 \tag{3}$$

where, for the present applications, i = 1, 2, 3 refers to the aleatoric parameters ρ_s, V_s and E_p. Values of S_ω greater than 1 suggests that a not sufficiently high number of samples have been considered. A comparison between MCS and Sobol' QRS is shown in Table 3 in terms of the mean value $\overline{S}$ of the sum of sensitivity indexes within the investigated frequency range, computed for different total numbers of processed analyses. It is worth noting that QRS performs much better than MCS. A reduction of the number of samples is gradually applied to reach an optimum on the minimum number of analyses to be performed with a maximum loss in precision equal to 1%. As a result, 10000 is chosen as the number of analyses to perform.

	Number of simulations			
	125000 (MCS)	25000 (QRS)	10000 (QRS)	5000 (QRS)
$\overline{S}$	1.164	1.002	1.006	1.012

Table 3: Evaluation of the sum of first-order sensitivity indexes.

5 RESULTS

5.1 Variability of impedance functions

Starting from previous considerations, 10000 analyses were executed on the soil-foundation model described in Chapters 2 and 3. The parameter distributions obtained through Sobol' QRS are illustrated in Figure 3 for the investigated aleatoric variables.

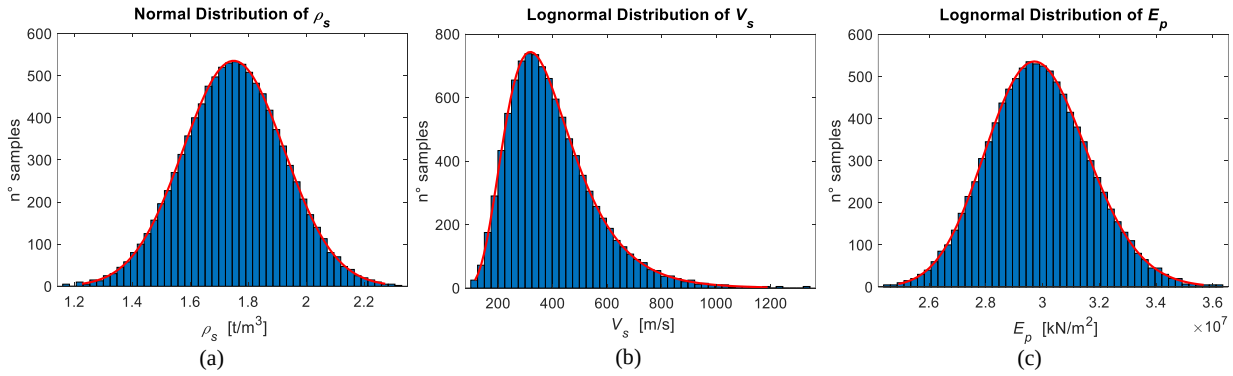

Figure 3: Sample distributions: (a) normal distribution of ρ_s, (b) lognormal distribution of V_s, (c) lognormal distribution of E_p

Boxplots in the following graphs show the statistic distribution of both real and imaginary components of the impedance functions in the frequency range 0-15 Hz, which may be considered of practical interest in earthquake engineering. In detail, the red dashed line represents the median trend of the response, the blue rectangular box encloses the 10th and the 90th percentile of the impedance at each frequency, black vertical dashed lines extend up to the 99th percentile of the output and red crosses represent the "outliers".

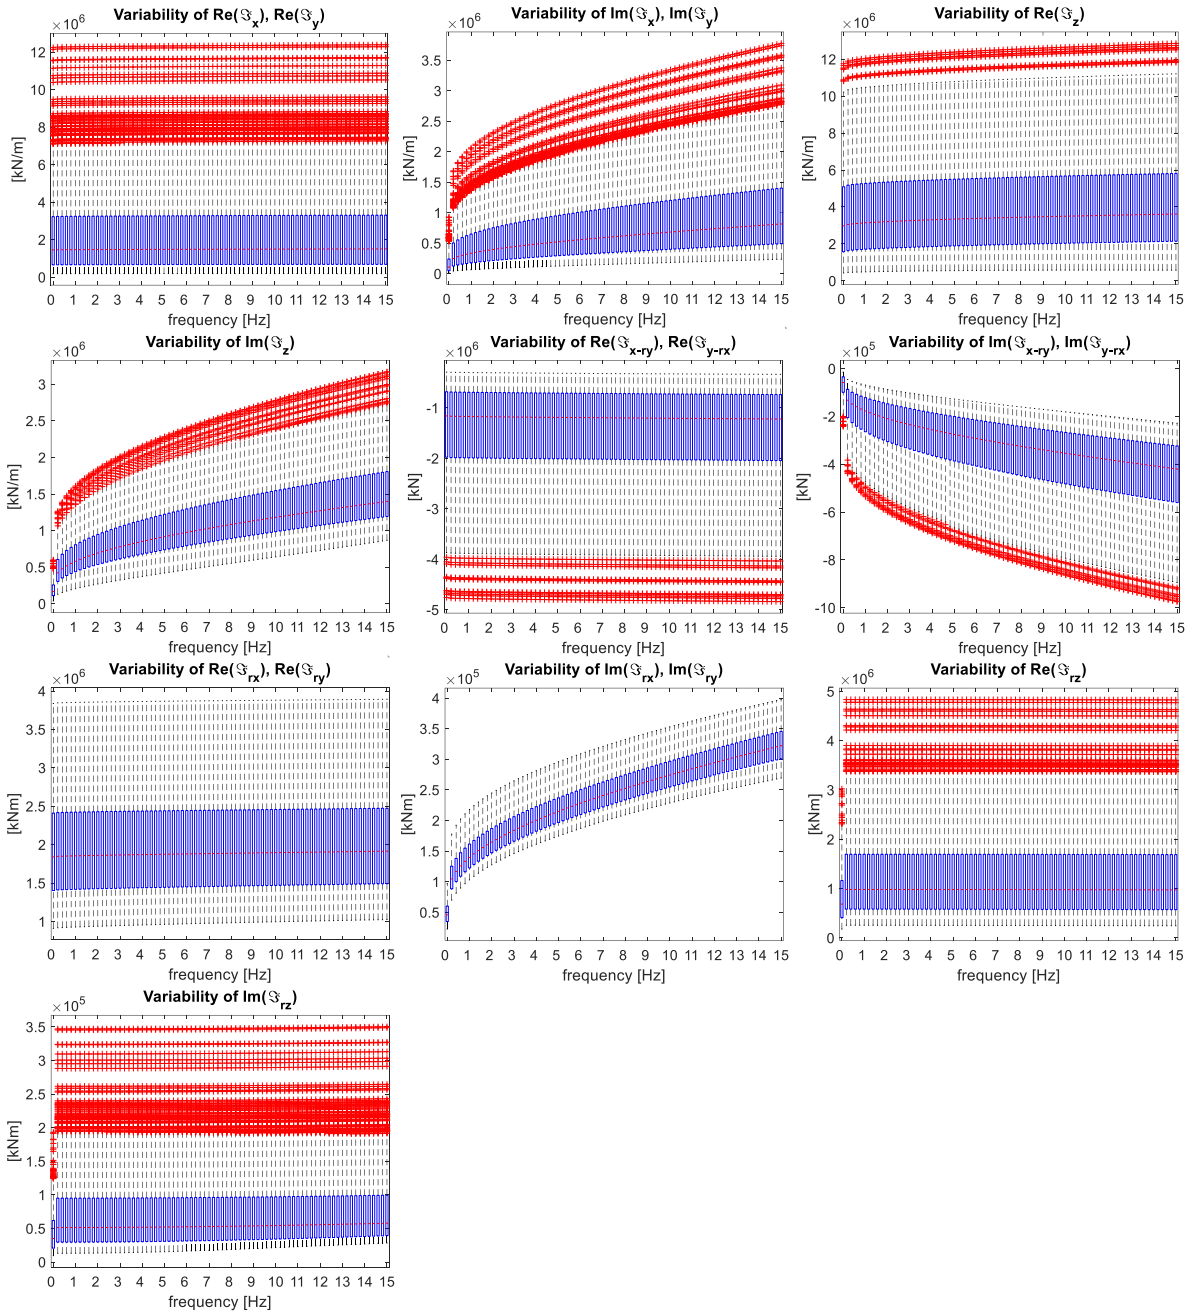

Figure 4: Impedance functions variability on the frequency range 0-15 Hz.

It is worth noting that the median trend well approximates the general one, while the ratio

$$r = \frac{\Im_{90th}}{\Im_{10th}} \tag{4}$$

between impedance values at 10th percentile and those at 90th can vary from 1.25 to 3, reflecting the great variability of the global response. Then, the variability of input parameters plays an important role in the definition of the soil-foundation response under the excitation produced by seismic waves, which should be properly addressed when the kinematic analysis is performed to reliably predict pile stress resultants, impedances and foundation input motion.

5.2 Sensitivity analysis on ρ_s, V_s and E_p

Sensitivity indexes are evaluated for each variable parameter. For sake of brevity, only sensitivity indexes of the real part of rotational impedance function $\Im_{rx}$ are illustrated in Figure 5. The graph shows the higher values on V_s, with S_{Vs} equal to 9 times S_{Ep} and over 10 times $S_{\rho s}$. Furthermore, a constant trend on the frequencies reveals that V_s is the most influential parameter for all the interest frequency domain. Similar results are obtained for other impedances functions. Hence, the response of the overall system is mainly governed by the variability of the shear wave velocity, while the soil density and the concrete elastic modulus have no predominant effect on the response in the frequency domain of interest.

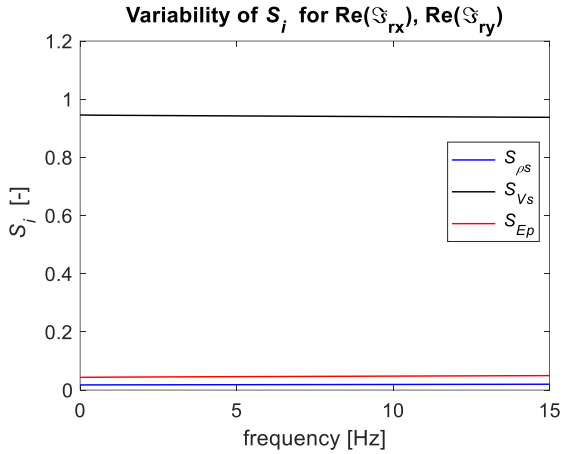

Figure 5: Sensitivity indexes of ρ_s, V_s and E_p; variability on the frequency range 0-15 Hz.

6 CONCLUSIONS

In this paper, first results of a research dealing with the effects of soil and foundation mechanical parameter uncertainties on soil-structure interaction analysis are addressed, focusing on the impedance functions of a single pile in a homogeneous soil deposit. Uncertainties are taken into account through statistical distributions of three fundamental parameters influencing the soil-pile system response, the soil density, the shear wave velocity and the elastic modulus of the pile concrete. The latter are assumed to be mutually independent. A Sobol's sequence Quasi-Random Sampling (QRS) technique is adopted to perform probabilistic analyses. A comparison between QRS and Monte Carlo Simulation (MCS) is discussed with the purpose of evaluating the optimal number of analyses to perform. The results of 10000 QRS analyses are shown and discussed, highlighting the not negligible role of uncertainties of the input parameters on the overall response. It appears that the variability of the input parameters should be included both in the kinematic analysis, where stresses on the foundation, features of the compliant base and foundation input motion are evaluated, and consequently in the inertial one, since the system "filters" the input experienced by the superstructure. Finally, sensitivity indexes of the three independent variables are calculated, addressing the soil shear wave velocity as the most influential parameter for the impedance variability. From the sensitivity analysis results, the primary influence of the shear wave velocity on the overall response allows to say that future applications may be developed considering the variability on V_s only, reducing the total computational effort without a significant loss in the result accuracy. Further studies are needed to investigate the role of uncertainties in the response of other kind of soil-substructure systems (for example, pile-group foundations), on both the impedance matrix and the FIM in order to characterize the kinematic interaction probabilistically.

Abstract

Tensile structures are one of the most convenient solutions for covering large spans. For both temporary and permanent uses, they are optimal as sport arenas, meeting rooms or concert halls. However, codes and literature neglect these structures thus making it difficult to carry out preliminary designs for this structural typology in order to estimate the cost-benefit ratio compared to others. On the contrary, parametric equations used to preliminarily estimate the static and dynamic behavior of these structures are useful to designers. In order to give parametric information about some examples of these structures, this paper investigates the initial natural frequency and vertical displacements under dead and permeant loads of cable nets, with a hyperbolic paraboloid shape and square plan, depending on geometry. In total, two curvatures of a hyperbolic paraboloid surface and five different plan sizes are calculated with eight different cable tractions in order to give design trends. The trends are illustrated with an error bar resulting from the variation between different tractions considered for each geometry. The results are useful to preliminarily estimate the cost and the range of interference between wind and structure.

Keywords: Tensile structures, Cable net, modal analyses, design trends.

1 INTRODUCTION

Tensile structures for roofs are a particularly convenient way of covering large spans for both temporary or permanent conditions. Commonly, they were used for sport arenas but recent studies have shown that they can also be used for music halls ([1],[2]). Focusing the study on the cable net hyperbolic paraboloid roofs, the strength of these structural typologies is the roof lightness and its short thickness compared to the span. In addition, the absence of pillars except around the borders allows a multifunctional use of the indoor space. The limits are many but the most important are the wind action sensitivity and the gaps in technical codes.

The cable net tensile structure's sensitivity to wind action is well known. Many studies ([3]-[21]) have confirmed that the cable nets and membranes need to be designed by taking into account the dynamic instability given by the wind – structure interaction. This aspect is crucial because it affects the design of the roof and its reliability that closely depend on the geometry. In section 3 some basic information about the cable net design and calculus are given.

To investigate the wind – structure interaction, the roof needs to be designed statically and dynamically. Currently however, the design phase suffers from a gap in codes and literature which neglect this structural typology. In particular two aspects are neglected, the wind action estimation for the hyperbolic paraboloid roof and the geometrical parametrization of structural elements (i.e. cables and membrane). In order to estimate the wind action, tunnel tests are necessary during the preliminary phase of the project. A great number of examples of wind tunnel campaign tests are described in literature ([22]-[29]) However, all references are unique cases and thus are not standardized for various geometries. Some examples follow a parametric approach that is useful for replicating the study. This approach was followed by [31], [30] and [13]. In particular, [31] and [30] have carried out pressure coefficients maps (i.e. mean, maximum and minimum) on a total of 12 different plan geometries of hyperbolic paraboloid roofs. Recently[32]and [33] have analyzed the distribution of the peak factors on a hyperbolic paraboloid roof. These studies allow designers to estimate the wind action on the roof before carrying out expensive wind tunnel tests. Some of these studies synthetized the results achieved by the Codes of Practice for other geometries ([34] - [38]). However, the parametric results published in literature should be categorized by codes. [35] discussed some of the most important Codes of Practice ([39] - [48]). The shortcomings regard the generalization and parametrization of the aerodynamic coefficients to the widest number of geometries derived from the hyperbolic paraboloid. Similarly, very little information is given regarding the structural design of cable nets and membranes which makes it difficult to develop these structural systems at the expense of their dissemination.

Based on these gaps, this paper discusses through a parametrical approach the dynamics of cable nets with a square plan and hyperbolic paraboloid surface roof. The paper in particular investigates the dependence on the geometry of the first natural frequency and the vertical displacements under dead and permanent loads (i.e. 0.5 kN/m^2), known as the final construction condition. The first natural frequency (i.e. mode with biggest participating mass) was estimated taking into account masses given by structural and permanent loads and it was given considering the initial pretension of cables. It is known that the cables strain and stress vary significantly under snow or wind action. This study is only focused on the structural response under structural weight and permanent loads. For this reason, equations and figures, that illustrate structural response variation, are only referred to the structural weight and permanent loads. A comparison between ten geometries with two different hyperbolic paraboloid surfaces and five different plan sizes (i.e. 100, 80, 60, 40 and 20 meters), respectively are discussed. With the purpose to compare only cable net performances, the distance between load bearing and stabilizing cables are kept constant for all geometries and span length. For this reason, the curvature

of the roof with the smaller spans (i.e. 40 m or 20 m) is badly reproduced. However, the distance between cables can be proportionally varied as function of the span. In this research the cable net is only investigated. For this reason the border structures are restrained. In addition, the membrane in terms of roof stiffness is not considered so as to study only the cable net performances.

It is important to note that the study is focused on structures with medium and small spans in order to promote the dissemination about these kind of structures. The purpose is to use cables nets as an alternative to steel truss or wood structures for small and medium sport arenas. That's because they have an efficient cost-benefit ratio also for small span ([6], [7]). In addition, it is important to specify that the geometrical span range (i.e. from 100 to 20) was chosen as linear variation of the span in order to give a measure of the structural response variation as function of the span.

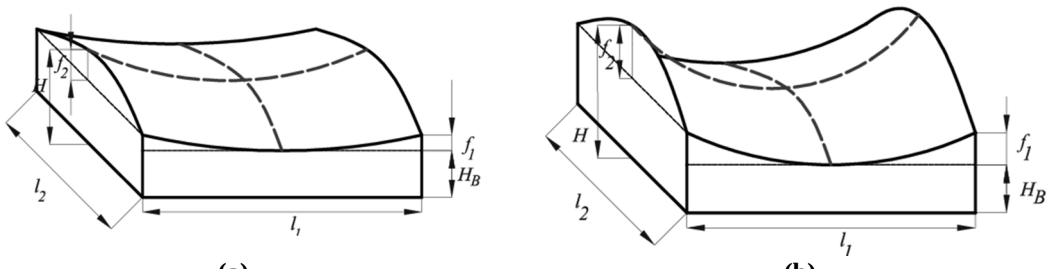
The aim is to give a range of the first natural frequency and vertical displacements for a preliminary structure design and to evaluate the cost-benefit. This last evaluation is possible because the vertical displacements depend on the cable traction and consequently on their section area. Section 2 describes the geometrical sample investigated while Section 3 gives some notions of the cable net calculation and information about the analyses carried out. Section 4 includes a short description of the analyses results.

2 THE GEOMETRICAL SAMPLE

The hyperbolic paraboloid surface equation is given by Eq(1). In the case of this research, the term *c* is equal to 1 (i.e. regular hyperbolic paraboloid). Consequently, the hyperbolic paraboloid cable net is made up of cables with the same curvature along one side. In Eq.(1), x, y and z are respectively the spatial variables; x_0, y_0 and z_0 are the coordinates of the origin of the axes while *a*, *b* and *c* are the geometric coefficients of the function. Parameter *c* was set equal to 1 making all the parabolas lying on the surface, parallel and of identical curvature ([6], [7]). Totally, the net is made up of two orders of cables, upward and downward, respectively. The upward cables are load bearing under gravitational loads, whereas the downward cables are stabilizing under gravitational loads. Under wind suction (i.e. upward action), the order is inverse. The global instability is usually due to the inversion of some cable curvatures caused by extreme wind or snow action; in the case of the cable net it is general due to the loss of the initial strain by cables.

$$\frac{(X-X_0)^2}{A^2} - \frac{(Y-Y_0)^2}{B^2} = \frac{(Z-Z_0)}{C} \quad ; 1/C = 1 \tag{1}$$

In this study, only the structural behavior under permanent loads is investigated. The aim is to compare different structural configurations in terms of weight, natural frequencies and difference in geometrical configurations between undeformed and deformed geometry under permeant loads.



(a) **(b)**

Fig.1 Geometrical parameters (a) geometry (1), (b) geometry (2).

Fig.1 shows the geometrical parameters listed in Table 1 for investigated geometry (1) and (2) ([31]). The two couple parameters l_1, f_1 and l_2, f_2 are the upward and downward cable sags and spans, respectively. In this case, l_1 is equal to l_2. H is the sum of $f_1 + f_2 + H_B$ and it is equal to 1/10 (i.e. geometry (1)) and 1/6 (i.e. geometry (2)) of l_1. The geometry was chosen based on the geometrical parametrization, as function of the optimal structural performances of the net, given by [31]. The various curvatures of the hyperbolic paraboloid surface and the different values of the span, affect the static and dynamic behavior of the structures. In Table 1, N represents the number of cables along l_1 that is equal along l_2. The i quantities in Table 1 represent the distance between the cables.

Table 1 Geometrical sample

Geom-etry	model	l_1 [m]	l_2 [m]	f_1 [m]	f_2 [m]	H [m]	H_B [m]	i [m]	N
	1	100.00	100.00	3.33	6.67	10.00	13.33	2.00	51

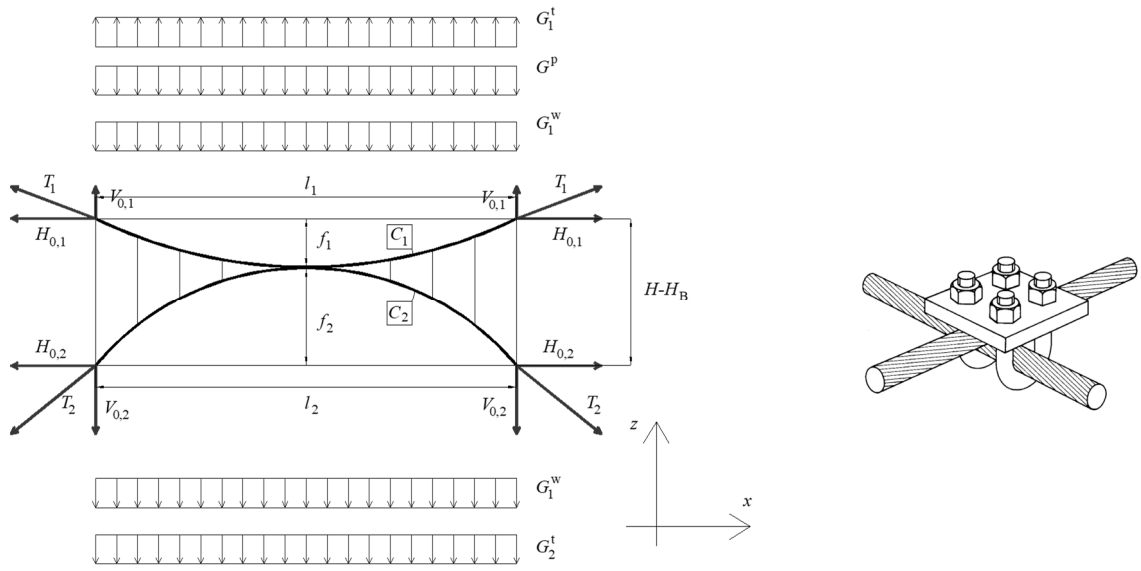
(1)	3	60.00	60.00	2.00	4.00	6.00	13.33	2.00	31
	4	40.00	40.00	1.33	2.67	4.00	13.33	2.00	21
	5	20.00	20.00	0.66	1.37	2.00	13.33	2.00	11
	1	100.00	100.00	5.55	11.11	16.66	13.33	2.00	51
	2	80.00	80.00	4.44	8.89	13.33	13.33	2.00	41
(2)	3	60.00	60.00	3.33	6.66	10.00	13.33	2.00	31
	4	40.00	40.00	2.22	4.44	6.66	13.33	2.00	21
	5	20.00	20.00	1.11	2.22	3.33	13.33	2.00	11

In Section 3, some base notions regarding the cable net theory are shortly given in order to clarify the static and dynamic response dependence on geometry.

It is important to note that in this study the ratio between f_1 and f_2 is equal to 0.5. This ratio was set based on [31], that gave a parametric study of geometries and suggested 0.5 as an optimal ratio in order to minimize the horizontal forces applied to the border structures.

3 METHOD OF ANALYSES

Hyperbolic paraboloid cable nets have a double curvature with different cable lengths and curvatures, and generally, different cable areas and pre-stresses. In addition, the shape plays a decisive role in the net deformation behavior under the action of external loads. The cable net deformation is given by vertical displacements of nodes. In fact, the two orders of cables are connected as shown in Fig.2 a. As discussed in Section 2, the two orders of cables become load-bearing or stabilizers depending on the direction of the acting load; the load-bearing cable is concave in the direction of the acting load. Therefore, in conditions of snow (i.e. gravitational) or wind (i.e. gravitational and suction), the two orders of cables may reverse their behavior. This inversion may be dangerous because it may lead to the instability of either the cable net or the border structures. It is worth noting that the theoretical geometry is only an initial condition and that the real geometry of the net is defined on the basis of the cable pre-stress under dead and permanent loads.



(a) **(b)**

Figure 2 The cable net model: the "Rope beam" model (a), the technological node detail (b).

The action given by loads and the pre-stress on the cables modify the theoretical geometry and the goal is to reduce the difference between theoretical and initial geometry. A small difference between the theoretical geometry and the deformed shape is important because, as it is known, the pressure coefficients evaluated in wind tunnel vary with the geometry. The theoretical fundamentals of the cable net calculation is its two-dimensional simplification model called "Rope beam" illustrated in Fig.2 a ([6], [7]). The equilibrium of the system forces in the mutual node ensures the forces' transmission between the two cables. The rope beam assumes the prefixed hypotheses listed in the following ([6], [7]). Vertical links in tension or in compression are treated as a continuous membrane between the two main cables. The horizontal displacements are neglected compared to the vertical ones which is due to the fact that the node connection permits the scroll between cables. The scroll results from the different strains of the two orders of cables (Fig.2 b). In order to preliminarily design the cable areas and strain, the rope beam model is used applying cable pretension as an equivalent distributed load. The system congruence is required only in the central span node. The mutual actions between cables are uniformly distributed as the external load, and consequently, load-bearing and stabilizing cable have a parabolic configuration also in elastic regime.

The stiffness coefficients are considered, respectively for the load-bearing cable (C_1) and stabilizing one (C_2) as expressed in Eq.(2) and Eq.(3), where k_1 and k_2 represent, respectively, the stiffness of the load-bearing cable C_1 and the stiffness of the stabilizing cable C_2, defined in Eqs.(4) and (5), while E is the Young Module of the cable steel assumed equal to 165000 Mpa and $A_{1,2}$are the cable areas.

As it is known, the yield stress of harmonic steel ranges from 1100 to 1700 Mpa, which is the limit under maximum loads (i.e. maximum wind and snow action). Consequently, under dead and permanent loads the cable stress should be smaller. It is worth noting that cables are made of ropes which are made of wires

$$\boldsymbol{C_1 = \frac{k_1}{k_1 + k_2}} \tag{2}$$

$$C_2 = \frac{k_2}{k_1 + k_2} \tag{3}$$

$$k_1 = \frac{EA_1}{l_1\left[1+\frac{8}{3}\left(\frac{f_1}{l_1}\right)^2-\frac{32}{5}\left(\frac{f_1}{l_1}\right)^4\right]} \quad (4)$$

$$k_2 = \frac{EA_2}{l_2\left[1+\frac{8}{3}\left(\frac{f_2}{l_2}\right)^2-\frac{32}{5}\left(\frac{f_2}{l_2}\right)^4\right]} \quad (5)$$

. The equivalent yield stress of the cable is not the same for a single wire. The initial stress (i.e. in traction) for cables is equal to 1150 Mpa to assume as maximum value under permanent loads. The applied load after construction and without snow and wind (Fig.2 a) corresponds to the sum of the cable weight (i.e. in the following dead loads, $G_{1,2}^{w}$), permanent loads (i.e. 0.5 kN/m^2, G^{p}) and initial pretension ($G_{1,2}^{t}$). Referring to Fig.2 a, the load balance is given by $+G^{p}$ (downward) $+G_1^{w}$ (downward) + G_1^{t} (upward) + G_2^{w} (downward) + G_2^{t} (downward) =0. Preliminarily, the cable weight was estimated based on the undeformed cable length, calculated according to Eqs. (6) and (7), referring to Fig.2 a (Majowiecki 1994).

$$\boldsymbol{L_{0,1,geom} = l_1 \cdot \left[1+\frac{8}{3}\cdot\left(\frac{f_1}{l_1}\right)^2-\frac{32}{5}\cdot\left(\frac{f_1}{l_1}\right)^4\right]} \quad (6)$$

$$L_{0,2,geom} = l_2 \cdot \left[1+\frac{8}{3}\cdot\left(\frac{f_2}{l_2}\right)^2-\frac{32}{5}\cdot\left(\frac{f_2}{l_2}\right)^4\right] \quad (7)$$

$L_{0,1,\mathrm{geom}}$ and $L_{0,2,\mathrm{geom}}$ are undeformed geometrical cable lengths ; the cable traction horizontal components$H_{0,1}$and$H_{0,2}$ are given by Eqs.(8) and (9) and they are assumed equal, ([6], [7]).The horizontal components depend on the cable geometry and it varies based on the different cable sags. If the sag of the two orders of cables are different, the cable traction (i.e. load bearing and stabilizing) has to be different. An iterative calculus procedure estimates the cable areas and strains in order to achieve the balance ([6], [7]).

Eqs. (8) and (9) link the geometry to the loads and consequently the cable traction to the geometry. Based on this, the initial traction into the cables gives the real geometrical configuration (i.e. f_1 and f_2) under dead and permeant loads (i.e. G). In this paper, in order to evaluate the geometry dependence on cable traction, five different values of T_1 are considered, 100 (A), 200 (B), 400 (C), 600 (D), 1000 (E), 2000 (F), 4000 (G) and 8000(H) kN respectively. It is important to specify that values bigger than 2000 kN are very big and they excessively overload the border structures.

$$\boldsymbol{H_{0,1} = \frac{G{l_1}^2}{8f_1} = \frac{T_1}{1+16\left(\frac{f_1}{l_1}\right)^2}} \quad (8)$$

$$H_{0,2} = \frac{G{l_2}^2}{8f_2} = \frac{T_2}{1+16\left(\frac{f_2}{l_2}\right)^2} \quad (9)$$

For this reason, it is suggested to balance these loads using stays. In this study, values of traction bigger than 2000 kN are used only to have a measure of the asymptotic trends of the displacements and first natural period. Consequently, having fixed the same exercise stress for both orders of cables, according to the Hook law (Eq.10), the initial cable elongation (ε)is defined equal for both orders of cables.

$$\begin{gathered}\boldsymbol{\sigma_1 = \sigma_2};\\ \sigma_1 = E \cdot \varepsilon_1;\ \sigma_2 = E \cdot \varepsilon_2\\ E \cdot \varepsilon_1 = E \cdot \varepsilon_2;\\ \varepsilon_1 = \varepsilon_2 = 0.0035\end{gathered} \tag{10}$$

$$\frac{\mathrm{T_1}}{1 + 16\left(\frac{f_1}{\mathrm{l_1}}\right)^2} = \frac{\mathrm{T_2}}{1 + 16\left(\frac{f_2}{\mathrm{l_2}}\right)^2} \tag{11}$$

$$\mathrm{T_2} = \frac{\mathrm{T_1}\left[1 + 16\left(\frac{f_2}{\mathrm{l_2}}\right)^2\right]}{1 + 16\left(\frac{f_1}{\mathrm{l_1}}\right)^2} = 1.05 \text{ or } 1.14\ \mathrm{T_1} \tag{12}$$

$$\begin{gathered}\mathrm{T_2} = E \cdot \varepsilon_2 \cdot A_2\\ \mathrm{T_1} = E \cdot \varepsilon_1 \cdot A_1\end{gathered} \tag{13}$$

$$A_2 = 1.05\ or\ 1.14\ A_1 \tag{14}$$

Consequently, assuming $H_{0,1} = H_{0,2}$, ratio T_2 / T_1 and A_2 / A_1 are geometrically calculated (Eqs. 11 to 13) and, for the case study considered, they are equal to 1.05 for geometry (1) and 1.14 for geometry (2). A_1 is assumed equal between geometry (1) and (2). The Based on Eq. (14) where the cable areas were evaluated. Table 2 lists the traction and areas of cables.

Table 2 Mechanical parameters after fixing the initial strength $\varepsilon_1 = \varepsilon_2 = 0{,}0035$.

Static and modal analyses are carried out using TENSO, a non-commercial software that includes modules for simulating cable and beam finite element models and for the study of wind-structure interaction phenomena through the generation of wind speed time histories and simulation of various aeroelastic loads. The main cables are discretized as rectilinear cable segments. The global stiffness matrix is updated at each load step by assembly of the stiffness sub-matrices of the elements, updated to account for the strain found at the previous time step. In this way the software considers the geometric nonlinearity of the structure. The TENSO software first solves the static equilibrium of the structure under dead, gravity and construction loads (prior to the application of the wind loads) through nonlinear static analysis whereby two methods are simultaneously used: step-by-step incremental method and a "subsequent interaction" method with variable stiffness matrix (secant method). The secant method is a finite-

difference approximation of the Newton-Raphson's modified method for systems of nonlinear algebraic equations ([49], [50]). For geometry (1), the first three mode shapes are the same for traction T_1 greater than 1000 kN for each value of L_1. On the other hand, the first mode shape for T_1, smaller than 1000 kN, is similar to the second mode shape for traction greater than 1000 kN, while for geometry (2) it is the same. The first three modes are in descending order of participating mass. It is obvious that the cable areas and the plan sizes (i.e. l_1 and l_2) closely affect the weight of the cable net and consequently the masses of the structures, listed in Table 3 for L_1 equal to 100 m.

In this study the first natural frequency with the bigger participating mass is only considered to make a comparison between geometry (1) and (2). The fist mode is symmetric for T_1 smaller than 1000 kN and L_1 equal to 100, 80 and 60 for geometry (1), and equal to 100 and 80 m for geometry (2). The first mode is antisymmetric for traction bigger and equal to 1000 kN and L_1 smaller than 60 m for geometry (1) and 80 m for geometry (2). For sake of brevity Table 3 shows values for L_1=L_2=100 m.

All geometries listed in Table 1 are modelled with a FEM model. They were statically and dynamically calculated by TENSO in order to estimate the maximum (i.e. in the middle of the roof) vertical displacements and the first ten natural frequencies. Only the value of first natural frequency is discussed in this paper.

As previously described, the initial cable traction (i.e. T in Fig.2) affects the structural response because it modifies the cable net stiffness. In particular, the border anchorage structures and the vertical displacements under loads are closely affected by the traction (T). In order to investigate the dependence on cable traction of displacements and of the natural frequencies, a range of eight different initial tractions (i.e. cables pre-stress) are investigated.

Tables 3 gives a list of the first natural frequency and period of the structures (1) and (2), for l_1 = l_2 = 100 80 60 40 20] m), with the eight cable tractions (i.e. between 100 kN and 8000 kN). The tables also give the mass (M_i) for square meters for a generic node *i* of the net.

4 RESULTS

Static and model analyses results have shown that the vertical displacements under dead and permanent loads (i.e. 0.5 kN/m^2) varies nonlinearly as a function of load bearing cable traction (T_1). Figs 3a and b show the vertical displacement trend as function of T_1 for geometry (1) and (2), respectively. For geometry (1) vertical displacement δ(i.e. in the middle of the roof) tends towards very high values for small values of T_1. For the smallest values of T_1 (i.e. 100 kN), δranges from about 5/250 l_1 to 1.5/250 of l_1. On the contrary, for the biggest value T_1 (i.e. 8000 kN), $\delta$is almost constant for all plan sizes and it is equal nearly 1/250 l_1. Similarly, for geometry (2) vertical displacement δ (i.e. in the middle of the roof) tends towards very high values for small values of T_1. For the smallest values of T_1 (i.e. 100 kN), δranges from about 3/250 l_1 to 0.8/250 of l_1. On the contrary, for the biggest T_1value (i.e. 8000 kN), $\delta$is almost constant for all plan sizes and it is nearly 0.6/250 l_1 equal.

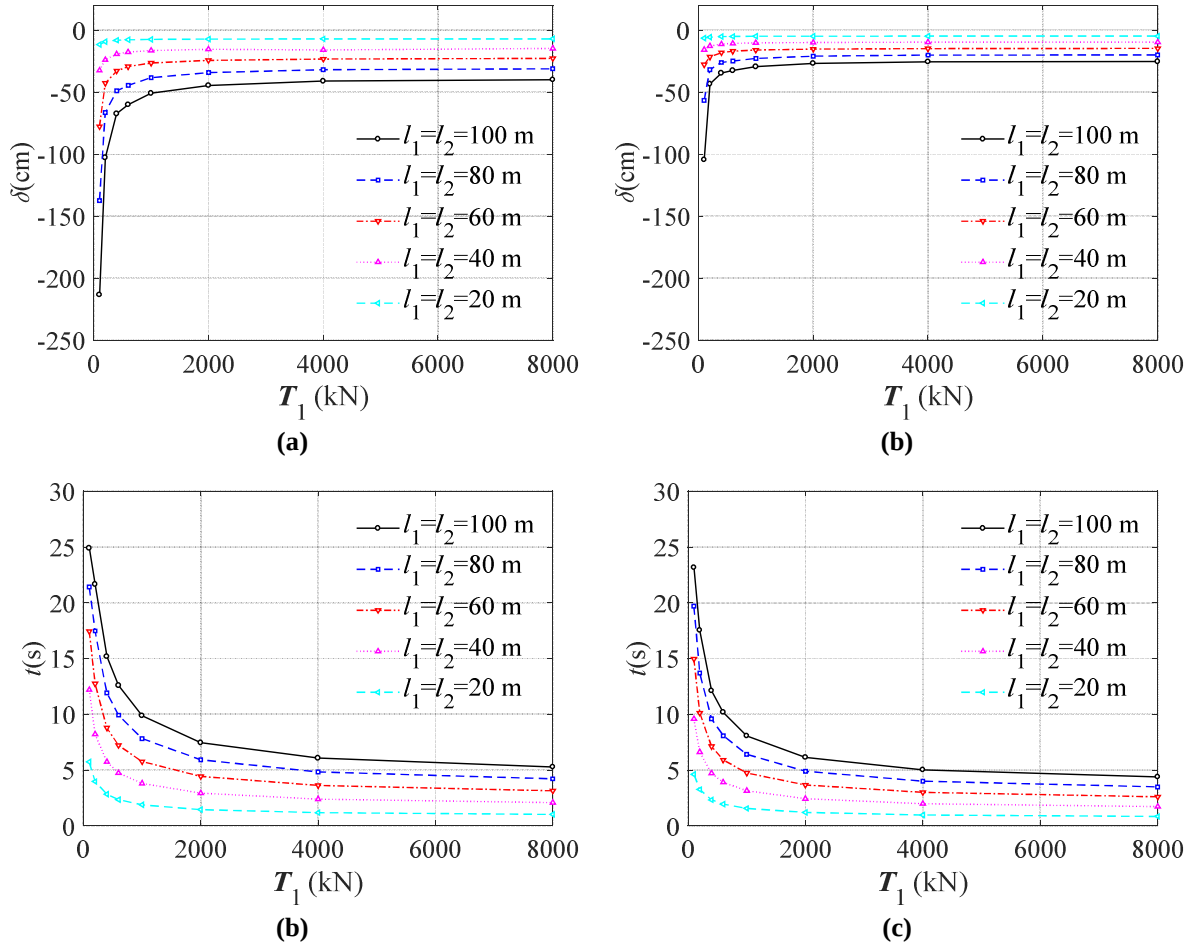

Fig.3 Vertical displacements under dead and permanent loads depending on cable traction, geometry

Fixed the cable stress limit due to the material yield stress, the T_1 variation depends on cable areas and consequently, the cable area variation gives the structural mass for square meter (M_i) variation. For the sake of brevity, Table 3 list the 1st natural frequency (ϕ) in Hz and period (t) in s values for all geometries (i.e. geometry (1) and (2) and conditions i.e. traction from (A) to (H)). Figs.3 c and d synthetized the values of t as function of T_1 for both geometry (1) and (2).M_i varies significantly between (A) and (H) traction condition and consequently, the 1st natural period varies too. However, it is quite constant for traction greater than 2000 kN. For geometry (1), the t values range from 24.90 s (i.e. l_1=100 m and T_1 = 100 kN) to about 1.03 s

(i.e. l_1=20 m and T_1=8000 kN). For geometry (2), the t values range from 23.17 s (i.e. l_1=100 m and T_1 = 100 kN) to about 0.85 s (i.e. l_1=20 m and T_1=8000 kN). As was expected, the first natural period of geometry (1) is slightly longer than geometry (2) and this is due to the larger radius of curvature of the hyperbolic parabolic surface for geometry (1) than geometry (2). The standard deviation of t ranges from 5.83 s (i.e. l_1=100 m) to 1.05 s (i.e. l_1=20 m) for geometry (1), whereas it ranges from 4.66 s (i.e. l_1=100 m) to 0.86 s (i.e. l_1=20 m) for geometry (2). The standard deviation decreases when the plan size decreases too.).

5 CONCLUSION

Design trends for the first natural period of a hyperbolic paraboloid cable net with a square plan depending on span length are given for two surfaces of the hyperbolic paraboloid. The H sum of the two orders of cable sags was divided by 10 (i.e. geometry (1)) and 6 (i.e. geometry (2)). For each geometry, the span length was varied between 100 m and 20 m. Static analyses were carried out with the aim to estimate the vertical displacements as function of the fixed cable traction in order to respect the material limits. The cable traction varied between 100 to 8000 kN. The structural mass variations due to the cable area variations gave different values of the first natural period for each geometry. Results showed that the first natural period varied very little for cable traction greater than 2000 kN and thus was described as a function of the cable span. The design trends showed that when the radius of curvature of the hyperbolic surfaces increases (i.e. geometry (1) radius is bigger than (2)), the first natural period slightly increases and it has greater values of standard deviation considering different cable tractions. The standard deviation increases when the span length increases too. The design trends are useful to designers in order to evaluate preliminarily the possibility of resonance due to wind – structure interaction. This knowledge, in the next development of the research, will be helpful to evaluate the structure reliability of existing roofs. The purpose is to design a retrofitting according the same scientific approaches followed for traditional structures as for examples structures made of reinforced concrete [51].

Abstract

The purpose of this study is to develop a damper to improve the seismic performance of storage racks, which are representative non-structural elements sustaining successive external loads, such as earthquakes. To evaluate the seismic performance of general storage racks, a shaking table test was conducted. As a result, the necessity of reinforcement of the general storage rack to prevent permanent deformation of the direction of passage was confirmed. In addition, the results of the member unit static experiment examining the function of the general storage rack proved the necessity of reinforcing a beam-column joint. To improve this performance, a viscoelastic damper was developed to strengthen the beam-column joint in the direction of passage. To verify the effect of improving the seismic performance of the developed viscoelastic damper, a shaking table test was conducted. The developed viscoelastic damper reduced not only the displacement in the time-domain when under an external load but also the damage of the storage racks due to permanent deformation.

Keywords: viscoelastic damper, storage racks, seismic performance, shaking table test, structural damage, permanent deformation

1 INTRODUCTION

Storage racks are representative nonstructural elements that are used to store and classify items from the point of origin to that of consumption. Multi-shelf storage racks are conventionally used as they are not only lightweight but can also support heavy loads. The number of shelves and the height of such storage racks tend to increase with the increase in volume of commodities that require efficient storage in a confined space. Typically, storage racks are simply assembled to immediately secure a space at a user's demand, and this assembly method implies structural instability [1]. The structural instability is an influential factor on the behavior characteristics of the storage rack under external loads, such as earthquakes, and this factor causes various damages. In addition, apart for some countries situated in earthquake fault zones, most other countries do not have any established standards for the installation and operation of storage racks. Therefore, the failure of a storage rack due to an external load is very likely to cause considerable damage

Seismic loads are representative of external loads that damage logistics facilities, including storage racks. The 1994 LA Northridge earthquake and the 1995 southern Hyogo earthquake caused financial damages of approximately US$ 40 billion and 9.7 trillion yen, respectively. Such enormous damages awakened people's interest in the seismic stability of storage racks, and new technologies for improving the seismic performance of storage racks started being developed. To date, various devices have been developed. Hydraulic damper, viscous elastic material damper, and base isolation system are devices that are commonly intended to enhance the seismic performance of storage racks. Fall prevention devices for objects stored have also been developed [2-5]. The majority of devices for enhancing the seismic performance of storage racks are based on either of the following two methods: In the first method, after large-scale storage rack sets form a single system through additional jigs, a large device is used to reduce the vibration of the storage rack. In the second method, after the operation of the existing storage rack is suspended, devices are installed on bottom surfaces and junction. These methods require the fabrication of additional jigs and have a high installation cost. Storage is also suspended while devices are being installed. As the use of small-scale storage facilities tends to increase, technical development needs to focus on ensuring the seismic safety of small storage racks.

This study was an attempt to develop a device that could solve the problems of existing devices and improve the seismic performance of small storage racks, thereby ensuring the safety of these racks under external loads. To develop such a device, the behavior characteristics of the existing storage racks were analyzed by conducting a test, in which seismic loads were applied. Based on the test result and the structural shape of the storage rack, the weak parts of the storage rack were identified. Then, a viscoelastic damper was developed to reinforce the identified weak parts and enhance the seismic performance of the storage rack. A static load test was also performed to evaluate the preliminary performance of the damper. Finally, a seismic load test for the storage rack, to which the proposed viscoelastic damper was applied, was conducted to experimentally verify the performance of the damper.

2 CONSTRUCTION AND BEHAVIOR CHARACTERISTICS OF THE BASIC STORAGE RACK

2.1 Construction

The storage rack is a nonstructural element of the logistics process used for efficiently storing objects either for a short or long period. As illustrated below, the storage rack simply consists of columns, beams, and bracings. Such a simple structure is easy to modify depending

on users' subjective judgments or situations. Specifically, the open down-aisle section is intended to prevent any interruption while objects are being loaded. In the cross-aisle direction, bracings are installed to supplement relatively smaller sections and ensure the structural stability of the storage rack. To secure a sufficient space for large objects, the simple hooked beam-to-column connection is applied, as shown in Figure 1.

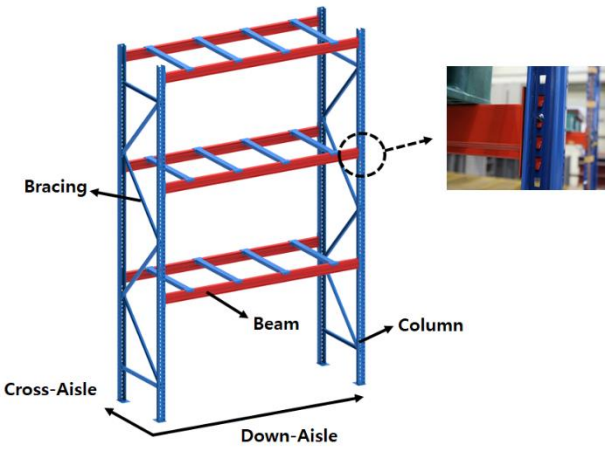

Figure 1: Construction of a storage rack

As there is no international standard for the specifications and dimensions of storage racks, majority of the storage racks are made-to-order to reflect the characteristics of each warehouse facility. Among the various storage racks, this study selected a three-shelf storage rack as the test object, which is widely used in mid- and small-sized logistics centers and warehouses in South Korea. The test object had a width of 2,785 mm, length of 1,000 mm, and height of 4,500 mm. M10 bolts were used for all the connections except the beam-to-column connections, for which M8 bolts were used along with hooks to prevent the separation of beams. Moreover, an additional load of 1.2 ton, which corresponds to 80% of the maximum designed load (1.5 ton), was installed on each shelf.

2.2 Behavior characteristics

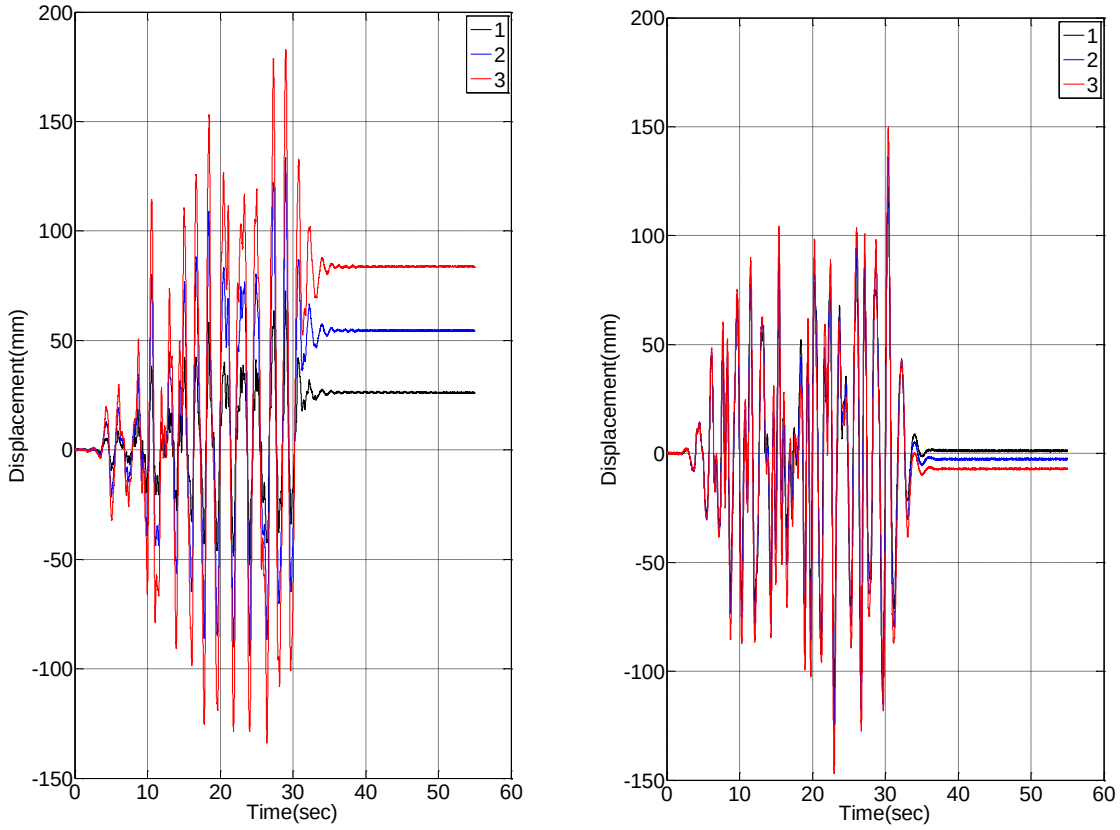
To improve the seismic performance of storage racks, the behavior characteristics of the racks under external loads need to be accurately identified. To analyze the behavior characteristics of the storage rack under external loads, the dynamic characteristic analysis was conducted using the shaking table of the Seismic Simulation Test Center in South Korea. The shaking table test for analyzing dynamic characteristics was based on AC156 (Acceptance Criteria for Seismic Certification by Shake-table Testing of Nonstructural Components, 2010) proposed by ICC-ES, which is a representative testing method for nonstructural elements [6]. In accordance with the seismic response spectrum of KBC2016, the shaking table was assumed to be installed on normal rock soil in the seismic zone I. Table 1 presents the information of the seismic response spectrum [7].

Building Code	S_{DS}	z/h	Horizontal		damping
			$A_{FLX\text{-}H}$ (g)	$A_{RIG\text{-}H}$ (g)	
KBC2016	0.37	0	0.37	0.15	5%

Table 1: Shaking table test parameters

For the analysis of dynamic characteristics, the shaking table was vibrated by doubling the maximum acceleration (PGA = 0.3 g) of the seismic waveform created from the seismic spectrum information. The test was conducted only in two horizontal directions, and no vertical direction was considered.

The test results revealed that the 1st mode natural frequencies of the test object were 0.750 Hz in the longitudinal direction (x) and 2.375 Hz in the lateral direction (y). The test object was not overturned, inverted, or damaged. The bottom fixture was not separated, and the bolts did not show any crack or deformation. However, as shown in Figure 2 below, 84 mm and 7 mm performant deformations were observed in the longitudinal direction (x) and lateral direction (y), respectively.



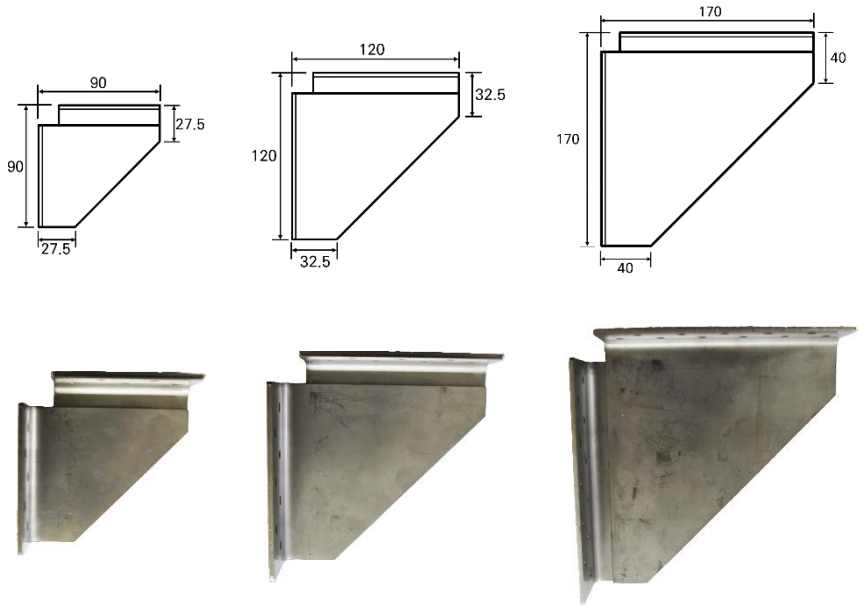
(a) longitudinal direction (x) (b) lateral direction (y)

Figure 2: Permanent deformation of storage racks

3 DEVELOPMENT OF VISCOELASTIC DAMPER FOR IMPROVING THE SEISMIC PERFORMANCE OF STORAGE RACKS

Based on the shaking table test results regarding the dynamic characteristics of the storage racks, a larger permanent deformation occurred in the longitudinal direction (x) than in the lateral direction (y). The reason for this phenomenon is the shape of the storage racks. Most components of a storage rack are connected through bolts. Conversely, the beam-to-column connection in the longitudinal direction (x) depends on a simple hook system. Unfortunately, this method cannot satisfy the longitudinal stiffness requirement. This study developed a damper that could enhance the seismic performance of a storage rack by reinforcing the beam-

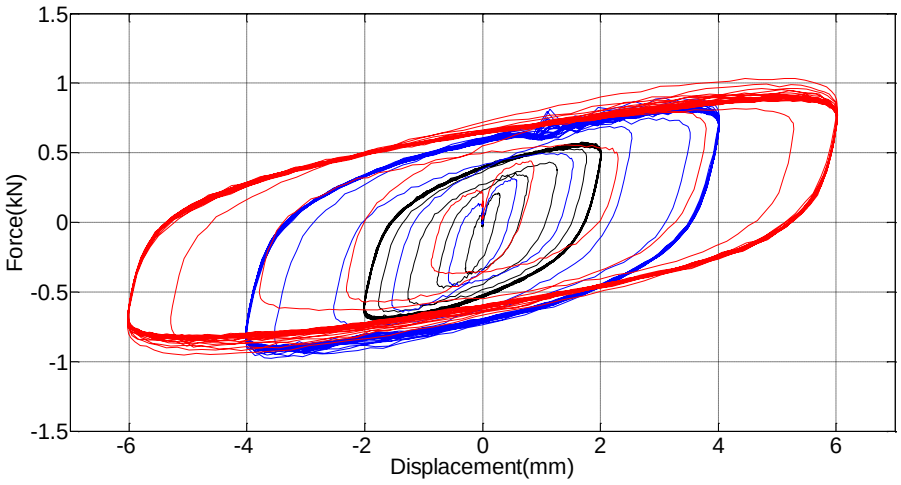
to-column connection in the longitudinal direction (x). ISD-111 VE polymer produced by 3M was used for the damper. The down-aisle direction of a storage rack should not be an obstacle in loading or unloading objects to achieve the purpose of the rack. In this regard, three types of small triangular viscoelastic dampers were developed, as illustrated below.



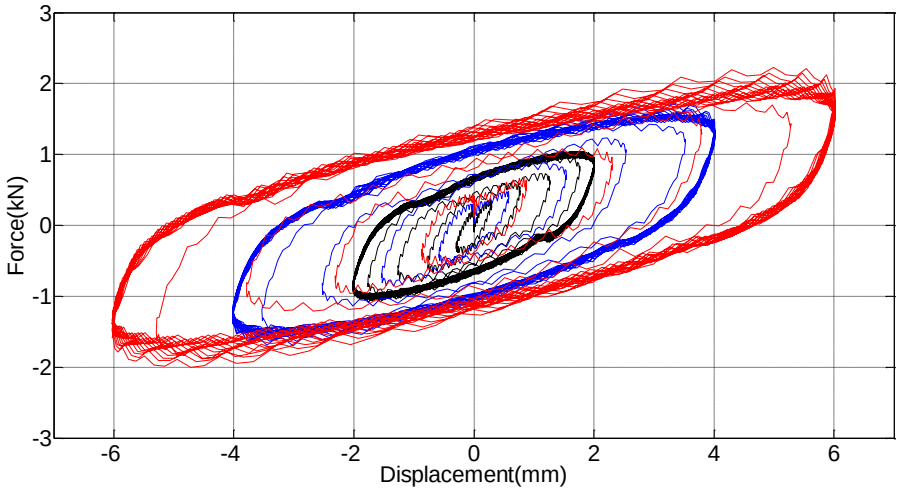
(a) 7 cm (b) 10 cm (c) 15 cm

Figure 3: Viscoelastic dampers for reinforcing the beam-to-column connection of storage racks

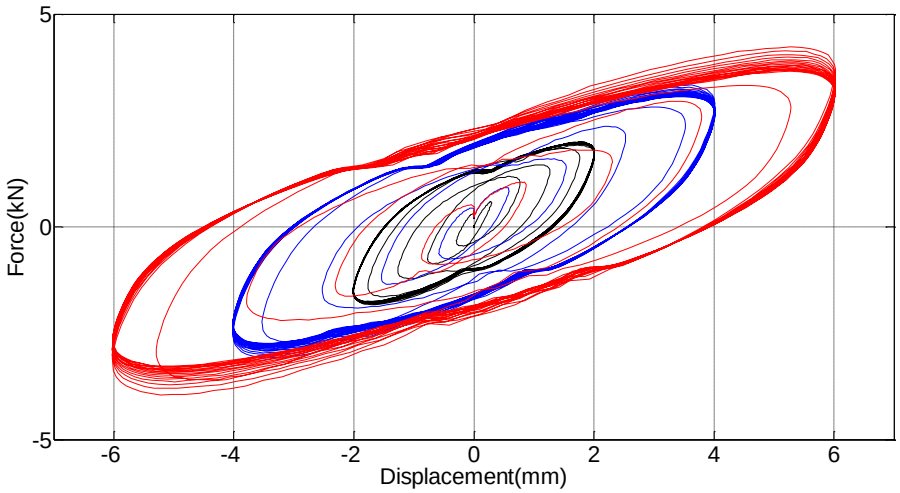
To verify the basic performance of the viscoelastic dampers, which were developed to improve the seismic performance of storage racks, a test was conducted using an actuator of the Advanced Construction Materials Testing Center in South Korea. In the performance test, the displacement condition varied (±2 mm, ±4 mm, ±6 mm) at 1 Hz. As the size of the viscoelastic damper increased, the control force was almost doubled. Additionally, the control force was proportional to the displacement. Figure 4 illustrates the force-displacement graphs obtained from the performance tests for the three dampers.



(a) 7 cm



(b) 10 cm

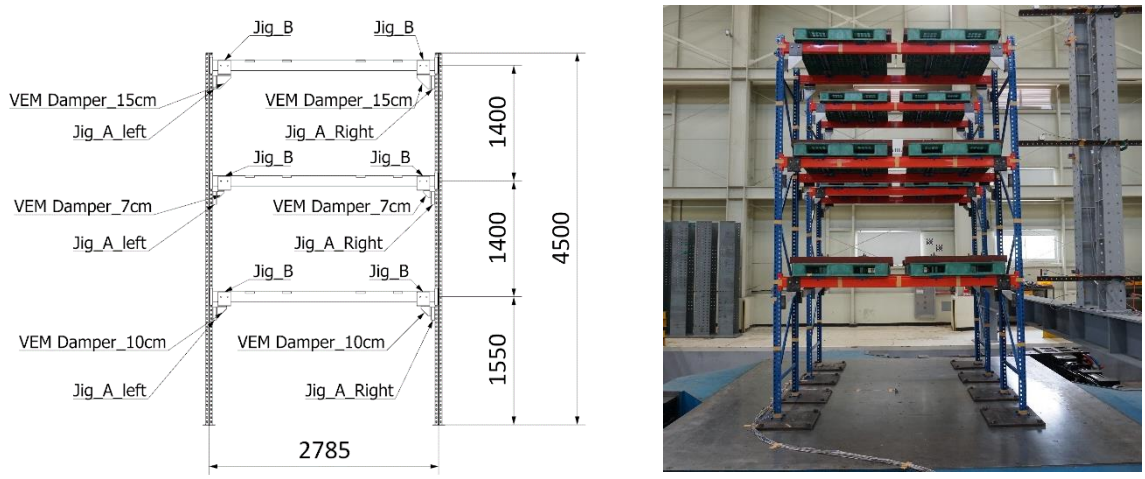


(c) 15 cm

Figure 4: Performance test results for viscoelastic dampers for reinforcing the beam-to-column connections of storage racks

4 ANALYSIS OF BEHAVIOR CHARACTERISTICS OF THE STORAGE RACKS WITH VISCOELASTIC DAMPERS

A shaking table test was performed to experimentally evaluate the performance of the viscoelastic dampers that were developed to reinforce the seismic performance of storage racks. The shaking table test was intended to identify the effect of reducing seismic loads and permanent deformation of the proposed dampers. For the test, three types of viscoelastic dampers were installed in each shelf of the basic storage rack, as shown below. The conditions of the dynamic characteristics test were applied to the shaking table test. Data obtained from the shaking table test were compared with the experimental data of the basic storage rack.



(a) Installation diagram of dampers (b) Storage rack with dampers

Figure 5: Test for reducing the seismic loads of the storage rack with viscoelastic dampers

Figure 6 depicts the displacement responses on each shelf, which were obtained from the basic storage rack and the storage rack with viscoelastic dampers. Table 2 presents the values of the maximum displacement and permanent deformation obtained from each test.

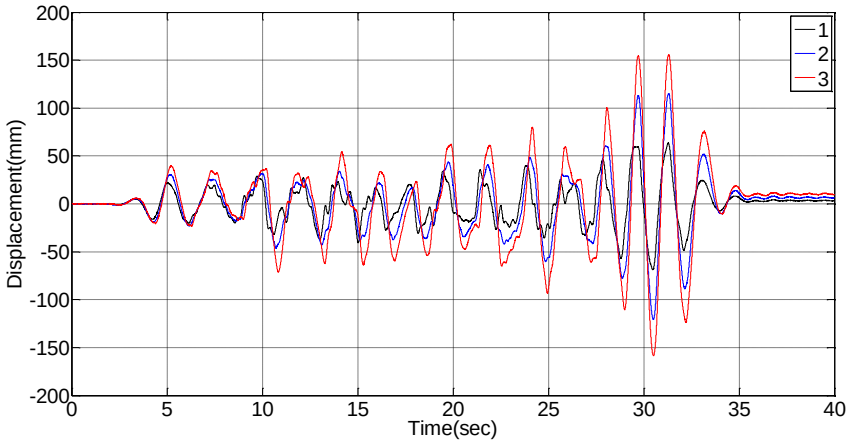


Figure 6: Shaking table test result (Displacement generated)

Experiment result	Maximum displacement (mm)			Permanent deformation (mm)		
	1st	2nd	3rd	1st	2nd	3rd
Basic storage racks	88	164	222	15.56	29.82	44.46
Storage racks using viscoelastic damper	67	121	162	3.72	6.69	10.78
Reduction rate (%)	23.9	26.2	27	76.1	77.6	75.8

Table 2: Maximum and permanent deformation of storage racks

As shown in the above figure and table, in comparison with the basic storage rack, the storage rack reinforced with the proposed viscoelastic dampers reduced the maximum displacement by 23.9% on the 1st shelf, 26.2% on the 2nd shelf, and 27% on the 3rd shelf. In addition, after the test, the permanent deformation, or residual displacement, improved by 76.1% on the 1st shelf, 77.6% on the 2nd shelf, and 75.8% on the 3rd shelf. Here, the maximum displacement is influential on the behavior characteristics of the stored objects, and the permanent deformation is related to the inversion of the storage racks.

5 CONCLUSIONS

The present study aimed to develop a damper to ensure the safety of storage racks. Although the demand for storage racks drastically increases due to the increase of logistics service, there is no standard concerning the design and operation of storage racks, and devices have not been sufficiently developed to enhance the safety of the racks under external loads, such as seismic loads. To develop an appropriate damper for storage racks, a shaking table test was conducted to analyze the behavior characteristics of the basic storage rack. Weak parts of the storage rack were identified based on the test result and the analysis result of the shape of the storage racks. Then, viscoelastic dampers were developed to ensure the safety of storage racks through the reinforcement of the identified weak parts. The performance of the developed dampers was evaluated by conducting the basic performance test. Finally, another shaking table test was also performed for the storage rack reinforced with the proposed viscoelastic dampers to experimentally evaluate the excellent performance of the dampers. The findings of this experimental study can be summarized as follows.

1) The test for analyzing the dynamic characteristics of the basic storage rack demonstrated that the permanent deformation was much larger in the down-aisle direction than in the cross-aisle direction. In addition, the analysis of the storage rack shape revealed that the hook system for the beam-to-column connections, which were installed in the down-aisle direction, was the most unsafe part of the storage rack. In other words, the reinforcement of the beam-to-column connections and the reduction of the down-aisle behaviors were of utmost importance to ensure the safety of storage racks.

2) Viscoelastic dampers were developed to reinforce the safety of storage racks. The dampers were designed to have a small triangular shape to minimize the interruption of loading or unloading objects. Three types of dampers with different sizes were developed. The test of the basic performance of the viscoelastic dampers showed that as the size of the damper increased, the control force was almost doubled.

3) A shaking table test was performed to check whether the storage rack with the developed viscoelastic dampers could reduce the seismic loads. The data obtained from the shaking table test were compared with the experimental data of the basic storage rack. In comparison with the basic storage rack, the storage rack with the viscoelastic dampers could reduce the maximum displacement by over 20% and the permanent deformation by approximately 76% or more on every shelf.

In conclusion, the viscoelastic dampers improved the stiffness of the beam-to-column connection, which was the weakest part, thereby demonstrating excellent performance of ensuring the safety of the storage rack under external loads. Moreover, because the dampers developed in this study were cheap and easy to install without any interruption of the operation of storage racks, they proved to be applicable to secure the safety of small storage racks.

FLOOR VIBRATION BEHAVIOR OF CAR PARK STRUCTURES – ASSESSMENT OF DIFFERENT STEEL CONCRETE SOLUTIONS

Riccardo ZANON[1]

[1] ArcelorMittal Global R&D
66 rue du Luxembourg, L-4009 Esch-sur-Alzette, Luxembourg
e-mail: Riccardo.zanon@arcelormittal.com

Abstract

This paper analyses the floor vibration behavior of typical car park structures made of steel - concrete composite decks. Two configurations are chosen amongst the most common on the European market and compared from the static and dynamic point of view. Beside a modal analysis made with different mass assumptions, time-history analysis are performed under realistic load cases with vehicle loading the deck at different speeds to test the realistic structural response.
The results show that standard steel-composite decks reasonably comply with acceptance criteria given in the literature. It is interesting to notice as different configurations with same static design may present significant differences in respect to the dynamic response.

Keywords: Floor vibration, dynamic acceptation criteria, steel-concrete composite structure, car park.

1 STEEL FRAMED CAR PARK STRUCTURES

1.1 Introduction and market overview

One of the major objectives of modern traffic planning is to reduce, as much as possible, the use of private transport in densely populated areas. Parking facilities located in the suburbs, having optimal connections with the public transport network (so called Park and Ride) are necessary prerequisites for this purpose. In this view open over ground car parks are gaining more and more relevance in dense urban areas as well as in medium cities, as the need towards improved mobility form is becoming more urgent.

Figure 1: External views of typical steel framed open car park structures.

Car Parks structure are therefore over ground or underground buildings providing parking facilities. From the Fire Safety Approach point of view, these buildings are classified either Open or Closed Car Parks – and this distinction has relevant consequences in the structural design. Open refers to the requirement that such buildings must provide sufficient natural ventilation through permanent openings along the façades so to exclude the occurrence of a generalized fire embracing the whole compartment. In this case only localized fire scenarios can be applied, which by mean of an adequate Natural Fire Safety approach lead to reasonable requirements for the fire design the structural elements [5]. The requirement to classify a Car Park as opens slightly different from country to country but is typically expressed as minimal ratio of permanent façade openings on built surface [2].

In most European countries this kind of buildings are realized by means of steel-framed structures when they are classified as open. This choice is based both on economical as well as on architectural aspects, since it is appreciated the possibility to avoid obstacles between parking lots which affect the functionality of the building. This leads to rather considerable main spans – usually from 16 up to 18 meters [7].

When the requirement concerning sufficient natural ventilation is not fulfilled, the Car Park is conversely classified as closed. This is typically the case for the car parks which are built under ground or below other buildings. One first important difference from the open overground car parks is that the structural grid is oven linked with constraint from the upper levels, from walls or stiffening systems as well as from the choice of the retaining walls. This fact in general limits the designer in the choice of an optimal structural grid and in the general case leads to significant shorter free spans (typically main spans about 8m, like the buildings on top) where the benefits of steel framed structures are less relevant.

Figure 2: Internal views of typical steel framed open car park structures.

The second reason is that Natural Fire Safety Concept is nowadays established in Europe for Open Car Parks which leads to unprotected steel structures therefore sparing the significant cost of fire protection. In the case of closed car parks the limited natural ventilation linked with the interactions with other structures makes the task more complicated. For this reason the conservative Prescriptive Fire Safety Approach based on ISO834 heating curve is adopted leading to severe requirements for 60, 90 or even 120 minutes. This prescriptive requirements may hardly affect the cost competitiveness of steel structures [5].

These two reasons are the main causes to explain why modern Open Car Parks are today a domain of steel framed structures, whereas conversely closed underground car parks remain the domain of traditional prestressed or reinforced concrete typology. In the scope of this paper will consider the first case, so standard steel framed car parks conceived for external building so in view of an optimized grid in view of architectural, functionality and structural requirements.

1.2 Floor vibration – Situation and scope of this paper

As every long-span slender floor, steel-concrete decks for car parks are exposed to the risk of vibration [1], [3], [8], [9], [10]. The complexity in the case of car parks is that two kind of loadings are present: human and vehicular. But beside this structural consideration, the experience shows that floor vibration is not an issue for car parks: in fact visitors are just shortly crossing by feet the lanes so floor vibration won't disturb them significantly, and once they are in the car they are well isolated from the floor vibrations. For this reason typically no serviceability requirements concerning deflection under live loads is imposed [3].

Nevertheless in some literature and design rules there are still some recommendation concerning the limit of eigenfrequencies, for example 3 Hz according [11]. Such prescriptive approach may in fact result in becoming the main design criteria and therefore affecting the competitiveness of the solution. Scope of this paper is to identify a realistic case study, define two different relevant structural configurations, and analyze their dynamic behavior under realistic assumptions in order to assess their dynamic behavior in view of human comfort criteria. With the help of this two representative examples we will furthermore evaluate whether such frequency limitation criteria are appropriate.

2 DEFINITION OF A GENERAL RELEVANT CASE STUDY

2.1 Geometrical layout

In the scope of this paper we will consider a standard layout of parking lots 5 x 2.5m with a central lane of 6m. This bay of 16.0m will be framed by steel construction, so we will consider a span for the secondary beam of 16.5m [5].

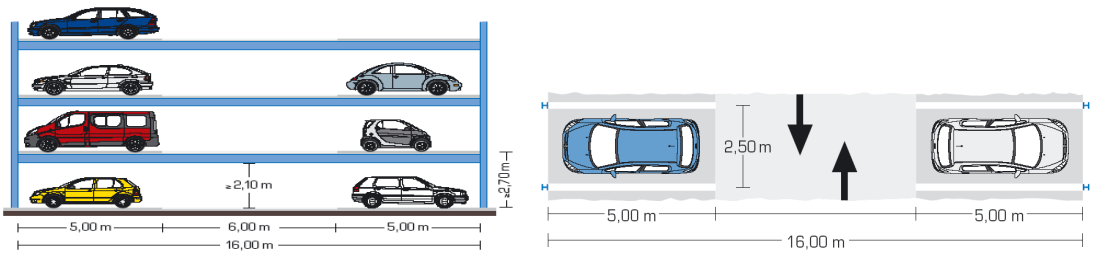

Figure 3: Standard geometrical layout

2.2 Structural deck - Configuration A and B

In the frame of this example we will consider a composite steel concrete structures according Eurocode 4 [6], as they are currently in use since decades for this kind of buildings. Secondary beams are stock hot rolled sections with headed studs welded on the top flange. The use of high steel strength S460 has become a standard for these elements since it permits to optimize the steel weight for strength design, whereas deformation under self-weight and permanent weight are compensated by adequate cambering (for this kind of structures typically in the range L / 100 … 120, where L is the span).

In the scope of this paper two different configurations will be considered and compared. Configuration A presents a shallow steel decking with depth 60mm (type Cofraplus 60 [13]) made composite with reinforced concrete depth of 70mm on top of the rib for a total depth of 130mm. The ribs have an center distance of 207mm. The decking is set on top of the beam flange and is pre-holed in correspondence of the headed stud location. The beam spacing which this slab system covers efficiently is 2.5m – corresponding to 1 parking lot. This typology corresponds to the classical steel-concrete composite floors in use since several decades.

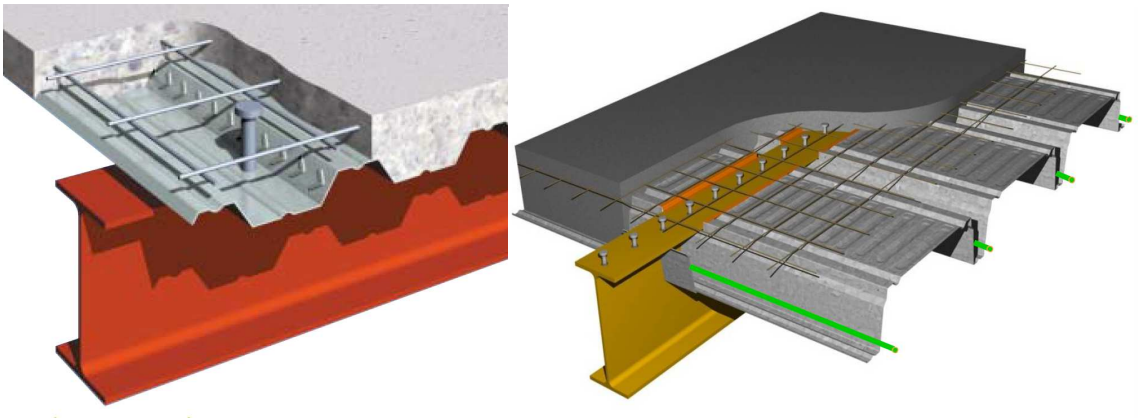

Figure 4: Configuration A (left), pre-holed shallow steel decking posed on top of the beam flange. Configuration B (right), deep steel decking set in the depth of the beam.

Configuration B is an alternative where the main aim is to cover 2 parking spaces instead of 1, which results in a beam spacing of 5.0m without propping in the construction stage. This is achieved with a deep steel decking of 220mm (type Cofraplus 220 [13]) with 90mm of reinforced concrete on top. The deep steel decking cannot be placed on the top of the flange due to their height, therefore they are integrated in the secondary beam height by fixing them on special supports welded onto it. These supports shoes where the ribs of the decks are supported are called wings. In the final phase, the steel-concrete floor behaves therefore as a ribbed deck, with a rib center distance of 750mm. This solution with 5m beam spacing has begun to spread in Europe in the ’90 thanks to the introduction of a successful decking – beam connection system and has afterwards evolved in the shape presented here.

In table 1 we present the principal data for each configuration presented. Configuration B has for sure the advantage to decrease the number of elements and is more efficient in steel consumption in the regular car parks bays. Configuration A is more flexible and requires usually less steel tonnage in the irregular part of the parking (slab ends, ramps, transition to staircases cores). Anyway as it can be seen the total steel consumption is comparable and both configurations are fit for use in this application; the choice between the two systems depends mainly on the designer and / or the steel contractors habits.

Configuration	A	B	
Span	16.50	16.50	[m]
Beam spacing	2.50	5.00	[m]

3 STRUCTURAL MODEL AND MODAL ANALYSIS

3.1 Base structural model

Self-weight and permanent loads are based on [4]. For the traffic loads we have considered §6.3.3 for garages and vehicle traffic areas, category F (Traffic and parking areas for light vehicles <30 kN gross vehicle weight and < 8 seats not including driver) [4] (see Table 2).

Configuration	A	B	
G : Self-weight	2.69	3.46	[kN / m^2]
P: Permanent loads	1.00	1.00	[kN / m^2]
Q_k: Design variable loads	2.50	2.50	[kN / m^2]
Q_{Real}: Realistic variable loads	1.25	1.25	[kN / m^2]

Table 2: Surface loads considered for design.

The design has been made according Eurocode 4 [4] for a simply supported standard composite beam. Freely available tools are available on the net for this kind of application (for example ABC edited by ArcelorMittal – CTICM [13]). As expected for this kind of structure, the value of the first frequency is between 2 and 3 Hz (see Table 3).

Configuration	A	B	
ULS utilization factor	95.6%	96.0%	[-]
Pre-cambering foreseen	140	180	[mm]
First frequency (G + P)	**2.71**	**2.27**	**[Hz]**

Table 3: Resume of most relevant design results.

3.2 Finite Element Model

A complex Finite Element Model has been built with the software SCIA Engineer [12]. For the scope of this study we have considered a portion of a car park structure with a bay of 20m (corresponding to 8 parking spaces, so 9 beams for configuration A and 5 for Configuration B) by 16.5m in the other direction (corresponding to the span of a simply supported beam). The slab is modeled with shell elements, whereas secondary beam and slab ribs re modeled by beam elements. It has been paid proper attention that in longitudinal direction (=beam direction) only the part of the slab above the dovetail is participating with the adequate offset. In transversal direction the ribs have been added as beam elements attached to the shell with an adequate offset. The model is linear concerning material and geometry.

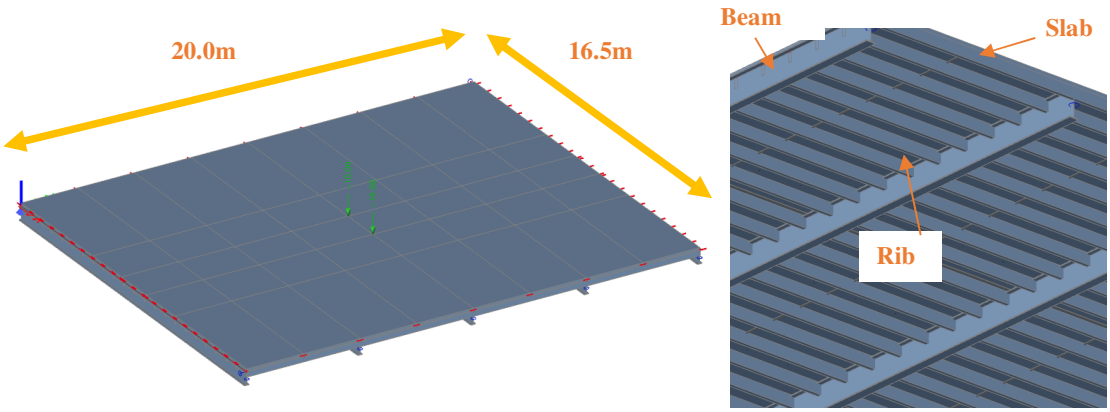

Figure 5: View of the FE structural model used for Configuration B.

3.3 Results of the modal analysis

The modal analysis is run with the model described above where the self-weight of the structure is given in table 2. It has been checked that for the load case self-weight and permanent loads (G+P), the first eigenfrequency calculated with the FEM software corresponds to the result of the analytical tool (compare Table 3 and table 4 for (G+P)).

When considering the mass linked with the presence of variable loads, only realistic configurations shall be considered. Therefore we have decided to consider a maximal value showed in table 2 but only in the parking lots where the presence of vehicles can expected. The realistic surface load corresponds to a vehicle of 1600 kg, which approximates the average vehicle weight in European countries, spread of a standard parking lot of 2.5m x 5m.

Configuration	A	B
G + P	**2.71**	**2.27**
G + P + Q_{Real} in every parking space	**2.56**	**2.18**
G + P + Q_{Real} in every parking space on one side of the lane	2.63	2.22
G + P + Q_{Real} in every second parking space	2.67	2.25
G + P + 0.8 * Q_{Real} in every parking space	2.59	2.20
G + P + 1.2 * Q_{Real} in every parking space	2.53	2.16

Table 4: First eigen frequency calculated for different load combinations.

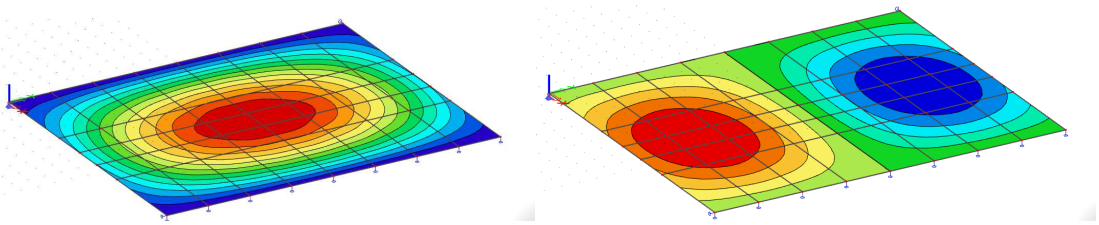

Figure 6: First two eigenmodes of the system

The eigenfrequencies have been afterwards calculated for each system with different combinations of parking lots being occupied (see load combinations in Table 4). In the scope of a sensitivity analysis, we have also evaluated the case of an exceeding of loading of +/- 20%, and as it can be seen the variation of the first eigenfrequency remains moderate as the main masses are still linked with the self-weight.

As it could be expected, all relevant modes, independently from the loading combinations showed before, are one-wave bending in the sense of the secondary beams (on the 16.5m length) and n-wave in transversal direction (mode 1: 1 wave which means all beams upwards or downwards together; mode 2: 2 wave in transversal direction, and so on).

It shall be noted that the first 4 modes are in a range of 1 Hz, which means that the transversal stiffness is relatibe small compared to the longitudinal one and it is rather easy to uncouple the bending modes of each secondary beam.

4 TIME-HISTORY ANALYSIS

4.1 Load model considered

For this study we have considered an axle load running in the middle of the central lane at a given speed. The load model is taken directly from [4] and is showed in Figure 7. The total load point load (Q_k in figure below) has been set equal to 20kN as the recommended upper boundary value.

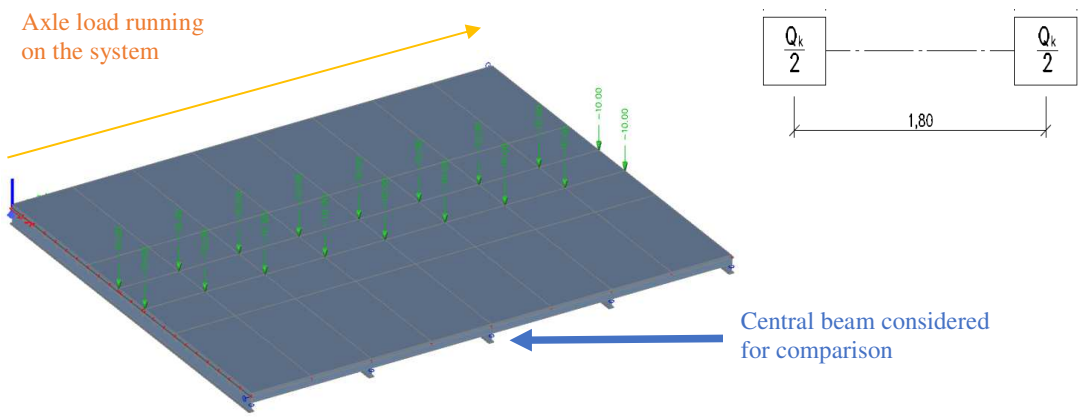

Figure 7: Loading model considered for the time-history analysis.

The load has been moving with different speeds chosen in the range from 18 km/h to 90km/h. The speeds exceeding 20…30 km/h in a parking are rather unprobeable event but are considered anyway as a term of comparison to establish an upper bound scenario.

In the meantime, the parking spaces have been considered full as per the previous simulation in order to achieve the lowest Eigen frequency that the system could possibly express. It has to be stressed that this corresponds to a very conservative approach, since an extreme vehicle load of 2tons (so quite unprobeable) is applied compactly on only single axle in a parking where are parking lots are full.

4.2 Analysis and damping ratio

The analysis has been run for each given speed for configuration A and B in a space of in a time step of 0.02s. The size of the mesh has been reduced to 0.25m so to achieve a good accuracy in the results. A damping ratio of 3% has been assumed in the analysis. This value is quite conservative as it applies, whereas a significant amount of the mass is given by the mass of the vehicles which provide a substantial higher damping ratio according to the literature [3], [11], [9].

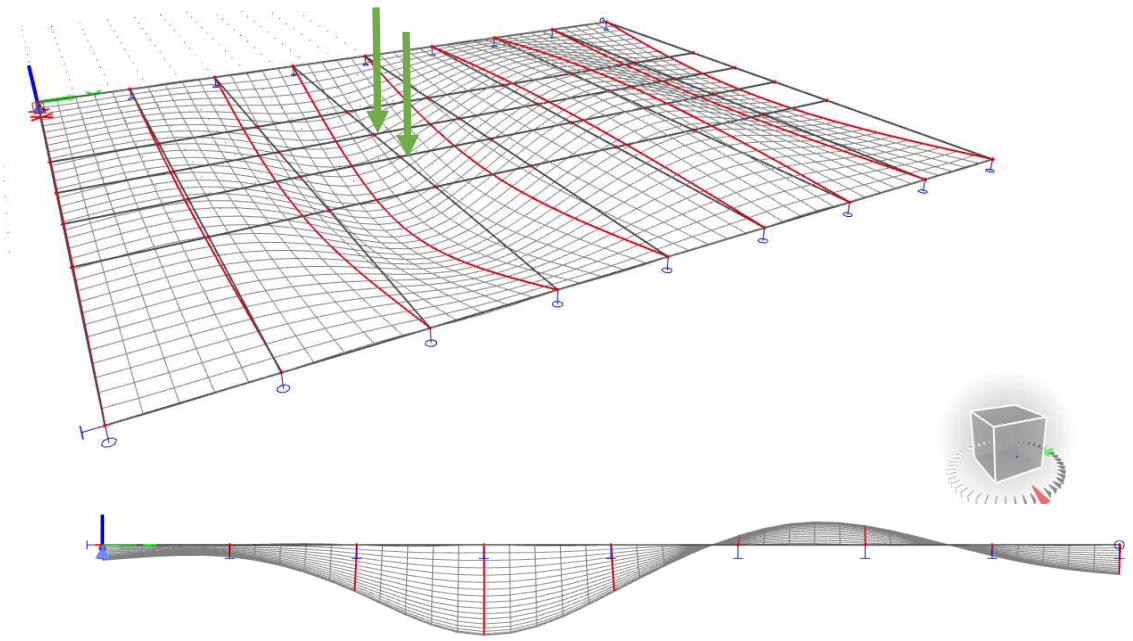

Figure 8: Example of displacement form achieved for a given load position in a dynamic analysis

4.3 Results - displacements

In figure 9 and 10 it is shoed the displacement curves of the midspan of the central beam in function of the time. The peak displacement corresponds to the moment where the vehicle is right above the central beam: this moment occurs in different time of analysis since the speed of the vehicle starting from the edge of the parking are different (the quicker the vehicle travels the sooner it will reach the central mid-span of the beam).

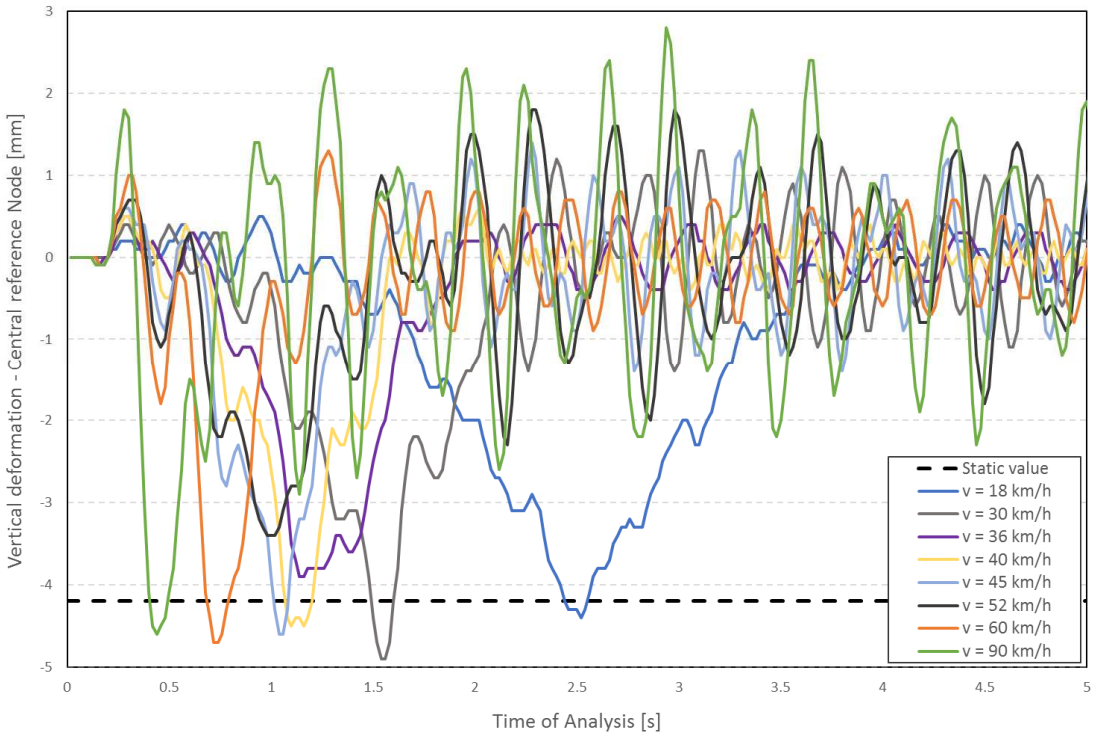

Figure 9: Configuration A – vertical deformation of central reference beam in function of different speeds.

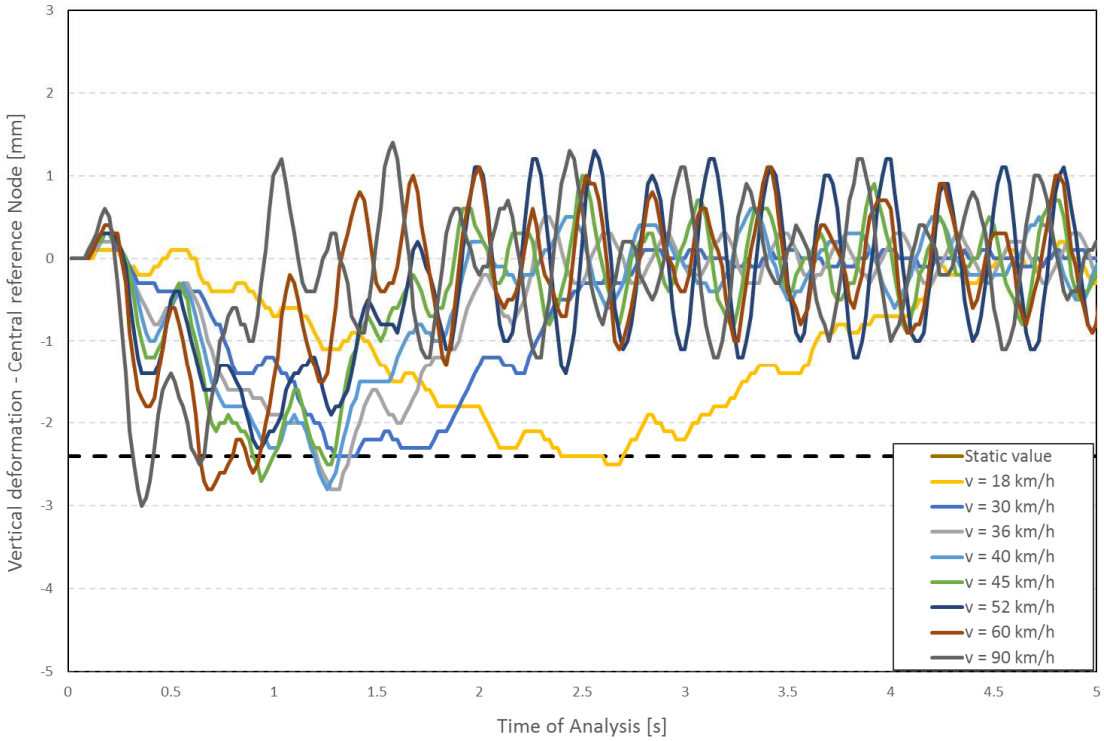

Figure 10: Configuration A – vertical deformation of central reference beam in function of different speeds.

Some key results are showed in the table below. It has to be stressed that despite configuration B presents an higher dynamic impact factor, nevertheless the displacement and the amplitude of the vibration is substantially lower (between 35% and 45%) than configuration A.

Configuration	A	B	
Static displacement	4.2	2.4	[mm]
Dynamic displacement	4.9mm	2.8	[mm]
Dynamic impact factor	1.17	1.25	[-]

Table 5: Dynamic impact factor concerning displacement.

4.4 Results - accelerations

In the assessment of the dynamic behavior of a floor the accelerations are far more important than the actual displacements. For the assessment of the floor vibration the guide [1], [11] will be followed. According the guidelines the root mean square acceleration has been calculated based on the calculated vertical values for each speed and each configuration. The results have been multiplied by two weighting factors, whereas the base curve for acceptance has been multiplied for a factor based on the type of structure considered.

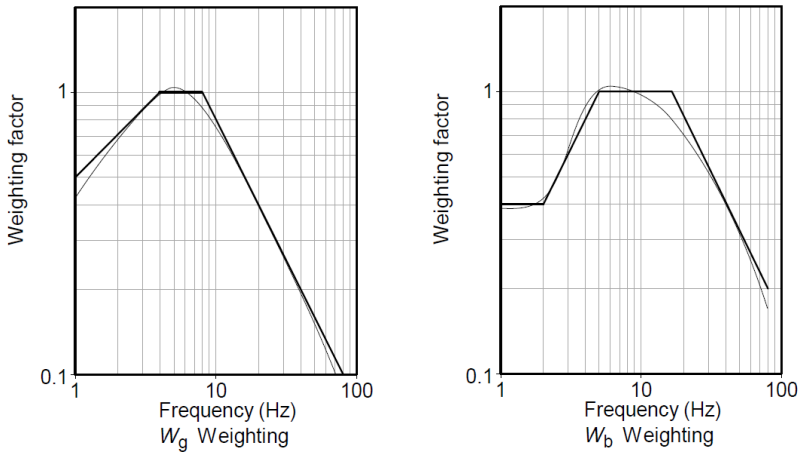

Figure 11: Weighting factors used as multiplier of the root mean square acceleration for each load case.

Configuration	A	B	
Wb	0.512	0.436	[-]
Wg	0.800	0.7382	[-]
Base curve multiplying factor	24	24	[-]

Table 6: Factors used based on BS 6472 [1] and [11]

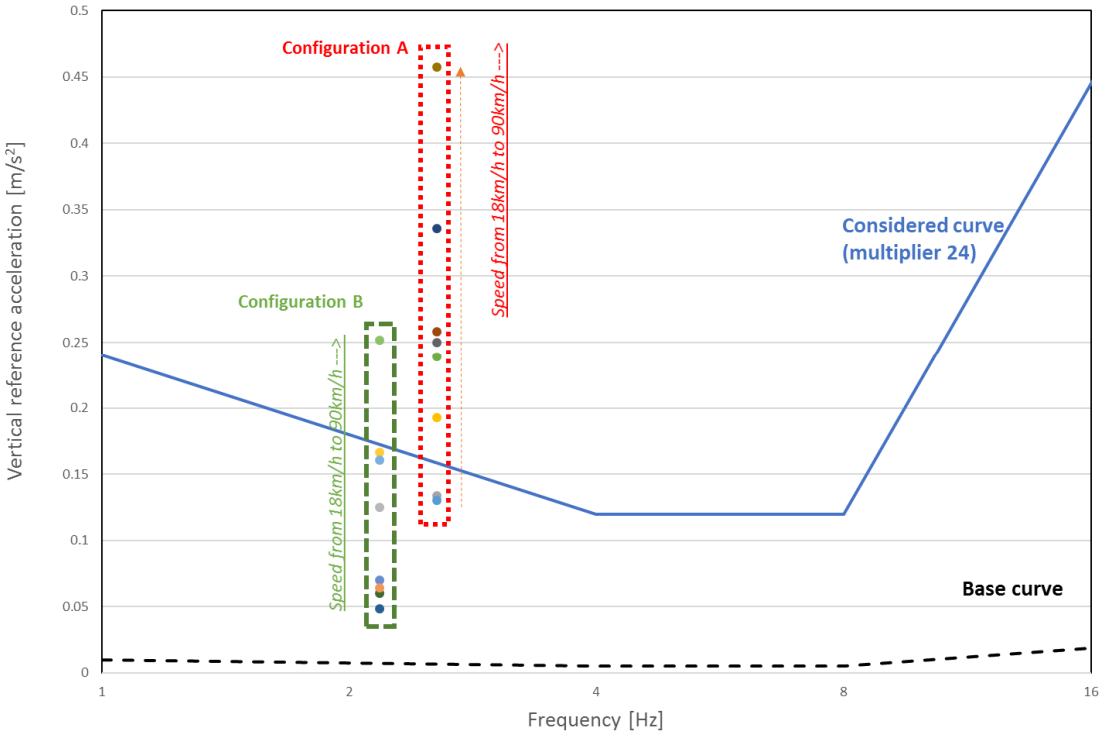

Figure 12: Vertical reference acceleration obtained for different speeds for Configuration A and B compared to the reference acceptance curve for floor vibration

4.5 Findings from the Time-history analysis

Figure 12 shows that several points lye below the considered acceptable floor vibration curve, whereas by increasing the speed the response of the system may result outside the conventional acceptance criteria. In order to express more clearly the results, the same points of Figure 12 have been replotted in Figure 13, but with the speed of the vehicle on the horizontal axis and the vertical reference acceleration in the vertical axis. The limits of the acceptance criteria have been set corresponding to the frequency of configuration A and configuration B.

Thanks to this representation we can clearly recognize that the acceptance criteria is satisfied for speed up to 22 km/h for Configuration A and up to 52 km/h for Configuration B, even under quite conservative assumptions that were taken to obtain these results. For vehicle speeds over this limit, the comfort acceptance criteria concerning criteria is not more guaranteed. Let's remind that current speed limitation criteria for cark parks are in the range of 20 km/h, so it can be considered that floor vibration disturbance can be excluded.

It is interest to remark that configuration B, despite having significantly lower eigenfrequencies, behaves consistently better than A under realistic traffic load. Even up to 60 km/h the vertical acceleration remains quite limited. This is mainly linked with the possibility of a larger transversal distribution under point loads. In this view it has to be stressed the importance of the continuity of the transversal ribs (there are systems with discontinuous slab ribs – in this case the dynamic behavior may be different due to a less efficient transversal distribution).

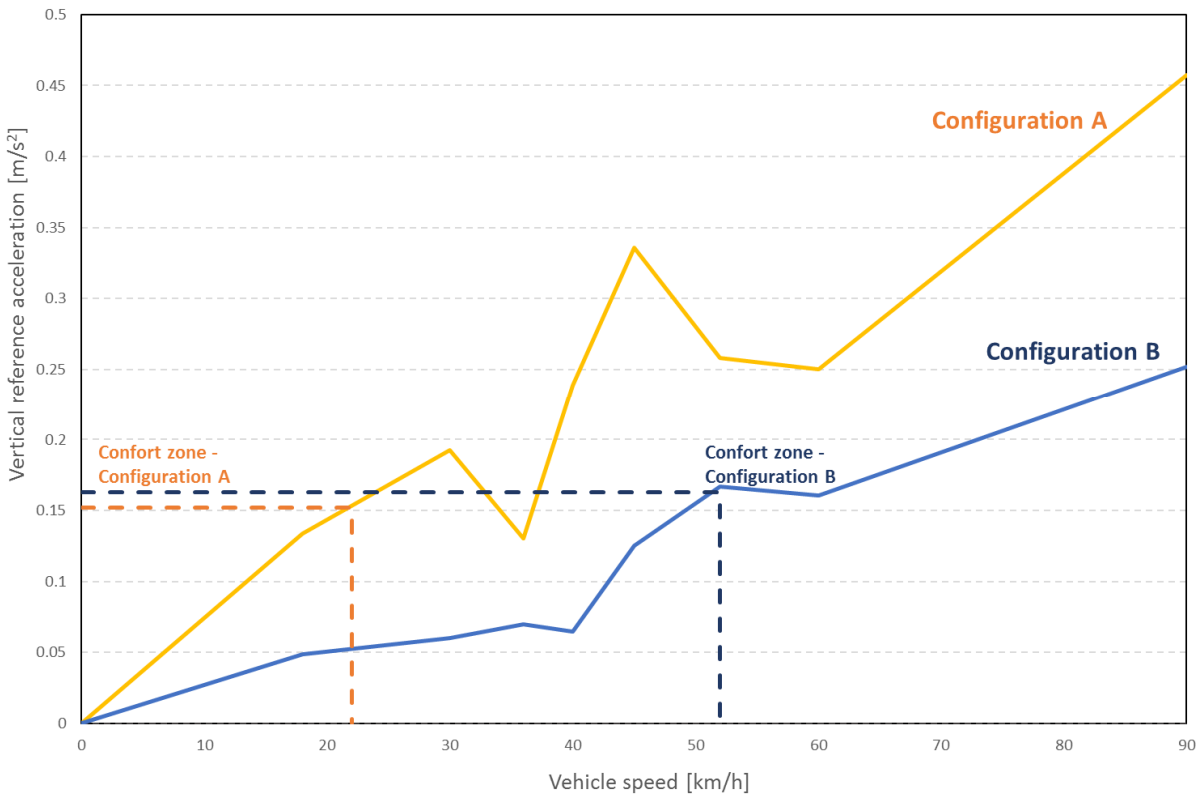

Figure 13: Vertical reference acceleration towards Vehicle speed

5 CONCLUSIONS

It is possible to resume the investigations showed in this paper in mainly three assessments:

- The two case studies considered, which are representative of the common solutions built nowadays, shows that steel-framed structures optimized for design strength behaves correctly also in serviceability limit states and more specifically regarding floor vibration. This shall confirm that no further serviceability criteria are needed.
- The first frequency is not a clear indicator for the dynamic performance of the system under traffic load, which is considered the more relevant for car park structure. Therefore imposing an arbitrary limit on this does not appear to be appropriate.
- For the loading considered and under same design assumptions, steel concrete composite structure with larger beam spacing (e.g. over two parking lots) and composite slabs with continuous ribs behave better from the dynamic point of view than comparable system with smaller beam spacing (e.g. over one parking lots). This is mainly due to a better load transversal distribution that in the case of localized loads (phenomena already known in bridge design).

Abstract

This paper reports an application of the Probabilistic Theory of Plastic Mechanism Control (P-TPMC) to a steel Moment Resisting Frames (MRFs) assumed as a case study. The validation of the accuracy of the proposed design methodology is given through non-linear dynamic analyses. In particular, the aim of the non-linear dynamic analyses is to check the collapse mechanism developed by the structures designed by P-TPMC. In fact, it is expected that the percentage of structures exhibiting a collapse mechanism of global type completely developed or compatible with it agrees with the fixed probability given as design achievement of P-TPMC. In other words, if the probability of having a collapse mechanism different from the global one is the 10% the aim of the non-linear dynamic analysis is to check if at least the 90% of the analysis output is entirely in agreement with the global mechanism.
The analysis results are given in terms of the number of plastic hinges developed in columns and beams. Each mechanism showing a lower number of plastic hinges on beams and first storey column bases is considered as compatible with a global mechanism while if plastic hinge also appears on columns of other storeys the mechanism has been considered partial.
The most significant part of analyses leads to the development of a collapse mechanism of global type. In quantitative terms, the percentage of success in achieving a collapse mechanism of global type is about 91% thus confirming the reliability of the design exploiting the P-TPMC.

Keywords: Theory of Plastic Mechanism Control, collapse mechanisms, moment resisting frames, stochastic frames, probability of failure, series systems.

1 INTRODUCTION

Under severe earthquake excitation, structures need to assure an adequate local [1]-[6] and global ductility and high-energy dissipation [7]-[12]. For this reason, the structure needs to exhibit the collapse mechanism of global type, where the dissipative zones are at beams ends and at the base of columns of the first storey, avoiding the partial failure mechanism. Modern design codes [13],[14] provide simple rules to prevent unsatisfactory collapse mechanisms. In case of Moment Resisting Frames (MRFs), the use of the so-called beam-column hierarchy criterion is suggested, but it is widely demonstrated that it is only able to prevent soft storey mechanism and generally it does not assure the development of a mechanism of global type.
In nineties, Mazzolani and Piluso suggested a deterministic procedure, the so-called Theory of Plastic Mechanism Control (TPMC) [15]-[28] to design Moment Resisting Frames able to assure a collapse mechanism of global type after a seismic event. The design rules are based on the extension of the kinematic theorem of plastic collapse to the concept of mechanism equilibrium curve to take into account second order effects. Recently, an improvement of this procedure has been proposed by taking into account the influence of random material variability. A probabilistic analysis is proposed to define the proper value of an overstrength factor to be applied as a multiplying coefficient of the bending resistance of dissipative zones. This approach is called Probabilistic Theory of Plastic Mechanism Control (P-TPMC) [29]-[31].
In this paper, the effectiveness of the P-TPMC is investigated through non-linear dynamic analyses. First of all, the benchmark structure has been defined, and it has been designed given a fixed reliability performance goal. To this scope, an adequate overstrength coefficient is used to increase the beam strength. As higher this coefficient is as highest is the expected probability of having a collapse mechanism of global type. After that, the deterministic TPMC is applied to design the structures considering the assigned overstrength. To check if the collapse mechanism of global type is verified under real earthquake record, the benchmark structure has been modelled and analysed by SAP 2000. A series of 84 real earthquake record for different soils conditions have been used to excite the structure.
For each earthquake, the collapse mechanism achieved is evaluated. Naturally, when the collapse mechanism of global type occurs, it is a success of P-TPMC. Conversely, the failure in the design purpose is verified when the structures exhibit a collapse mechanism different from the global one. Finally, the probability of success in applying the TPMC is defined as the ratio between the number of times when the global mechanism is verified and the total number of analyses.

2 DESIGN OF MOMENT RESISTING FRAME ACCORDING TO P-TPMC

In this section, the design of steel moment resisting frame is presented according to the Probabilistic Theory of Plastic Mechanism Control [29]. The considered benchmark structure is characterized by 4 storeys (number of storeys: n_s), 5 bays (number of bays: n_b) The interstorey height is 3.50 m and the bay span is equal to 6.00 m. The considered steel grade is S275. Moreover, in this step the hypothesis on the soil characteristics are not provided because the design procedure is dependent on the horizontal action distribution only [17]. Therefore, the seismic actions are deterministically distributed according to the first vibration mode of the structure.

2.1 Definition of overstrength factor

In previous works [29], a probabilistic procedure is proposed to compute an overstrength factor to apply to the deterministic version of TPMC which considers the aleatoric uncertainty of material properties. This probabilistic approach is based on the application of the First Order Reliability Method (FORM), and the Ditlevsen Bounds applied for events located in series [32]-

[35] combined with Theory of Plastic Mechanism Control [16]-[31]. Moreover, the same authors provided a mathematical relationship for computing the overstrength factor depending on the number of beams:

$$\gamma_{ov} = -0.0192 n_b + 1.2036 \tag{1}$$

Eq.(1) is derived by a parametric analysis performed for steel grade S275 and for fixed reliability level equal to 90%, which represents the success probability of the TPMC in the development of collapse mechanism of global type. In this case, the overstrength factor to be applied to the deterministic procedure of TPMC is equal to 1.11. More details on the probabilistic approach applied to TPMC and on the parametric analysis carried out to define Eq.(1) are provided in [29].

2.2 Application of Theory of Plastic Mechanism Control

In this section the steps followed in designing the member sections of the examined frame are presented:

Step 1

Definition of the ultimate displacement δ_u, compatible with the ductility supply of the dissipative zones:

$$\delta_u = \theta_u h_{n_s} \tag{2}$$

where θ_u is the steel plastic rotation assumed equal to 0.04 rad, and h_{n_s} represents the total height of the structure. In this case, the ultimate displacement is 0.56 m.

Step 2

The beam sections are the same for all the bays, and they are designed for gravity loads whose values are $G_k = 15.00\ kN/m$ and $Q_k = 6.00\ kN/m$ for permanent and live load, respectively. Referring to the non-seismic load combination, the maximum gravity load acting on the beams is:

$$q_v = 1.35 G_k + 1.50 Q_k = 28.50\ kN/m \tag{3}$$

This value is assumed as a deterministic quantity. The selected beams are IPE 360.

Step 3

All the collapse mechanism equilibrium curves are identified for the studied frame:

$$\alpha = \alpha_0 - \gamma \delta_u \tag{4}$$

where α is a collapse multiplier of structures, α_0 represents the first order multiplier, γ is the slope of curve depending on the second-order effects and, finally, δ_u is the ultimate displacement of the structure. The definition of the column sections is carried out, amplifying the plastic modulus of beams with the overstrength factor γ_{ov} and applying the following design condition:

$$\alpha^{(g)} \leq \alpha^{(t)} => \alpha_0^{(g)} - \gamma^{(g)} \delta_u \leq \alpha_{0.i_m}^{(t)} - \gamma_{i_m}^{(t)} \delta_u \quad for\ t = 1,2,3\ and\ i_m = 1,2,\dots n_s \tag{5}$$

where "g" indicates the global mechanism while "t" represents a generic collapse mechanism different by the global type and i_m is the generic storey of the structure. It is important to underline that the Eq.(5) ensures that the curve of the global mechanism is located below those corresponding to all the other undesired mechanisms until the ultimate displacement δ_u [16],[17]. The column cross-sections are given in Figure 1.

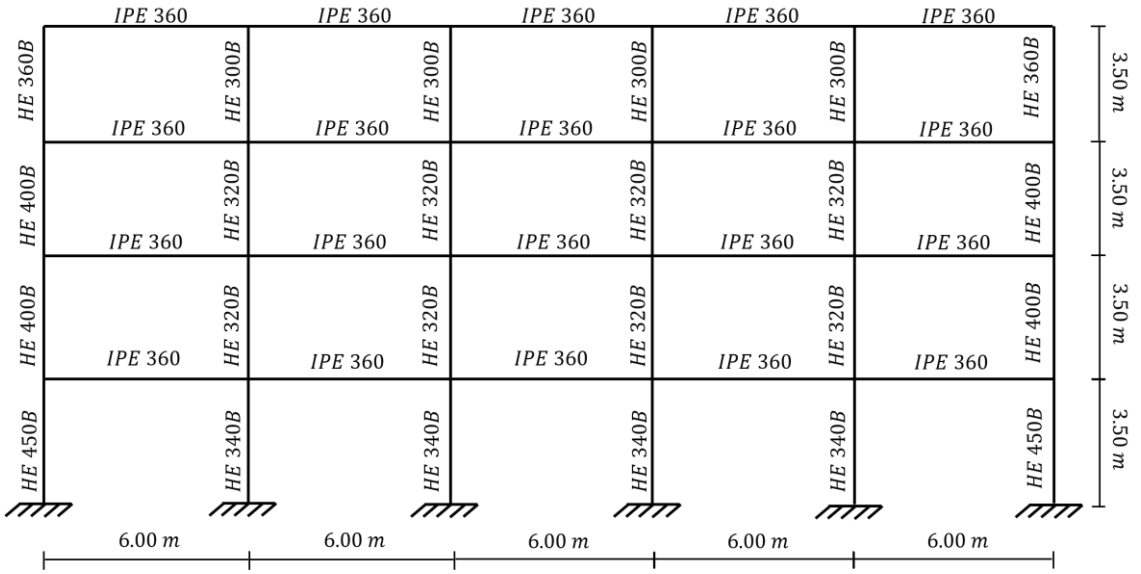

Figure 1: Case-study Frame.

3 VALIDATION BY MEANS NON-LINEAR DYNAMIC ANALYSIS

The aim of the non-linear dynamic analyses presented in this section is to check the collapse mechanism developed by the structures designed by P-TPMC [36]-[39]. In fact, it is expected that the percentage of structures exhibiting a collapse mechanism of global type completely developed or compatible with it agrees with the fixed probability given as design achievement of P-TPMC. In other words, if the probability of having a collapse mechanism different from the global one is the 10% the aim of the non-linear dynamic analysis is to check if at least the 90% of the analysis output is completely in agreement with the global mechanism. The same structure, reported in Figure 1, has been undergone to a set of 84 recorded accelerograms selected from OFEUS database [40]. In particular, 16 earthquake ground motions for soil A, 34 for soil B and 34 for soil C have been selected. Rayleigh formulation for a 5% damping has been assumed with the proportional factors computed with reference to the first and third mode of vibration (T_1=0.74 s and T_2=0.22 s). In Table 1 the analysed records (name, component, date, magnitude, soil, the ratio between PGA and gravity acceleration, length and magnitude) have been reported. The step recording is equal to 0.005 s for each signal. Each earthquake has been scaled to achieve the same level of spectral acceleration. The reference spectrum is Type 1 according to EC8 with a a_g/g equal to 0.35.

The scaling factor the earthquake has to be scaled with is different for each soil category, and it has been computed by multiplying the collapse mechanism multipliers reported in Table 2 with the spectral acceleration achieved in correspondence with the first period of vibration of the structure. In this way, the structure is expected to overcome the elastic phase.

The structure has been modelled and analysed in SAP 2000 [40]. The geometrical and mechanical model is given by beam-column element whose yielding has been taken in account by P-hinge properties.

Two rigid-plastic hinges are located at the member ends. Plastic hinge properties are defined in pure bending (M3 hinge) for beams while in case of columns they are defined to account for the interaction between bending and axial force (P-M3 hinges).

Both geometrical and mechanical non-linearities have been accounted for in the analysis phase [41].

Table 3. Results of non-linear dynamic analysis referred to soil A.

The analysis results are given in terms of the number of plastic hinges developed in columns and beams. The maximum number of plastic hinges able to develop at beam ends is 30 while only 6 plastic hinges at column bases should develop if the mechanism exhibited by the structure is compatible with the global one. Each mechanism showing a lower number of plastic hinges on beams and first storey column bases is considered as compatible with a global mechanism while if plastic hinge appears also on columns of other storeys the mechanism has been considered partial.

From Table 3 to Table 5 it is observed that the largest part of analyses lead to the development of a collapse mechanism of global type. In quantitative terms, the percentage of success in achieving a collapse mechanism of global type is about the 91% thus confirming the reliability of the design exploiting the P-TPMC.

Table 5. Results of non-linear dynamic analysis referred to soil C.

4 CONCLUSIONS

- In this paper an application of the Probabilistic Theory of Plastic Mechanism Control (P-TPMC) to a steel Moment Resisting Frames (MRFs) assumed as a case study is reported.
- Non-linear dynamic analyses on a base of 84 earhquake records have been performed to assess the accuracy of the design procedure proposed.
- The expected percentage of success is equal to 90%.
- The obtained percentage of success is 91% thus confirming the reliability of the proposed procedure.

Abstract

In the present work, the design and the non-linear static analysis of innovative steel seismic-resistant perimeter systems are reported. In particular, Moment Resisting Frames (MRFs) and Dual-Concentrically Braced Frames (D-CBFs) were designed by using the Theory of Plastic Mechanism Control (TPMC). Eight structures, having the same geometric characteristics and the same seismic parameters of the site and the structure, were designed for each structural typology. The structures differ in the number of storeys, number of bays, bay length but they were designed for a Peak Ground Acceleration equal to 0.35g. The innovation consists in locating friction dampers of FREEDAM typology at the beam ends and at the intersection of chevron braces. The FREEDAM dampers can dissipate input seismic energy through the relative slippage between pads, of which they are made up. They preserve the main structural elements, such as beam ends and chevron braces, from damage. In the case of MRFs, FREEDAMs replace the traditional dissipative zones. In Dual CBFs, a share of FREEDAMs substitute the aforementioned dissipative zones and, besides, those located at the top of chevron braces, represent a supplement to the seismic energy dissipation. In this way, the structure remains intact even after severe earthquakes; meanwhile, the dampers can be easily substituted. Furthermore, the TPMC design procedure, based on the kinematic theorem of plastic collapse, allows all the dissipative zones are involved in the yielding, thus developing a collapse mechanism of global type. Thanks to the design procedure, it is sure the yielding occurs in the dissipative zones, where dampers are located, and not in any other parts of the structure.
The work aims to analyse and compare the two structural typologies both in terms of design results and in terms of seismic performance. It has been investigated which is the more convenient structural typology, keeping in mind the Eurocode 8 limitation on the interstorey drift. In addition, the design procedure has been validated using non-linear static analyses, such as pushover analyses. The designed structures have been finally compared also in terms of seismic performances.

Keywords: Plastic design, Connections, Friction Dampers, Moment Resisting Frames, Concentrically Braced Frames, FREEDAM Project.

INTRODUCTION

The use of friction devices is increasing all over the world because of their clear advantages. Adequately replacing the dissipative zones, or just added to the frames as an additional dissipative resource, they safeguard the main structural elements from damage with effectiveness and versatility [1]-[8].
The structural damage is essential to dissipate the earthquake input energy, but it is the main source of direct and indirect losses. Many researchers have focused their attention on the strategy of supplementary energy dissipation with the aim to reduce the structural damage under destructive seismic events. This strategy is based on the use of specific energy dissipation devices to be inserted between couples of points of the structural scheme for which high relative displacements or velocities are expected under the action of severe ground motions [9]-[12]. In the framework of passive control [13]-[17] dampers can completely substitute the dissipative zones, i.e. beam ends. To this purpose, beam-to-column connections can be equipped with friction dampers, which can be located either at the level of the two flanges or at the bottom flange level only. In this paper, reference is made to beam-to-column FREEDAM connections that have been widely tested at the Laboratory of Materials and Structures of University of Salerno in the framework of FREEDAM project.
In particular, two structural typologies are investigated in this paper, the first one refers to Moment Resisting Frames (MRFs) while the second one relates to Moment Resisting Frames-Concentrically Braced Frames dual systems (MRF-CBFs dual system). In fact, in many cases, MRFs could be highly oversized due to the need to respect serviceability requirements. This can be specially highlighted in structures where the primary beam is parallel to the secondary beams of the floor, i.e. when the beam sections are not deeply loaded. In such cases, indeed, to respect the serviceability limitations, could be useful adding chevron braces which can be dimensioned only to limit the lateral displacement. Furthermore, the braces intersection can be the natural location of an additional friction damper helping in the overall dissipation capacity of the structure. Given the above, the scope of the paper is highlighting the differences occurring between MRFs and Dual systems in terms of structural weight and seismic performances. Moreover, structures are designed according to the Theory of Plastic Mechanism Control [18]-[30], which assure that all dissipative zones are involved in yielding showing at the collapse a global mechanism. In particular, the design procedure adopted for designing MRFs and MRF-CBF dual systems is reported in a previous paper [20] and it is not herein reported for the sake of shortness. Both MRFs and Dual systems are also analysed by pushover analyses to highlight the difference between the two structural schemes investigated.

1 FREEDAM DAMPERS

The FREEDAM dampers are dissipative elements which can dissipate the input seismic energy using the slippage force arising between the pads constituting the device [17],[31]-[35]. In this work, the FREEDAM dampers are used in the field of both the substitution and the supplementary seismic design strategy. Indeed, a FREEDAM damper is located at the intersection of the chevron braces of MRF-CBF dual systems and in beam-to-column joints of MRF, respectively. The two different details are reported in Figure 1 and Figure 2 and are better described in the following. The main advantage of these connections is that their flexural resistance can be calibrated to transmit, as carefully as possible, the bending moments occurring under the seismic load combination, thus promoting the simultaneous activation of all the friction dampers. In particular, the dissipation is concentrated in the friction pads, located at the bottom flange level of beams, whose slippage is the basis of the energy dissipation process. The other elements

constituting the FREEDAM connections are designed to remain in elastic range as the column sections at each storey.

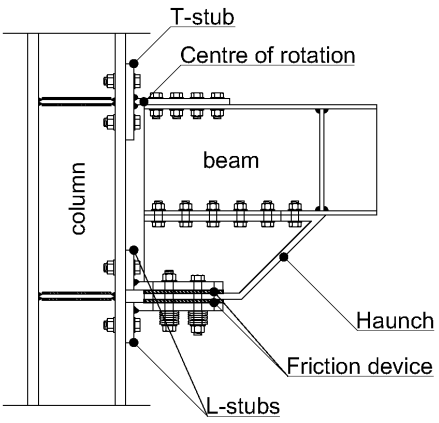

Figure 1: FREEDAM Beam-to-column connection

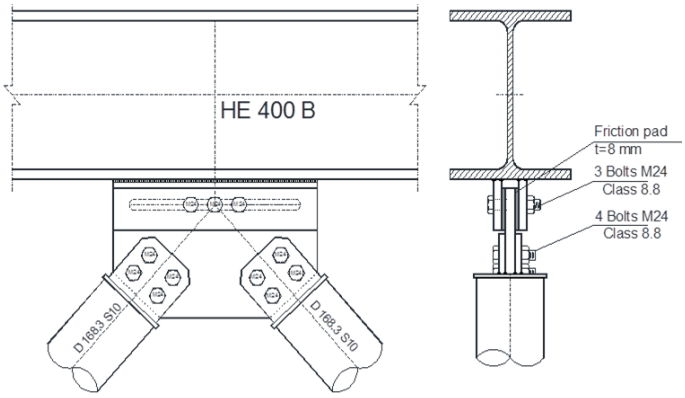

Figure 2: FREEDAM friction damper to the chevron brace

The FREEDAM beam-to-column joint is made up of an upper beam flange, connected to the column by means of a classical T-stub, in which the rotation centre of the joint is located. The friction damper is at the bottom flange level where slippage occurs due to the use of slotted holes, realised on the additional haunch. The friction pads are preloaded by means of high strength bolts [17],[31]-[35]. The FREEDAM damper located at the top of chevron braces is made up of a haunch composed by vertical steel plates with horizontally slotted holes. The only exception is the inner plate realised in Stainless Steel and bolted to the pre-stressed friction shims.

In order to design the joint [36]-[37], the two principles of capacity design are applied. According to the first one, the dissipative zones are designed using the maximum stress deriving from load combinations. Moreover, the second principle states that the non-dissipative zones have to be designed according to the maximum internal actions that dissipative ones can transmit in their full yielded and strain hardened conditions.

In the study cases herein reported, the FREEDAM beam-to-column dampers have been designed once the beams and columns had already been sized. This happens because the Serviceability Limit State checks are the most stringent requirements. The maximum value due to the seismic actions and to the vertical loads has to be chosen [19] to evaluate the flexural resistance of each joint. The former is evaluated using distribution along the storey height analogous to the seismic storey shear distribution, as suggested by Goel and Lee [38]. Hence, the slip force, F_{slip}, acting on the FREEDAM damper at j-th bay of k-th storey has to be evaluate by dividing the joint flexural resistance, $M_{f.Ed}$, by the lever arm, z:

$$F_{slip} = \frac{M_{f.Ed}}{z} \tag{1}$$

The lever arm is the sum of the beam depth, d_b, and of the haunch height, h_h.

Similarly, also the slip resistance of the friction dampers located in series with the chevron braces is distributed along the building height according to the seismic storey shear distribution [21], [39]-[42]. However, in this case, friction dampers are properly designed at first, while the remaining structural elements have been obtained as a result. For the non-dissipative zones, such as beams and diagonal, the second principle of capacity design is applied. In particular, for the beam, it has to be check that the capacity design value of bending moment is less than

the bending resistance of the beam. Moreover, as soon as the design resistance of such chevron braces dampers has been established, the braces can be designed by considering the maximum friction resistance which the dampers are able to transmit in their ultimate condition. The columns, also constituting the non-dissipative zones, will be derived from the TPMC design procedure.

2 THEORY OF PLASTIC MECHANISM CONTROL

The Theory of Plastic Mechanism Control (TPMC) is a design procedure based on the kinematic theorem of plastic collapse and extended to the concept of mechanism equilibrium curve:

$$\alpha = \alpha_0 - \gamma\delta \tag{2}$$

where, according to the theory of rigid-plastic analysis, α_0 is the first order collapse multiplier of horizontal forces, γ is the slope of the linearized mechanism equilibrium curve due to second-order effects and δ is the plastic top sway displacement. Differently, from the Eurocode 8 provisions [43]-[44], TPMC can directly and rigorously take into account the second-order effects. As illustrated in Figure 3, this theory states that the curve corresponding to the global mechanism has to be located under those corresponding to all the undesired mechanisms, until a design displacement δ_u, compatible with the local ductility supply [19], is achieved. Starting from the design of the dissipative zones, the TPMC design procedure provides the column sections by which a global collapse mechanism is assured.

More details about this design procedure applied can be found in [19] for steel MRFs and in [20] for MRF-CBF dual systems equipped with friction dampers.

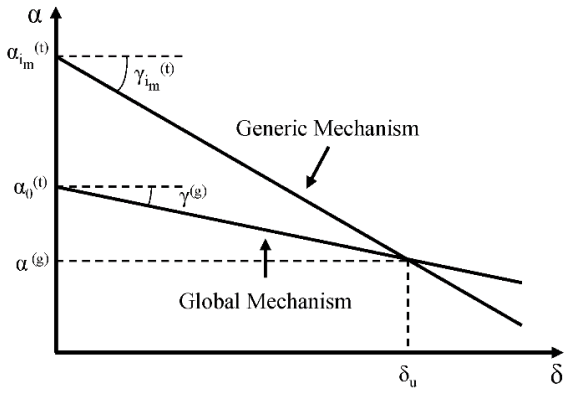

Figure 3: TPMC statement

3 DESIGNED CASE STUDIES

The plan configuration of the study case is reported in Figure 4. The material adopted for all the members is S355 steel grade (f_{yk}=355 MPa). The buildings are made up of a pinned internal part and of a perimeter seismic-resisting system. For this latter, two structural typologies have been designed: MRFs and MRF-CBFs dual systems, both equipped with FREEDAM dampers. In particular, for MRF-CBFs dual systems not only beam ends but also the intersection between diagonal is equipped with FREEDAM dampers. Eight structures for each typology have been resulted by varying the span length, the number of bays and the number of storeys. The values of the considered span length are 6 and 8 meters. The number of bays is 3 or 5 and the buildings consist of 3 and 6 floors. In elevation, all the buildings consist of a first-floor interstorey height equal to 4.5 m and of 3.5 m interstorey height for the other floors. Table 1 shows all the designed structures including the relative characteristics.

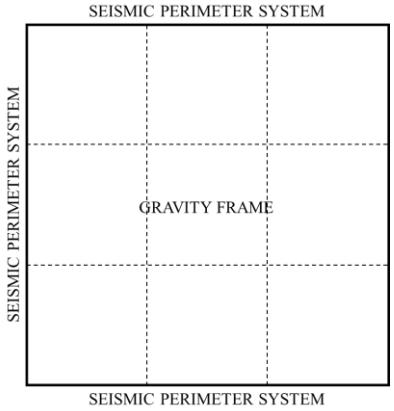

Figure 4: General plan configuration of the designed buildings.

Scheme name	Number of storeys	Number of spans	Span length [m]	Designed structural typology
Scheme 2	3	3	6	MRF MRF-CBF
Scheme 4	3	3	8	MRF MRF-CBF
Scheme 6	3	5	6	MRF MRF-CBF
Scheme 8	3	5	8	MRF MRF-CBF
Scheme 10	6	3	6	MRF MRF-CBF
Scheme 12	6	3	8	MRF MRF-CBF

Scheme 16	6	5	8	MRF MRF-CBF

Table 1: Report of the structures and their geometric features.

The permanent (G_k) and live (Q_k) loads have been chosen within a practical range and are reported in Table 2. This latter also includes the values of the combination coefficients for the variable actions ψ_2 and ψ_E used, respectively, for the quasi-permanent value of the variable actions and for determining the effects of the seismic design action.

Location	Type	Load [kN/m^2]	$\psi_{2,i}$	$\psi_{E,i}$
Roof	Permanent Variable	4.5 2	0.3	0.24
Intermedi-ate stories	Permanent Variable	4.5 2	0.3	0.15

Table 2: Characteristic values of loads

The structures have been subjected to the Lateral Force Method of analysis, according to Eurocode 8 [44], assuming a Peak Ground Acceleration (PGA) equal to 0.35g, a seismic response factor equal to 2.5, a behaviour factor equal to 6.5 for the design spectrum with a 2%

damping, a response spectrum Type 1 and soil Type C. In addition, the serviceability conditions have been checked, such as the interstorey drift has been kept under the limitation of 1% of the interstorey height, as the code [44] requires. It is important to underline that this kind of check significantly conditions the designing, being the most restrictive condition to comply with.

Table 3 sums up the results of the design, while Figure 5 shows the members size of Scheme 2 and allows to understand the column labels reported in Table 3.

Table 3: Size of the members resulting from the design.

The MRF-CBF dual systems structures have shallower sections than the related ones designed as MRF. The difference in weight obtained between the two structural typologies has been evaluated. In general, it is possible to state that the use of MRF-CBF dual systems allows a moderate weight reduction of the structure, on average, which results in economic savings. In Table 4 the weights of designed structures and the weight loss in per cent are reported. These values are better shown in Figure 6.

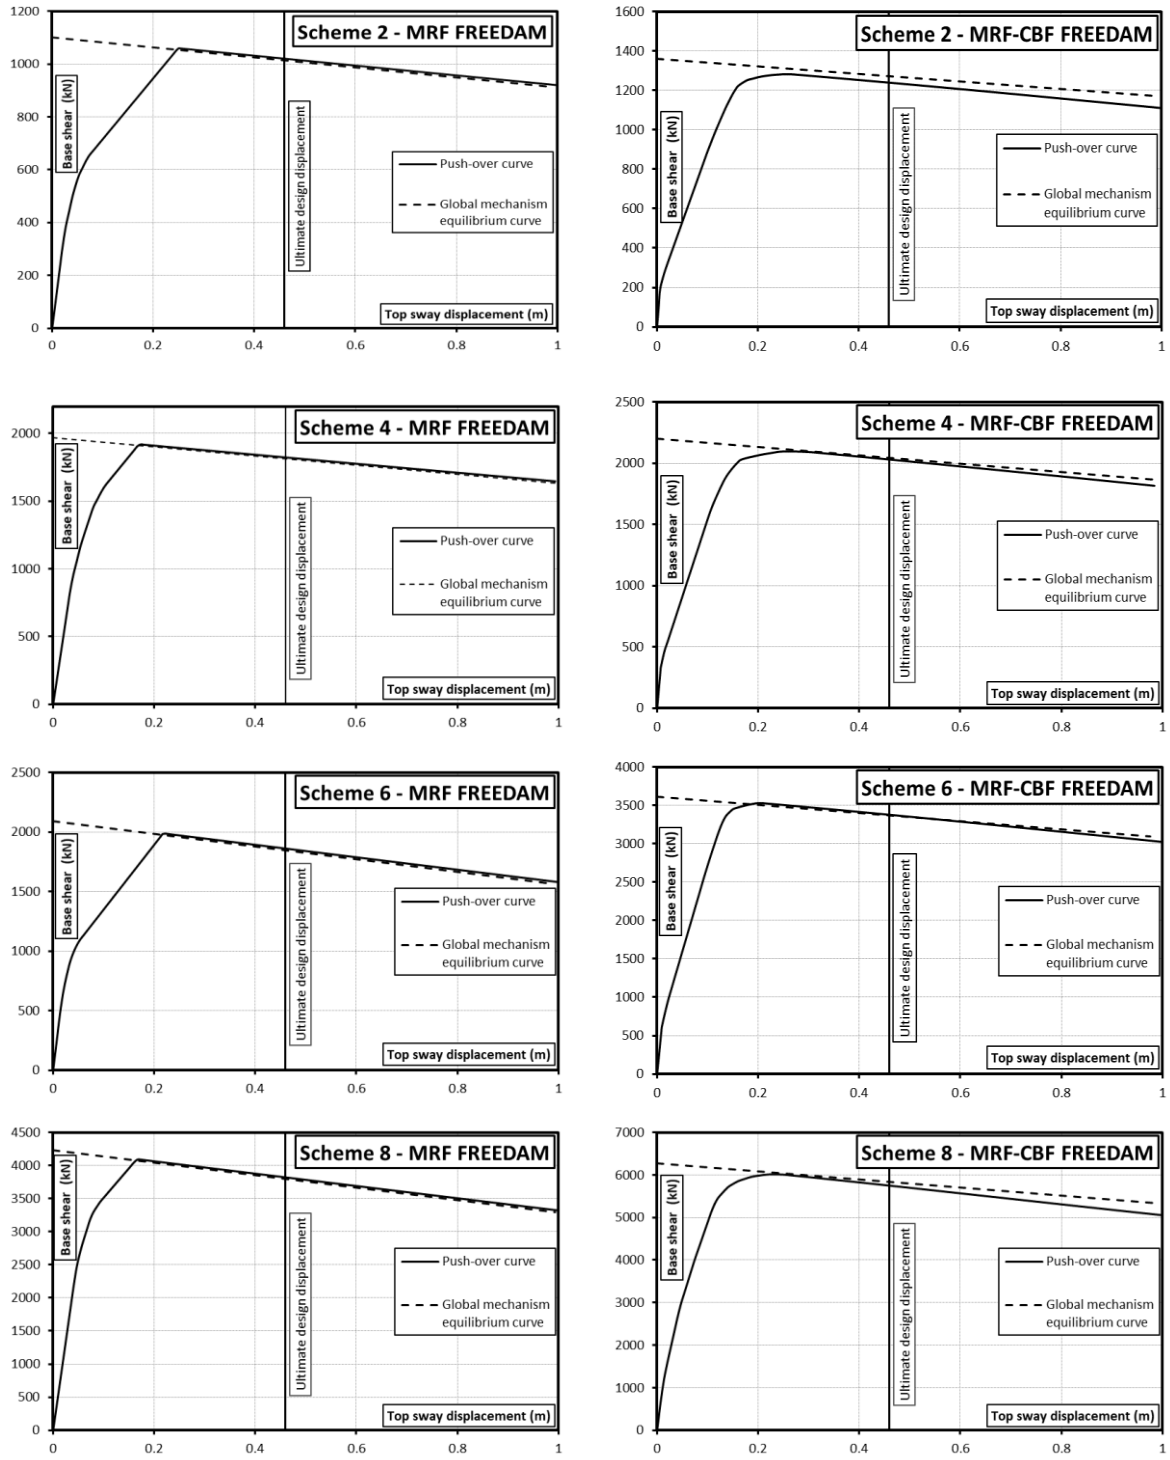
4 SEISMIC ASSESSMENT BY PUSHOVER ANALYSES

The designed structures have been subjected to pushover analyses employing SAP2000 [45].

All the structural elements constituting the structures, i.e. beams, columns and diagonal braces, have been modelled by means of beam-column elements. The non-linearities are located in plastic hinges ("P-hinge" elements), equipping the ends of the abovementioned elements. The plastic hinges put at the ends of diagonals and columns account the interaction between axial force and bending moment. The plastic hinges have been modelled in pure rigid-plastic bending, resulting from the product between the slippage resistance of the friction damper and the lever arm. For what concerns the FREEDAMs located at the chevron braces intersection, they have been modelled by means of a short beam-column element equipped with rigid plastic P-hinge properties in shear, whose threshold is calibrated to represent the slippage resistance of the friction damper. The slippage resistance of friction dampers accounts for the over-strength

due to the random variability of the friction coefficient and the uncertainties of the bolt preloading level. The elastic component of the structural behaviour is directly taken into account by the elasticity of the beam-column element.

In Figure 7, the pushover results are reported concerning the MRFs and MRF-CBF dual systems both equipped with FREEDAM connections. The softening branch of pushover curves is in perfect agreement with the global mechanism equilibrium curve for each structure. It means that all the structures develop a collapse mechanism of global type, i.e. all the dissipative zones are involved in yielding and the dissipation of the seismic energy is maximised.



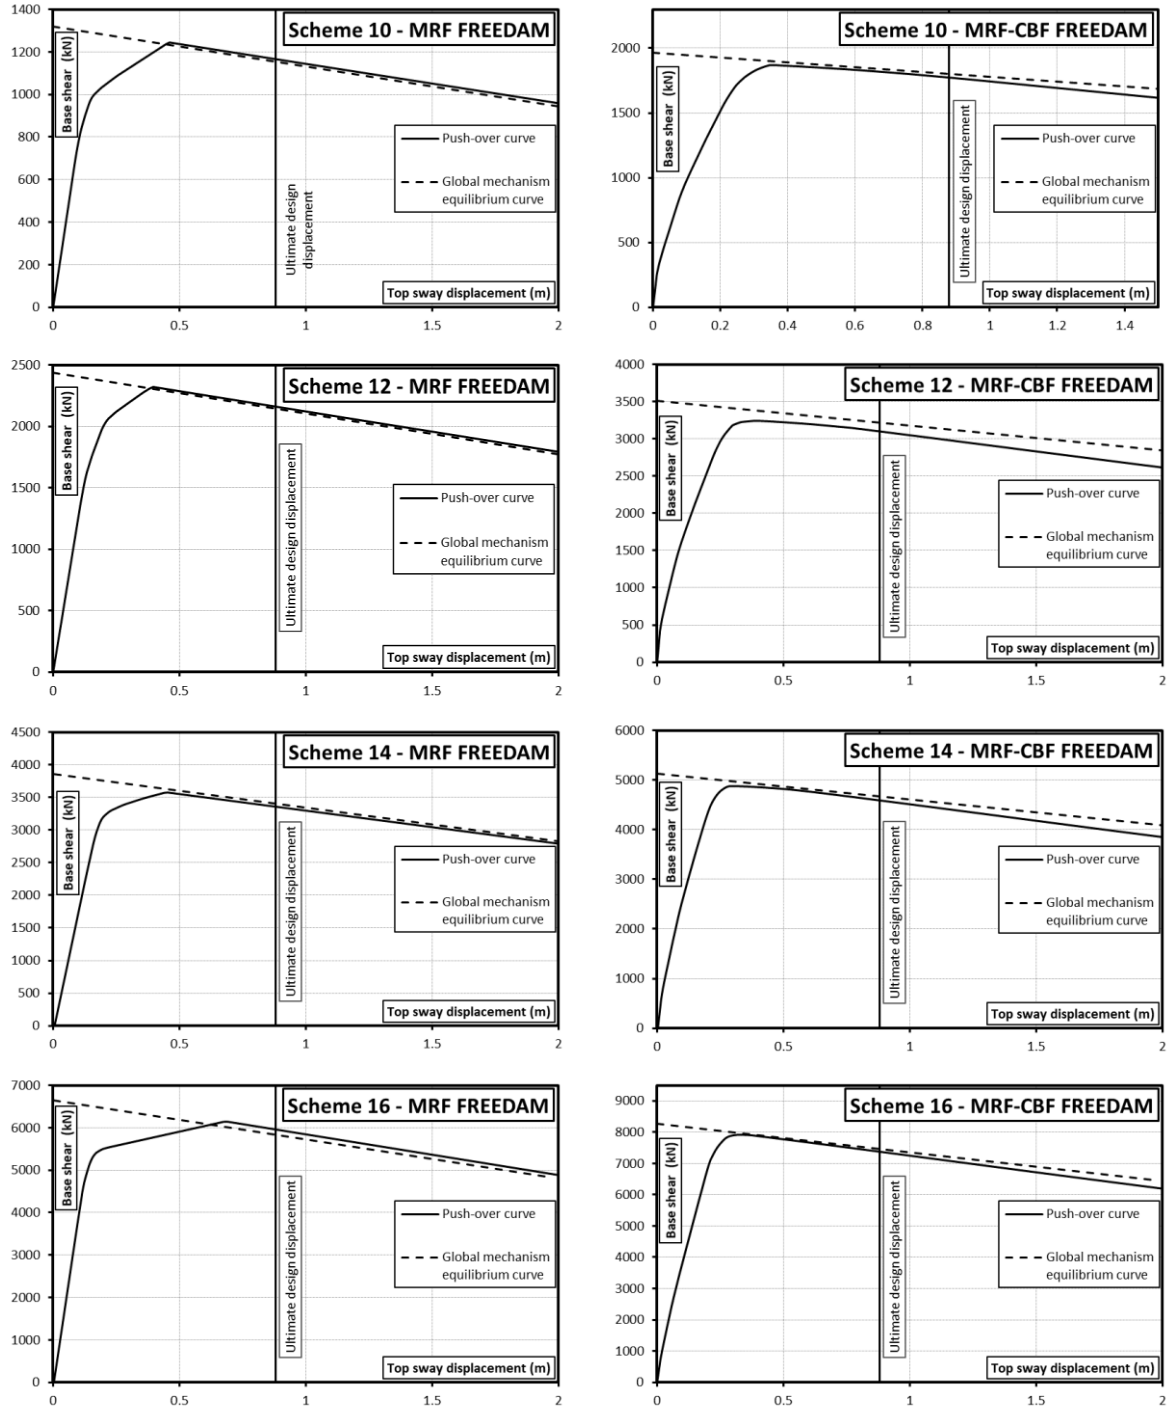


Figure 7: Pushover curves

5 CONCLUSIONS

- In this paper, many samples of steel structures designed according to the TPMC have been presented.
- MR-Frames and MRF-CBF dual systems equipped with FREEDAM dampers in beam-to-column joint and in the intersection of chevron braces have been considered. They have the same geometrical features and seismic parameters.

- In terms of weight, MRF-CBF dual systems show shallower sections if compared with MRFs. On average, the weight loss between the two different typologies is about 15.15%.
- Pushover analyses demonstrate that TPMC guarantees the development of a collapse mechanism of global type, thus engaging all the dissipative zones in yielding.
- Pushover curves show that the MRF-CBF dual systems, even if shallower, can achieve higher resistance than MRFs with lower displacement.
- Finally, in light of the considerations made so far, when the issue governing the design is the respect of serviceability limitation, the use of MRF-CBFs is more convenient if compared with MRFs because they allow obtaining lighter structures respecting the drift limitations and with higher seismic performances.

Abstract

Numerical liquefaction model and analysis procedure are verified based on the dynamic centrifuge test results. The test was a part of the Liquefaction Experiments Analysis Project (LEAP). The model ground was formed inside of the rigid box by using the submerged Ottawa F65 sand with a relative density of 55% and 5 ° of surface inclination. A tapered sinusoidal wave with a frequency of 1 Hz was applied to the base of the model box. Numerical analyses were performed under two and three-dimensional condition in prototype scale. The soil is modeled to show hysteretic behavior before shear failure, and Mohr-Coulomb model is applied for shear failure criterion. Byrne's liquefaction model was applied to track the changes in pore pressure due to cyclic loading after static equilibrium. The numerical analyses performed in this study showed good agreement with the physical test results.

Keywords: Liquefaction, Numerical Analysis, Centrifuge Test, Finite Difference Method, Liquefaction Model.

1 INTRODUCTION

The liquefaction phenomenon occurs during the earthquake in the saturated silty to sandy ground began to be noticed after the 1964 Niigata and the Alaska earthquake. The Kobe earthquake, which occurred in 1995, is well known as the earthquake that clearly shows the extent of damage according to the application of liquefaction mitigation measures. The existing liquefaction assessment procedures have been focused on whether liquefaction occurs and how to select the mitigation method. However, in order to evaluate the seismic safety of the overall structure system, a reliable method to predict liquefaction, as well as post-liquefaction behavior, should be provided and applied to soil-structure interaction analysis. There are several types of the numerical soil constitutive model to account for the above liquefaction phenomenon. However, the reliability of the model is still questionable. Thus, there have been effort to verify the existing liquefaction model as well as the experimental technique. For this purpose, the Liquefaction Experiments Analysis Project (LEAP) -the UCD-2017 project was carried out by nine institutes from all over the world. The round-robin liquefaction test was conducted using the dynamic centrifuge test equipment of each institution for the given test conditions. The aim of the project is to evaluate the reliability of dynamic centrifuge test procedure and the numerical model. This paper aims to verify numerical liquefaction model and analysis procedure. The verification is made based on the dynamic centrifuge test results conducted at the KAIST Geocentrifuge center [1].

2 DYNAMIC CENTRIFUGE TEST

2.1 Centrifuge facility

A dynamic geotechnical centrifuge facility at KAIST was utilized to perform the tests for LEAP 2017. An electro-hydraulic earthquake simulator was mounted on the centrifuge with a platform radius of 5 m and maximum capacity of 240 g-tons. The main body of the centrifuge has the unique feature of an automatic balancing system and includes parts, such as fluid rotary joints, slip rings, and a fiber optic rotary, for general testing purposes [2]. The centrifuge test of KAIST was conducted with a gravitational acceleration of 40 g. Target excitations were applied using an earthquake simulator that adopted a dynamic self-balancing technique to eliminate a large portion of the undesired reaction forces and vibrations transmitted to the main body. The earthquake simulator was designed to operate at up to 100 g of centrifugal acceleration, and the base shaking acceleration can be exerted to the maximum value of 20 g at 40 g of centrifugal acceleration with the maximum payload of 700 kg. The dimensions of the slip table were 670 mm (length) × 670 mm (width).

2.2 Test model setup

The model ground was formed inside of the rigid box by using the submerged Ottawa F65 sand with a relative density of 55% and 5 ° of surface inclination. The grain size characteristics and properties of the soil are as follows: Gs = 2.665, D_{10} = 0.13 mm, D_{30} = 0.17 mm, D_{50}=0.20 mm and D_{60}=0.21 mm [3]. The sand layer was formed by dry pluviation through a sieve. The density of the soil model was determined by the size of the opening slot and the drop height, and a calibration test is necessary when the geometry is changed. After the sand was pluviated to the target elevation, an inclined guide of 5° was installed on the top of the box. The manufactured scraper was connected directly to the inclined guide and was carefully scraped according to the slope. The viscous fluid is used to saturate model soil layer and to simulate viscosity of water under the centrifugal force. The viscous fluid was a mixture of water and methylcellulose, and the target viscosity was set to 40 cSt as dictated by the scaling law defined by Garnier

[4]. A rigid box with a transparent window was manufactured with internal dimensions of 570 mm × 225 mm × 450 mm (length × width × depth). This will simulate 22.8 m × 4 m × 9 m box in prototype scale under centrifugal acceleration of 40 g. Saturation process was made with starting the box to be completely sealed from the external air. In order to replace air in void with viscous fluid, vacuum pressure was applied first then the void is filled with CO2 gas, repeatedly. Finally, the viscous fluid slowly dripped into the ground model. Okamura's method was used to measure the degree of saturation for the saturated model [5]. The degree of saturation 99.4% is achieved for a relative density of 55%. The responses of the soil model during the shaking were monitored using accelerometers along the direction of shaking and pore pressure transducers. The 18 surface markers were installed on the ground surface uniformly with a spacing of 2 m × 2 m in prototype scale. A high-speed camera was mounted at the centrifuge arm to measure the plane view lateral displacements of the surface markers during the shaking. Cone penetration test (CPT) was conducted under centrifugal force to evaluate the shear modulus changes of the sandy soil with confining pressure before and after the excitation motion was applied. A tapered sinusoidal wave with a frequency of 1 Hz was applied to the base of the model box (Figure 1). Figure 2 shows schematic diagram of the test setup.

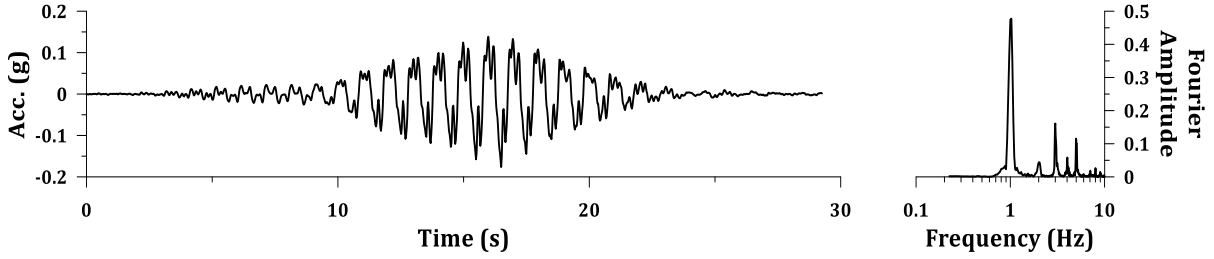

Figure 1 Applied excitation motions

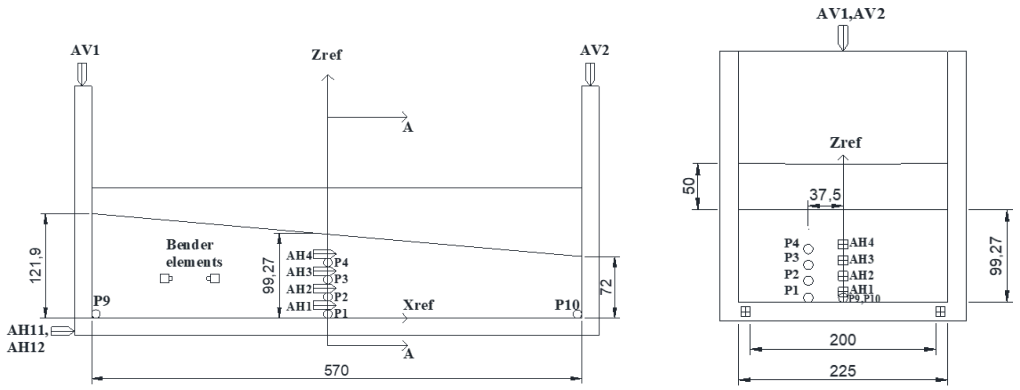

(a) Side view (b) Cross section view

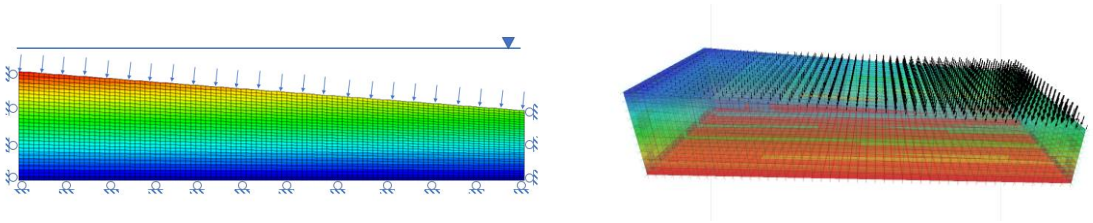
3 NUMERICAL ANALYSIS

Numerical analysis was performed under two-dimensional plane strain condition and three-dimensional space in prototype scale. The finite difference analysis program, FLAC2D and 3D, is used for the analysis, respectively [6].

3.1 Numerical model and boundary condition

The numerical model is made in prototype scale. Fixed boundary condition for the bottom and side wall of the box is applied because the physical test model is made inside of the rigid box. The excitation motion recorded at the bottom of the box is applied at the bottom of the numerical model as well as along the side of the numerical model in forms of the acceleration. The minimum size of the finite difference element is 0.2 m and 0.5 m for two- and three-dimension model, respectively. The size of the element is determined to capture the response of the soil when the excitation motion propagates in upward direction. The numerical models used in this study are shown in Figure 3.



Two-dimension model (b) Three-dimension model

Figure 3: Numerical models

3.2 Soil properties and liquefaction model

The soil is modeled to show hysteretic behavior before shear failure, and the Mohr-Coulomb model is applied for shear failure criterion. The shear wave velocity of the soil is estimated from the CPT penetration results. Nonlinear stress-strain behavior of soil is modeled by using the hyperbolic model suggested by Hardin and Drnevich [7]. Byrne's liquefaction model was applied to track the changes in pore pressure due to cyclic loading after the static equilibrium [8]. The model parameters C_1, C_2, and C_3 for Byrne's model is derived from the relative density of the soil. The other parameters are referenced form the previous work done by Para [9]. The engineering properties used for the soil model is listed in Table 1.

The Max. Shear Modulus (kPa)	Dry Density (kg/m^3)	Porosity (%)	Cohesion (Pa)	Internal Friction Angle (°)	Dilation Angle (°)	Liquefaction Parameters		
						C_1	C_2	C_3
Eqn. (1)	1,592	40.1	300	24.6	0	0.215	0.930	1×10^{-5}

Table 1: Engineering properties of the soil model.

The static equilibrium is achieved under the Eulerian coordinate system. Static pore pressure distribution, hydrostatic pressure is applied, and the maximum shear modulus is re-distributed according to the effective confining pressure in Eq. (1).

$$V_s = 1.18 \times 10^4 exp\left(\frac{-0.125}{\bar{\sigma}_m + 1.19}\right) - 1.16 \times 10^4$$

$$G_{max} = \rho V_s^2 \tag{1}$$

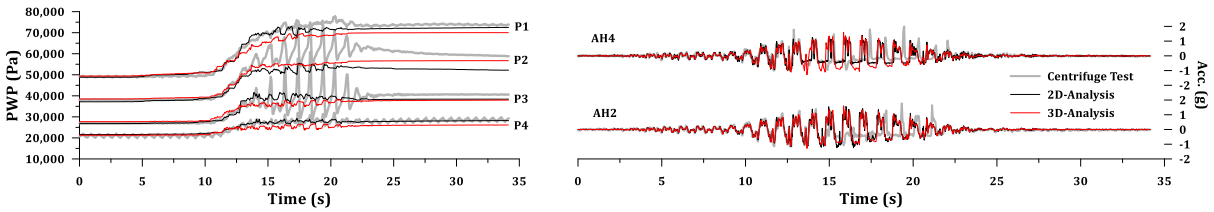
Where, V_s is shear wave velocity in (m/s); $\bar{\sigma}_m$is mean effective stress in (Pa); G_{max} is the maximum shear modulus in (Pa), ρ is the saturated unit density of the soil (kg/m^3).

3.3 Dynamic analysis

The Lagrangian coordinate system is applied before dynamic analysis. The analysis is performed in undrained condition during the shaking. Thus, the fluid properties for the undrained condition; fluid modulus of 2×10^9 Pa and fluid tension of 1×10^{10} Pa are adopted for the analysis. Cyclic threshold shear strain and the minimum required number of timesteps for counting strain reversal were also considered by reflecting the characteristics of the explicit time integration method.

3.4 Analysis results

The numerical analysis results are directly compared with the physical test. Time histories for the horizontal acceleration and porewater pressure are compared. The residual displacement of the soil surface is also compared with the physical test results obtained from the high-speed camera images. Figure 4 shows comparison of the time histories. Both two- and three-dimensional numerical analysis show good agreement with the physical test results. The spikes shown in the pore water pressure histories of the physical test can occur after the excess pore pressure reaches the initial effective stress and is termed as the de-liquefaction shock [10]. It is shown that these spikes cannot be simulated by the numerical analyses.



(a) Pore water pressure (b) Horizontal acceleration

Figure 4: Comparison of the time histories

Figure 5 shows horizontal displacement contour of the physical model after shaking. It was captured by the high-speed camera installed on the top of the model. The surface slope goes down to the right side of the image shown in the Figure 5. The permanent horizontal displacement ranges from 45 to 251 mm.

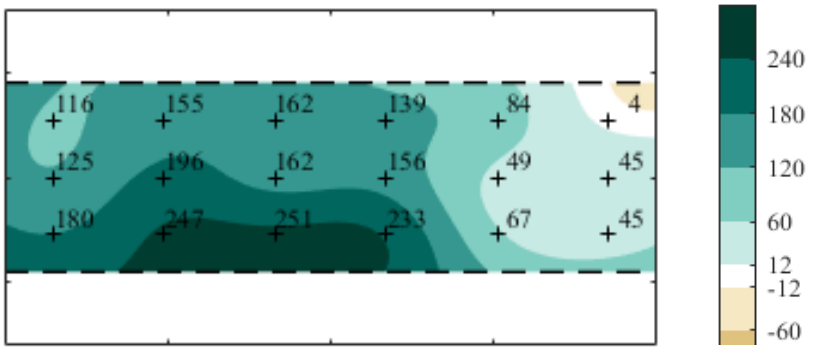


Figure 5: Horizontal displacement contour after shaking (from the centrifuge test, unit in mm)

Figure 6 and 7 shows horizontal displacement contour of the two- and three-dimensional numerical analysis after shaking, respectively. In the two-dimensional analysis, the residual displacement ranges from 50 to 140 mm. The maximum displacement occurs around the down side of the slope. However, in the tree-dimensional analysis, the residual displacement ranges from 70 to 180 mm and shows the maximum value around the upper side of the slope.

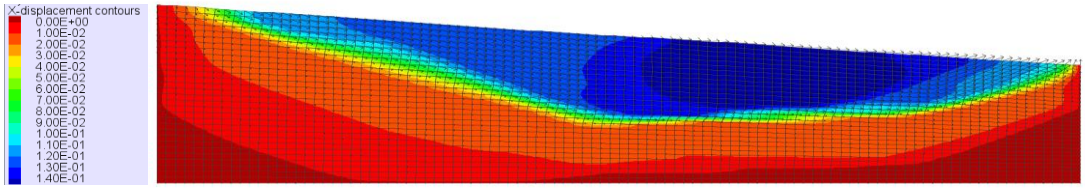

Figure 6: Horizontal displacement contour after shaking (Side view, from two-dimensional analysis, unit in m)

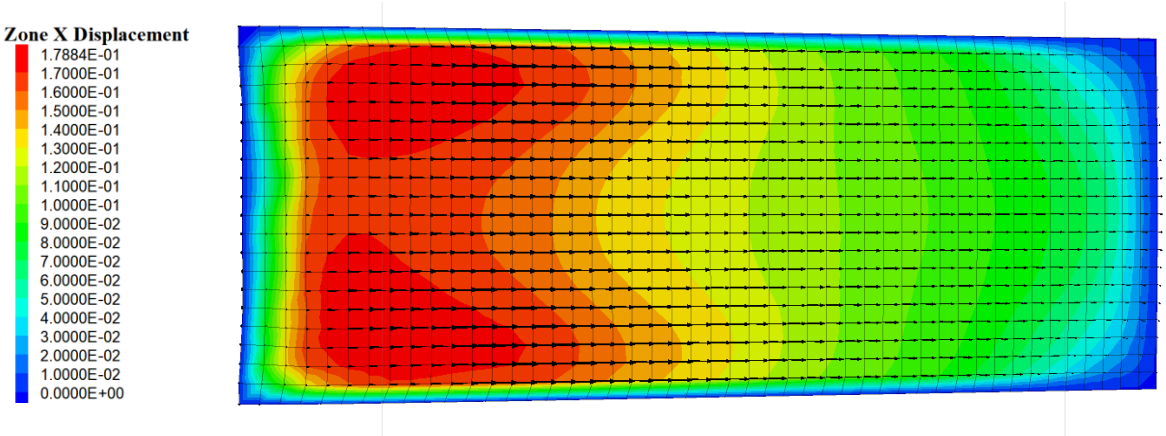

Figure 7: Horizontal displacement contour after shaking (Top view, from three-dimensional analysis, unit in m)

The amount of permanent horizontal displacement is similar with the physical test for the two types of the analysis. However, distribution of the permanent displacement is quite different because the two-dimensional plane strain analysis is unable to capture frictional effect acting on the side of the box.

4 CONCLUSION

- Numerical liquefaction model is verified with the dynamic centrifuge test results for two- and three-dimensional analysis.
- The numerical models show good agreement with the test results for the horizontal acceleration and pore water pressure histories
- Three-dimensional analysis yields more reasonable result for estimating permanent displacement distribution of the slope.

Abstract

The connection condition of pile head with the raft i.e. rigid and hinged connection plays an important role in defining the behavior of piled raft system under seismic loads. In the present study, an attempt is made to understand the effect of different pile head connections on the response of piled rafts subjected to earthquake motions by using finite element-based program PLAXIS 3D. Here, the pseudo-static approach is used by substituting the real earthquake load with an equivalent static horizontal load on the foundation. This pseudo-static load is calculated by multiplying the applied vertical load with the seismic coefficient of a particular earthquake and applied at the raft level. A three-dimensional numerical model of piled raft, validated using a geotechnical centrifuge test data available in the literature, is used to study the response of piled raft for Uttarkashi (1991) and Sikkim (2011) earthquake pseudo-static loading conditions. Analyses results are presented in terms of pile-raft load sharing, normalized lateral displacement and bending moment of pile. Results show that piles in a piled raft foundation carry about 25% to 57% and raft carries about 43% to 75% of the pseudo-static load depending upon the pile head connection conditions. The lateral displacement is maximum at pile head portion for both the connections. For rigidly connected piles, the maximum bending moment occurs at the pile head whereas, piles with hinged connection show zero bending moment at top and maximum value at a certain depth from pile head.

Keywords: Piled Raft, Connection Condition, Pseudo-Static Analysis, Finite Element Model, Lateral Displacement, Bending Moment.

1 INTRODUCTION

Piled raft is widely recognized as an efficient foundation type for high-rise buildings due to its effectiveness in load sharing between the raft and piles under the action of vertical load. The settlement of the raft can be limited to acceptable value by incorporating the piles under the raft [1]. A number of design concepts and guidelines regarding piled raft foundations have been reported by various researchers [2, 3, 4, 5, 6] over the years. But in earthquake-prone areas, the safety of the piled raft foundation against earthquake forces should be ensured during the design process of the foundation. In this connection, one of the very popular and practical method is to analyze the seismic behavior piled raft by applying an equivalent static horizontal force at the foundation level. The connection condition of piles with the raft (rigid and hinged) plays an important role in defining the response of piled raft under seismic loading condition. Few numbers of literatures have been published regarding the lateral and cyclic loading tests on piled rafts [7, 8, 9, 10, 11]. However, the response of piled raft foundation with different pile head connections subjected to horizontal and seismic load in addition to vertical load has not been well explored till date due to intrinsic complexities related to pile-raft-soil interaction.

In this paper, the influence of different pile head connections i.e. rigid and hinged on the response of piled raft under pseudo-static load of Sikkim (2011) and Uttarkashi (1991) earthquakes is studied using finite element method. The responses of piled raft are presented in terms of pile-raft load sharing, lateral displacement and bending moment of piles.

2 FINITE ELEMENT MODEL AND PSEUDO-STATIC LOADING

The numerical modelling of the present study is done using finite element-based software PLAXIS 3D [12] which is an efficient tool to deal with soil-structure interaction problem. The schematic diagram of the 3D finite element (FE) model is presented in Figure 1.

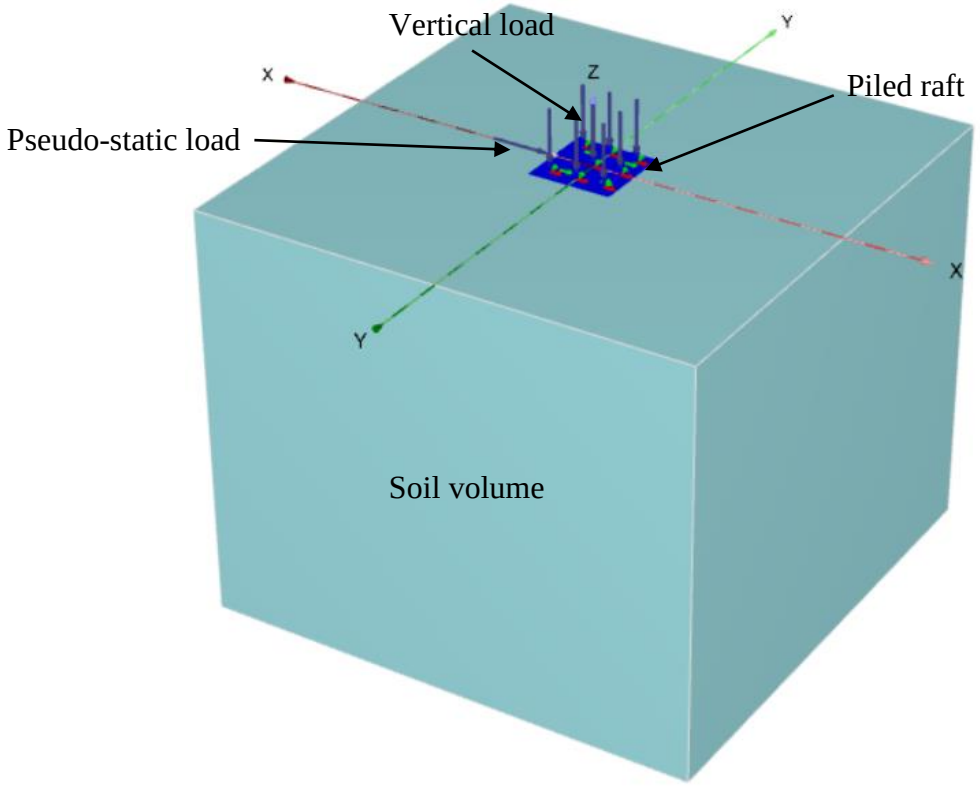

Figure 1: Finite element model of piled raft system.

Sides of the model are restricted to lateral movement and the base is restrained from both horizontal and vertical movements. The soil domain is created using the borehole option in PLAXIS 3D. The soil volume is modelled using 10-noded tetrahedral soil elements. The displacement of the soil particle due to externally applied load is calculated at the nodes of the soil element. Medium meshing scheme is selected for the present FE model.

The conventional linear elastic perfectly plastic Mohr-Coulomb model is used to simulate the behavior of the sand. This model requires fewer number of input parameters for the soil i.e. Young's modulus (E), Poisson's ratio (ν), Angle of internal friction (ϕ), cohesion (c). A 4 m square raft having 1 m thick-ness is modelled using a plate element. The embedded pile element option is used to model 4 no of 9 m long piles having 500 mm diameter (d). The piles are placed at 2 m center-to-center spacing under the raft. The raft and piles are considered to behave linear-elastically in this study. Rigid and hinged connections are considered between the pile heads and raft using the available options during the modelling of the piles. In PLXIS, the rigid connection indicates a case where the displacement and rotation of the pile head are both coupled with the displacement and rotation of the raft. On the other hand, hinged connection refers to a case where only the displacement of the pile head is directly coupled with that of the raft [12]. A vertical load of 5880 kN is applied on the piled raft model. The properties of sand, pile and raft used for the analysis are taken from [13] and presented in Table 1.

Properties	Soil	Pile	Raft
Elastic modulus, E (kN/m^2)	40×10^3	42×10^6	70×10^6
Friction angle, ϕ (Degree)	31	-	-
Cohesion (c)	1	-	-
Poisson's ratio, ν	0.3	0.2	0.35
Unit weight, γ (kN/m^3)	16.3	24	24

Table 1. Properties of soil, pile and raft used for analysis.

In the current study, the three-dimensional piled raft model is validated using the results presented in [13]. The vertical settlement of piled raft and the pile load proportion are compared with the reported values. Table 2 shows the comparison between the present FE analysis and the reported value in the literature.

Parameters	Settlement (mm)	Pile load proportion (%)
Present FE analysis	22.53	45.3
Kumar et al. [13]	21.0	47

Table 2. Comparison of results.

Here, the pile load proportion is calculated as the percentage of total applied vertical load carried by the piles only in a piled raft. From Table 2, it can be seen that the obtained results of the current FE analysis are in close agreement with that of the literature. The settlement of piled raft is over predicted by only 7.4% whereas, the pile load proportion is under predicted by only 3.6% in comparison to the reported values. Therefore, this validated 3D FE model is used to investigate the response of piled raft foundation for different pile head connections under pseudo-static loading condition.

The current study is carried out to investigate the response of piled raft system under the action of seismic load using the pseudo-static approach. In this method, the seismically induced load is replaced with equivalent static horizontal load to be acted at the level of the raft along with the application of vertical load. This particular horizontal load is known as pseudo-static load. This load is calculated by multiplying the applied vertical load with the seismic coefficient of a particular earthquake. The soil amplification effect is not considered in this approach. Figure 2 shows the time-acceleration histories of the earthquake input motions i.e. Sikkim (2011) and Uttarkashi (1991) used for the pseudo-static analysis. The peak ground accelerations (PGA) of the Sikkim (2011) and Uttarkashi (1991) earthquakes are 0.202g and 0.38g respectively. The equivalent static horizontal loads for Sikkim (2011) and Uttarkashi (1991) earthquakes are calculated as 1187.1 kN and 2234.4 kN respectively.

3 RESULTS AND DISCUSSION

This section highlights the results obtained from the finite element analysis. Emphasis is given on the load sharing between piles and raft as well as on the structural behavior of piles in a piled raft system for both rigid and hinged connections.

3.1 Load sharing between piles and raft

The proportion of load sharing between piles and raft is presented in the Table 3.

Pseudo-static Load	Rigid Connection		Hinged Connection	
	Pile load proportion (%)	Raft load proportion (%)	Pile load proportion (%)	Raft load proportion (%)
Sikkim (2011)-1187.1 kN	51.3	48.7	25.5	74.5
Uttarkashi (1991)-2234.4 kN	56.8	43.2	37.4	62.6

Table 3. Proportion of load shared between piles and raft.

From Table 3, it is evident that piles carry majority of the applied pseudo-static load as compared to the raft component in a piled raft system in case of rigid pile head connection. It is noteworthy that with the increase of the horizontal pseudo-static load, the piles share more load than the raft in a piled raft system. However, in case of hinged connection, the raft takes higher load than the piles. It can also be noted that the raft load proportion decreases with increasing pseudo-static load i.e. increasing PGA values of earthquake motions.

3.2 Lateral displacement of pile

Figure 3 shows the normalized lateral displacement (*U/d*) profile along the length of pile for rigidly connected piles with raft. Here, *U* is lateral displacement and *d* is diameter of pile.

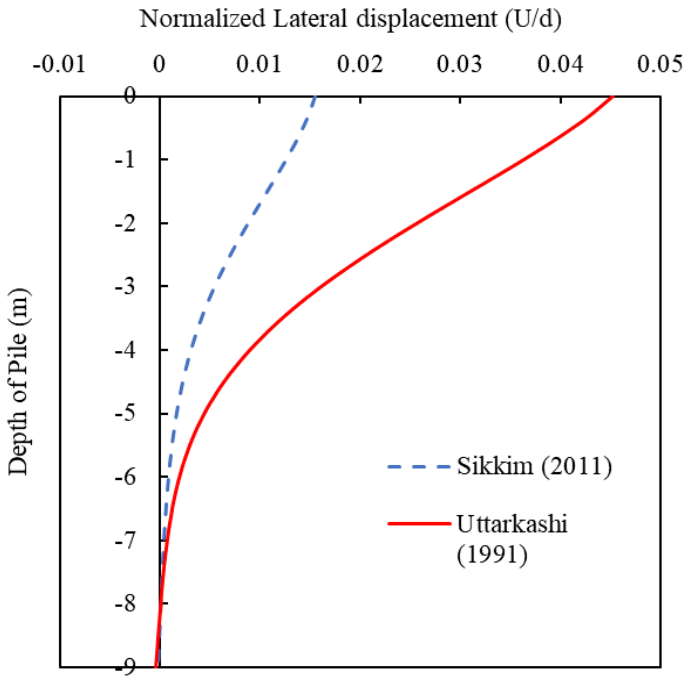

Figure 3: Variation of lateral displacement with depth of pile for rigid connection.

It can be noticed from Figure 3 that the lateral displacement is maximum at the pile head and becomes zero at pile tip. The normalized lateral displacements are found 0.016 and 0.045 for Sikkim (2011) and Uttarkashi (1991) earthquakes receptively. With higher magnitude of pseudo-static force, the lateral displacement also becomes larger. The lateral displacement (*U/d*) profile along the length of pile for hinged connection is shown in Figure 4.

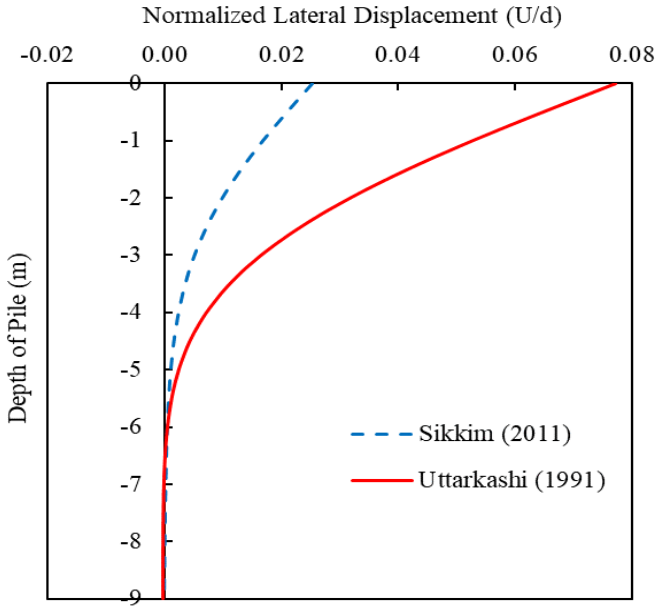

Figure 4: Variation of lateral displacement with depth of pile for hinged connection.

In this case the lateral displacement becomes higher than the rigid connection case. The normalized lateral displacements are found 0.025 and 0.078 for Sikkim (2011) and Uttarkashi (1991) earthquakes receptively.

3.3 Bending moment of pile

Figure 5 shows the bending moment distribution along the length of the pile for rigidly connected piles with the raft.

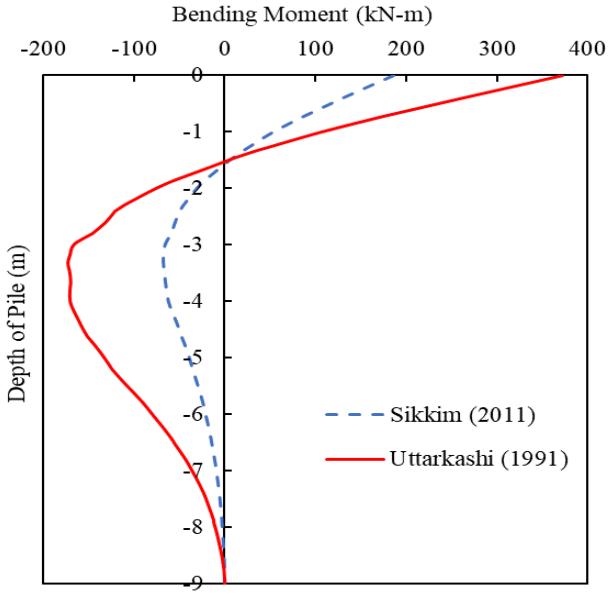

Figure 5: Variation of bending moment with depth of pile for rigid connection.

It can be observed from Figure 5 that the maximum bending moment occurs at the pile head due to fixed connection with the raft. It can also be noted that bending moment gets transformed from positive to negative along the pile length and finally comes to zero at pile tip. The maximum bending moments, as found from Figure 5, are 192 kN-m and 380 kN-m for Sikkim (2011) and Uttarkashi (1991) earthquakes respectively. Here also the bending moment increases with the increase of PGA of the earthquake motion. Figure 6 presents the bending moment profile for piles having hinged connection with the raft.

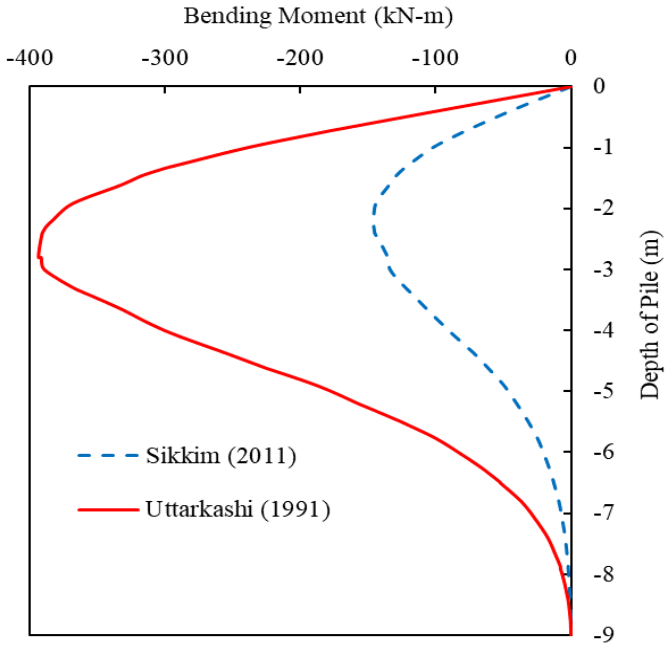

Figure 6: Variation of bending moment with depth of pile for hinged connection.

It is noticeable that for the hinged connection, the bending moment of pile starts from zero and attains the maximum value at the pile depth ranging from 2 m to 3 m and finally comes to zero again at the pile tip. The maximum bending moments, as noted from Figure 6, are 147 kN-m and 394 kN-m for Sikkim (2011) and Uttarkashi (1991) earthquakes respectively.

4 CONCLUSIONS

From the present study, the following can be concluded.

- The piles in a piled raft foundation are found to carry 25% to 57% and raft is found to share 43% to 75% of the pseudo-static load depending upon the pile head connection conditions.
- The load proportion of raft is found to decrease with increasing magnitude of pseudo-static load i.e. increasing PGA value of earthquake motions irrespective of the pile head connection condition.
- The lateral displacement is observed to have the maximum value at the pile head portion for both the connections.
- For rigidly connected piles, the maximum bending moment occurs at the pile head and the bending moment profile changes from positive to negative at a pile depth of 1.5m. However, piles with hinged connection exhibit zero bending moment at the pile head and maximum value at the pile depth ranging from 2m to 3m.

Abstract

Underground railway tunnels are the most preferred option for Mass Rapid Transit Systems (MRTS). The circulation of trains inside underground tunnels generate noise and vibrations, which propagate through soil and reach building foundations to cause noise and vibration inside the building. Buildings susceptible to vibration damage such as heritage structures and sensitive buildings may show signs of distress like damage of architectural façade or widening of cracks in members. The ground-borne vibrations and noise due to underground trains sometimes cross the threshold value for human perception leading to inconvenience of residents.

Therefore in the present study, a two-stage coupled analysis is carried out to estimate ground-borne vibrations in the free field due to moving train for different soil stiffness, tunnel depths and train speeds. Two sub models are generated – (a) train-track sub-model and (b) tunnel-soil coupling sub-model. The first model estimates the dynamic force exerted by a moving train on track structure. In the second model the calculated dynamic force is applied at track locations of a 2D FE model generated in PLAXIS. The numerical models are validated using measured results available in the literature. The train data and tunnel dimensions are taken from the MRTS projects in Delhi, India.

It is found that the noise and vibration due to underground rail depends on distance and depth of tunnel, stiffness of soil and train speed. In some cases, the estimated vibration levels at ground cross the threshold limit to damage of sensitive buildings and therefore additional care should be taken when tunnel alignment is close to heritage or sensitive buildings. The conclusions obtained from this parametric study can be useful for practicing engineers for prediction of ground vibration due to railway traffic in MRTS underground cut and cover tunnels in Delhi.

Keywords: Ground vibration; Free field; Finite element; Railway traffic; Tunnel; Stiffness; Underground

1 INTRODUCTION

In metropolitan cities Mass Rapid Transit Systems (MRTS) are lifeline to the daily commuters. Underground railway tunnels are the most preferred option for such rapid transit systems. However, ground-borne vibrations due to underground railway traffic can disturb life and property of residents living in buildings in close proximity of underground tunnels. When trains move along underground tunnels vibrations are generated. The vibrations thus generated radiate away from the railway tunnel and may cause disturbances to the nearby residents. Structural damage of the sensitive buildings may also happen depending on vibration intensity at ground surface and building built quality. To address such problem study of vibration characteristics of underground tunnels certainly become an important research subject. Several research works have been carried out in this regard which are based on actual site measurements, numerical analysis or a combination of numerical and experimental results.

Analysis of train-induced vibrations and their propagation can be done with 2D as well as 3D models. The vibration source, i.e. the train is generally considered as an oscillating force. The propagation path between the source and the receiver is commonly modelled as a plane perpendicular to the tunnel. NGI (2004) and Lai et al. (2005) pointed out that the propagation between source and receiver is a true 3D problem when heterogeneities are included since the vibration propagates along the most beneficial path. Liu et al. (2014) developed analytical solution by using Navier's wave propagation theory in 3D elastic medium and found that frequency and vibration characteristics match with FEM solutions with acceptable error limits. Xu et al. (2015) made comparison of 2D and 3D prediction models for environmental vibrations induced by underground railway. It is found that with a suitable equivalent force, 2D prediction models can be used to assess environmental vibrations with considerable accuracy for engineering problems. However, 2D prediction models are not suitable for evaluating structures with sensitive instruments. Based on 2D finite difference model results, Nejati et al. (2012) found the most important factor influencing vibration is train axle weight, spacing of axles and speed of train.

Most of the studies available were carried out for a specific case and parametric studies involving different parameters are not available. This paper is targeted to cover a parametric study with varying soil stiffness, depths of tunnel and train speeds. The train and tunnel data are taken from the executed underground MRTS projects in Delhi. In the present study the soil is considered as isotropic and tunnel is considered on a straight alignment, hence, 2D FE model is used. A two-stage coupled analysis approach is followed to estimate ground-borne vibrations in the free field when the origin of vibration is moving train. Two sub models are generated – (a) train-track sub-model and (b) tunnel-soil coupling sub-model. The first model is an analytical model which estimates the dynamic force generated by the moving train on rail tracks. The second model is a numerical 2D model created using PLAXIS. In the second model the calculated dynamic force is applied at track locations on the tunnel base slab and wave propagation through ground is estimated.

2 MATHEMATICAL MODELS

Prediction of train-induced environmental vibration has to cope with the problem of complexity of the dynamic interaction between train, track and soil. Two mathematical sub-models are used to represent the problem.

2.1 Train-track sub-model

When a train moves on infinitely long rail then dynamic force is generated on the substructure which gets transmitted to the tunnel structure. This dynamic problem can be solved analytically by classical theory of beam on elastic foundation. In the present analysis the rail is considered as an infinitely long Euler – Bernoulli beam having constant cross section. The foundation material is represented as linearly elastic Winkler springs. Both beam and foundation are assumed to be isotropic and homogeneous. The differential equation of motion considering vertical equilibrium of forces on beam element is solved and closed form solution for the deflection due to moving load P is given by Kumari et al. (2012).

The load P is the wheel load of the train and spring constant k is obtained from a static FE analysis of tunnel section embedded in soil. Fig. 1 shows a time-displacement curve generated for train speed of 60 km/hr inside a rectangular cut and cover tunnel at 10 m depth (measured at tunnel axis) from ground having average standard penetration test (SPT) value of 20.

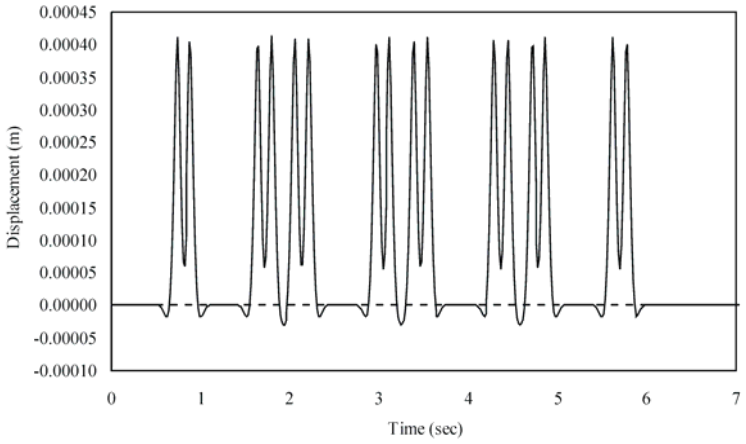

Figure 1: Time vs. Displacement plot for train speed of 60 km/hr

2.2 Tunnel-soil coupling sub-model

This is the second stage of analysis where calculated dynamic force from first stage analysis is applied on a 2D FE model generated in PLAXIS software. A plain strain analysis is done with 6 noded elements. Concrete is considered as an elastic material, soil is considered as mohr-coulomb elasto-plastic material. The dynamic modulus of soil layer is calculated by knowing shear wave velocity through that layer. The radiation damping and material damping are considered in the analysis. For material damping Rayleigh damping coefficients are calculated. The train details used in analyses are similar to metro rail corridors managed by Delhi Metro Rail Corporation (DMRC). Train speeds of 40 km/hr, 60 km/hr, 80 km/hr, 100 km/hr and 120 km/hr are considered for the study. Dimension and loading details of one passenger coach is shown in Fig. 2. The train is made up of four coaches. The track is considered as ballast-less direct fixation track. The section of rail considered is UIC60.

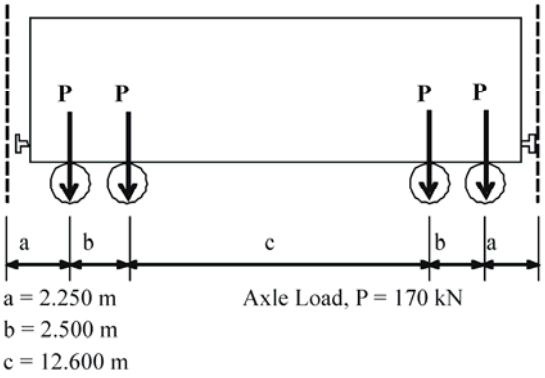

Figure 2: Details of a passenger coach used in analysis

3 INPUT PARAMETERS FOR ANALYSIS

Cut and cover tunnels have been used in several MRTS projects in Delhi, India. In this method excavation is done by earth retaining system like soldier pile wall, secant pile, sheet pile and diaphragm wall. Tunnel lining is then cast inside the excavation followed by back filling over the tunnel. The tunnel lining thickness is considered as 0.7m and internal clear dimension of tunnel is considered as 5.25 m x 5.75 m. Concrete grade for lining is considered as 35MPa.

3.1 Dynamic properties of soil

In this study the dynamic soil properties are co-related with Standard Penetration Test (SPT) results as this test is widely used and easy to perform with acceptable level of accuracy. Hanumantharao and Ramana (2008) had done microzonation of Delhi and given relationship between SPT values and dynamic soil properties. Based on their observation shear wave velocity has been calculated.

The wave propagation depends largely on the stiffness, density and Poisson's ratio of soil. The shear strength parameters are generally less significant unless a large strain which may cause plastic deformation is expected to happen. The dynamic problems are generally small strain problems, hence the shear strength parameters can be assumed to be same even if the SPT values are varied. To verify this, PLAXIS runs with different shear strength parameters are investigated and the results obtained show insignificant change in PPV. Therefore, variation in shear strength parameters is neglected in present study.

3.2 Soil damping

Geometric damping in soil is about 30% of critical damping and is taken care by assigning absorbent boundaries in the FE Model. The material damping of soil generally ranges from 0% to 10%. This damping behavior is considered in FE Model in terms of Rayleigh Damping Coefficients. Whitman and Richard (1967) suggested material damping in range of 0% to 10%. In the present study for "Delhi Silt" damping ratio of 5% is considered.

4 VALIDATION OF MATHEMATICAL MODELS

The validation of mathematical models with actual field measured data is important as the reliability and correctness of the whole study can be thus established. The two models are

used in this study – (a) train-track sub-model and (b) tunnel-soil coupling sub-model, both are validated with measured results from site.

4.1 Validation of train-track sub-model

The train-track sub model is validated with actual measurements from high-speed track of Beugnâtre site observed by Ferreira (2010). The substructure of the reference track consists of 35 cm thick ballast, 30 cm thick granular subballast and 60 cm thick form layer having Young's modulus of 150 MPa, 100 MPa and 80 MPa respectively. The track was resting on a subgrade having Young's modulus of 80 MPa. For a train speed of 300 km/hr, the measured and calculated time versus acceleration data are shown in Fig. 3. The measure time versus acceleration plot is similar to that of calculated and the peak values are satisfactorily comparable.

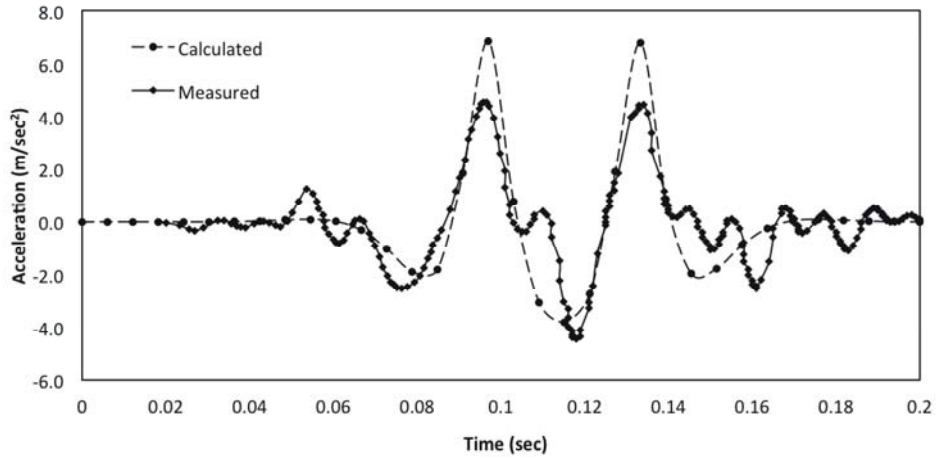

Figure 3: Time vs. acceleration data at Beugnâtre track section at 300 km/hr measured by Ferreira (2010) and as calculated in present study

4.2 Validation of tunnel-soil coupling sub-model

This model is validated with site measured data from metro tunnel on the line RER B at Cité Universitaire measured within the frame of the EC-Growth project CONVURT and reported by Chatterjee (2003). The metro tunnel was a shallow cut-and-cover tunnel in masonry structure. The depth of the tunnel was about 9.3 m below ground and the overall width of the tunnel was 11.9 m. The thicknesses of the top slab, bottom slab and side walls were 0.6 m, 0.4 m and 1.5 m respectively.

The FE model to represent tunnel-soil coupling behaviour is generated in PLAXIS software using actual tunnel and soil data. The time history of the vertical velocity as measured at sleeper position during passage of test train at speed of 80 km/hr is applied in the FE model at track location. The site measured time history of free field vertical velocity at 8 m distance from longitudinal axis of tunnel during passage of test train is compared with that calculated from FE model as shown in Fig. 4. It can be seen from Fig. 4 that the peak amplitude values of free field vibration from the site measurement and that calculated by FE model are fairly close.

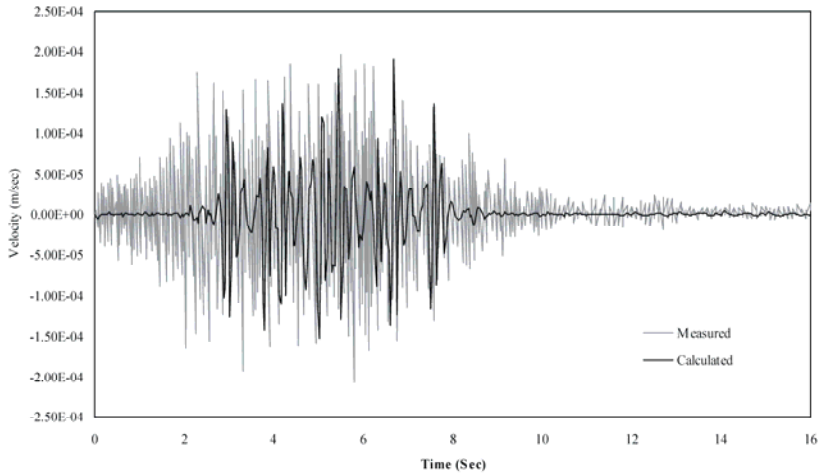

Figure 4: Time history of free field vertical velocity at 8m from longitudinal axis of tunnel during passage of test train at speed of 80 km/hr as observed by Chatterjee (2003) and as calculated in present study

5 ANALYSIS RESULTS

The dynamic effects of underground moving trains inside tunnels are studied in free field. The impacts of ground stiffness, tunnel depth and train velocity are studied. Based on free field vibration, researchers have established guidelines which give limits of vibration for structural safety.

5.1 Study on cut and cover tunnel

Cut and cover tunnel in rectangular box shape having tunnel lining thickness of 0.7m and internal clear dimension of tunnel 5.25 m x 5.75 m is considered in present study. Tunnel axis depths are considered as 10 m, 20 m and 30 m. The results are noted at 0 m, 10 m, 20 m and 30 m distances from tunnel axis at the ground level. From Fig. 5 it can be seen that vibration is maximum at the tunnel invert as the dynamic load from railway track is applied directly here. As the vibration travels through the lining and surrounding soil the magnitude of vibration attenuates due to damping.

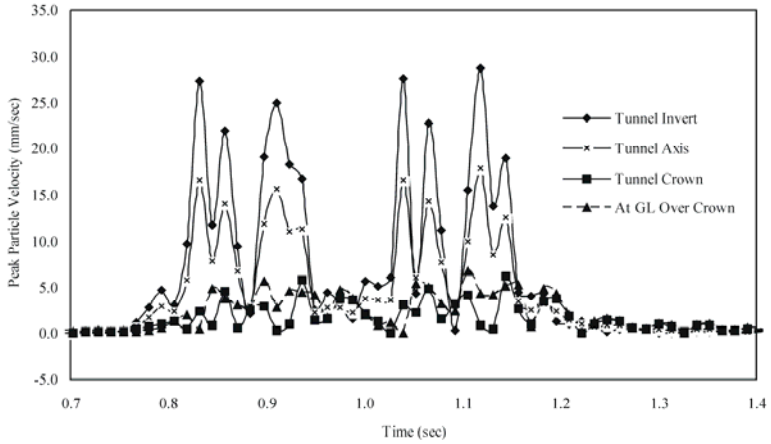

Figure 5: Time vs. peak particle velocity at tunnel invert, axis, crown and ground for train speed of 120 km/hr in 10 m deep tunnel in soil with SPT value of 20.

5.2 Dependency of vibration magnitude on different parameters

The ground-bone vibration due to underground moving train is found to depend of the following parameters – (a) Distance from tunnel, (b) Train speed, (c) Soil stiffness, (d) Depth of tunnel below ground. The vibration is also dependent Tunnel geometry and Lining stiffness.

Distance from tunnel

Time versus vertical velocity in free field are plotted for different distances from tunnel axis for a 10 m deep tunnel in soil having SPT value of 20 and for a train speed of 120 km/hr as shown in Fig. 6. It can be seen from the obtained results that the amplitude of vibration reduces drastically as the distance from the tunnel increases. A phase difference in vibration can also be noticed in the plot. With increase in distance from tunnel axis the vibration wave reaches there later than the nearer points. This happens as the wave travels through the soil with certain velocity depending on stiffness of soil.

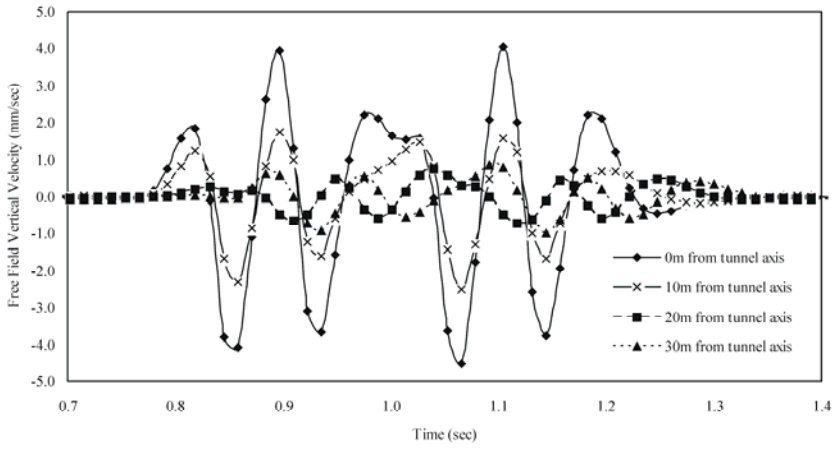

Figure 6: Time vs. vertical velocity in free field at different distances from tunnel axis for train speed of 120 km/hr in 10 m deep tunnel in soil with SPT value of 20

Train speed

To study variation of PPV as a function of distance from tunnel axis, a parametric study is done in which at a time only one parameter is varied keeping all other parameters constant to see the change in result. Fig. 7 shows PPV versus distance from tunnel axis for different train speeds when all other parameters are unchanged, such as tunnel depth of 10 m and soil stiffness corresponding to SPT value of 20.

It can be seen that with increase in train speed the observed PPV increases. At 40 km/hr speed the maximum PPV observed at ground at 0 m from tunnel center is just 1.0 mm/sec whereas when the train speed increase to 120 km/hr, the PPV at the same location increases to 4.5 mm/sec.

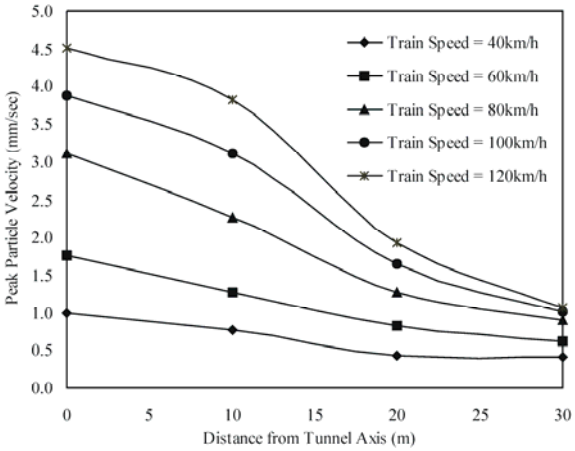

Figure 7: PPV vs. distance from tunnel axis for different train speeds for 10 m deep tunnel in soil with SPT value of 20

Soil stiffness

The shear wave velocity is a function of soil stiffness. As the soil stiffness increases the shear wave velocity also increases. A parametric study is done considering soil stiffness corresponding to SPT values of 20, 40, 60 and 80 while all other parameters are unchanged. From Fig. 8 which shows the change in PPV with ground stiffness, it can be seen that the vibration at ground increases in softer ground condition.

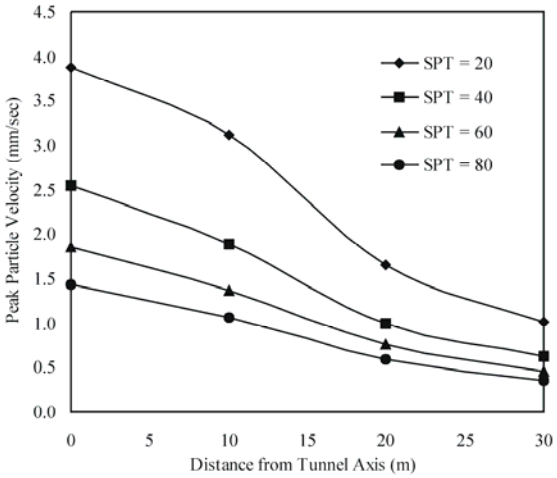

Figure 8: PPV vs. distance from tunnel axis for different soil stiffness for 10 m deep tunnel when train speed is 100 km/hr

Tunnel depth

The soil vibrations attenuate due to radiation damping and material damping with distance from the source of vibration. A parametric study is done considering tunnel depths of 10 m, 20 m and 30 m while all other parameters are kept unchanged. The increase in tunnel depth reduces the vibration at ground level. It can be seen from Fig. 9. With increase in tunnel depth the distance of source of vibration increases from the observation points at ground level. Due to attenuation of vibration when waves are propagating through the ground, the vibration amplitude reduces with increasing tunnel depth.

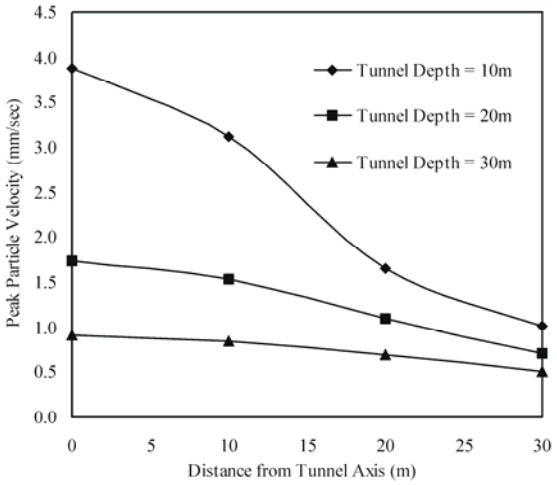

Figure 9: PPV vs. distance from tunnel axis for various depths of tunnel when train speed is 100 km/hr and soil has SPT value of 20

6 CONCLUSIONS

In the present scope of study vibration problem of underground moving train is studied. The tunnel dimensions are taken from MRTS Projects in Delhi, India. The present study includes the calculation for generated dynamic loads from moving trains, propagation of the wave through the tunnel lining and soil medium. A coupled analysis is followed in which two sub models are generated – (a) train-track sub-model and (b) tunnel-soil coupling sub-model. Both the mathematical models are validated with actual site measured values.

From this study it is noticed that the Free Field ground vibration depends on parameters – (a) Distance from tunnel, (b) Train speed, (c) Soil stiffness, (d) Depth of tunnel below ground. The ground vibration is found to be inversely proportional to distance from tunnel, soil stiffness and tunnel depth, while the vibration is directly proportional to the train speed. Buildings closer to the tunnel alignment are more susceptible to get damaged.

The tunnels in soils having SPT value higher than 40 generally do not exhibit any significant vibration. In case the soil is poor, then vibration can be reduced by either increasing the proposed depth of the tunnel or by reducing the design speed of the tunnel in the affected section.

Abstract

Modelling of dynamic soil-pile interaction behavior is very complex. Different soil models have been proposed to model the complex soil-pile behavior under dynamic loading. Applicability of different soil models for dynamic loading is very limited for batter piles. To study the dynamic response of batter pile, three different soil models are used; (i) Linear Model : This model that considers no slippage between the pile and soil; (ii) Nonlinear Model 1: This model that includes a cylindrical zone around the pile with less inner zone soil modulus than outer zone and neglects the inner weak zone soil mass to avoid the wave reflections between the inner zone and outer zone; (iii) Nonlinear Model 2: Nonlinear soil model that uses a nonreflective boundary formed between the inner zone and outer zone to account for the mass of soil in the cylindrical boundary zone.

In this present study the frequency dependent stiffness, damping and amplitude of soil-pile system under vertical vibrations are calculated using continuum approach by Novak with three soil models. A series of vertical field vibration tests were also conducted on a single batter driven pile (L/d =26) of inclination 10 degrees for different eccentric moments (0.449, 0.670, 1.664 and 1.830 Nm) with static load of 12 kN. The effectiveness of the soil models has been checked by comparing the test results with the analytical results obtained using three soil models. It has been observed that the frequency amplitude responses obtained from Nonlinear Model 1 for a precise range of boundary zone parameters are found close to the experimental results. So it can be concluded Nonlinear Model 1 predict the dynamic response of batter pile under vertical vibrations more accurately than Linear Model and Nonlinear Model 2.

Keywords: Batter piles; Soil models; Dynamic loading; Stiffness; Damping; Amplitude; Vertical vibration; Field vibration test; Boundary zone.

1. INTRODUCTION

Pile foundations are often used to support structures that are exposed to dynamic loads such as earthquakes, wind, wave and machine induced vibrating machines. They are used to large vertical or lateral or combined loads which may be static or dynamic in nature. In situations, where there are excessive lateral and vertical loads coming from the superstructure, batter piles in combination with vertical piles are used to increase the stiffness of soil-pile system.

For the evaluation of the dynamic response of pile foundation involves the calculation of stiffness and damping values of soil-pile system considering the actual soil conditions. Several researchers [1,2,3,4] contributed to formulate and postulate the continuum approach to analyse the dynamic response of pile foundation. The continuum approach was mainly given by Novak and Aboul-Ella [5] for deriving the complex stiffness of soil-pile system of single pile in layered medium [6]. Novak and Sheta [7] later contribute with the development of weak boundary zone around the pile with less shear modulus ratio and increase damping to account for the nonlinearity of the soil-pile system while neglecting the mass of the inner zone to prevent the spurious reflections between the inner and outer zone around the pile. Later Velestos and Doston [8] overcome the assumption given by Novak and Sheta [7] by introducing the mass of the inner zone. Han and Sabin [9] proposed a new model of boundary zone with nonreflection interface in which parabolic variation of the medium properties in assumed (the boundary zone has properties smoothly approaching those of outer zone). Based on this model Han [10] done a parametric study on boundary zone parameter under vertical vibration.

Extensive studies have been done by various researchers on the dynamic behavior of single vertical and group piles under machine induced vibrations. To investigate the dynamic behavior of vertical pile and pile groups and to understand the soil-pile interaction, various full scale and model-prototype tests were conducted by various researchers [11,12,13,14,15,16,17].

From the literature review it is understandable that both the analytical and experimental study on the batter pile under rotating machine induced vertical vibrations are rarely performed. Hence, in this paper with the help of the continuum approach by Novak for different soil stiffness models [6,7,9] are used to analyse the complex soil -pile stiffness of batter pile. To verify the applicability of the proposed model, dynamic forced vibration tests were performed in the field on a hollow steel pipe ($L/D = 26$) with angle of inclination of 10 degrees.

2. CONTINUUM APPROACH

The dynamic response of batter pile is governed by complex interaction phenomenon between the soil and the pile. This complex soil-pile interaction phenomenon can be modeled by using the complex impedance functions where the real and imaginary parameters represent the stiffness and damping of the soil-pile system. The stiffness and damping are calculated based on the assumption that the soil is perfectly bonded to the circumference of the pile and the behavior of the soil is governed by the law of viscoelasticity. The complex stiffness of vertical pile is calculated by using the methodology given by Novak and Aboul-Ella [5].

There is no analytical solution for the calculating the impedance function (stiffness and damping) of the battered pile but they can be established by using the observations made by Poulos and Madhav [20]. They theoretically investigated the static displacement of the battered pile by using the Mindlin's equation. They applied the axial loads (longitudinal direction) to the battered pile and found out that that axial displacements are almost unaffected by the batter of pile. Only 4 percent was the maximum effect for pile with batter angle up to 30 degrees. So, it can be concluded that the impedance function of the battered pile up to 30 degrees can be calculated using the impedance function by means of dynamic solution available for vertical piles [21]. , the complex stiffness of the batter pile-soil system can be calculated using the

stiffness along the local axes of the single vertical pile then transforms the stiffness into the local axes by multiplying the stiffness by a transformation matrix [21] which is given by

$$[K^1_{vb}] = [T]^T [K^1_w] [T] \quad (1)$$

where K^1_{vb} = complex dynamic stiffness of batter pile, [T] is the transformation matrix which depends on direction cosines and K^1_w is the complex stiffness of the vertical pile. With the stiffness and damping of the batter pile, the vertical response of the batter pile is calculated.

To account for the nonlinearity and slippage, the consideration of linear viscoelastic medium can be divided into an outer infinite zone and inner weak boundary zone with reduced shear modulus and higher soil damping as compared to the outer zone. Without any modification in theory, the soil reactions of the composite medium are introduced into the dynamic analysis of batter pile foundation. In this study, three different soil models are used to analyze the nonlinear behavior of batter pile foundation.

- Linear Model: In this model the dynamic complex stiffness function of the soil medium in calculated considering no slippage between the pile and the soil. The complex stiffness of the soil is derived using the solution of the equation of the motion of viscoelastic medium using the hysteric damping which is obtained from the solution of wave propagation of elastic medium [6].
- Nonlinear Model 1: In this model, Novak and Sheta [7] considered a cylindrical annulus of soft soil around the pile which has less shear modulus and high damping than the outer zone. The mass of the inner weak zone is considered as zero ($\rho = 0$) to avoid any wave reflection between the interface of inner and outer zone. This soil model with continuum approach is available in the computer software package DYNA 6 [18].
- Nonlinear Model 2: This model assumes the boundary zone has a nonzero mass and a smooth variation into the outer zone by introducing the parabolic variation function [9]. This type of soil model with continuum approach is programmed in a software named DYNAN [19].

3. EXPERIMENTAL INVESTIGATION

The test site was situated in between Block II and Block III at the Indian Institute of Technology Delhi, Hauz Khas, New Delhi, India. The soil properties were determined by laboratory and in situ tests. Standard penetration tests (SPT) were conducted in the field to determine the N values of soil layers. It is found that soil is predominately sandy silt up to depth 6.0 m. Piles were made of hollow steel pipes of outer diameter (d) 0.114 m and length (L) of 3 m. Initially, a borehole of 0.1 m diameter was made to reduce the resistance of pile driving. The pile was then driven into the ground by dropping of SPT hammer of weight 65 kg from a height of 0.3 m. During driving, the batter angle was maintained with the help of guide rod fixed at required batter angle. A steel plate of dimension 0.9 m $\times$ 0.9 m $\times$ 0.037 m was used as a pile cap which was connected rigidly with the pile. Forced vertical vibration tests were conducted on model single batter pile ($\beta = 10^o$). The dynamic forces are produced by Lazan type mechanical oscillator in the form of harmonic motion. Two counter rotating-mass are moved inside the oscillator to develop the dynamic forces on the pile. The amplitude of the dynamic force was controlled by adjusting the eccentricity (θ) of the rotating masses. The excitation force, $P(t)$, is given by

$$P(t) = m_e.e.\omega^2 \sin \omega t = (W_e/g).e.\omega^2 \sin \omega t \quad (2)$$

where, W_e and *me* are the weight and mass of eccentric rotating parts of the oscillator, respectively, *e* is the eccentric distance of the rotating masses, *g* is the acceleration due to gravity and ω is the circular frequency of vibration. The magnitude of the exciting force was changed by adjusting the angle of eccentric mass. The mechanical oscillator was connected by means of a flexible shaft with a DC motor and the speed of DC motor was controlled by a speed control unit. The oscillator was run slowly through a motor using speed control unit. Mild steel plates of size 0.5 m $\times$ 0.5 m $\times$ 0.022 m were placed on the pile cap to provide

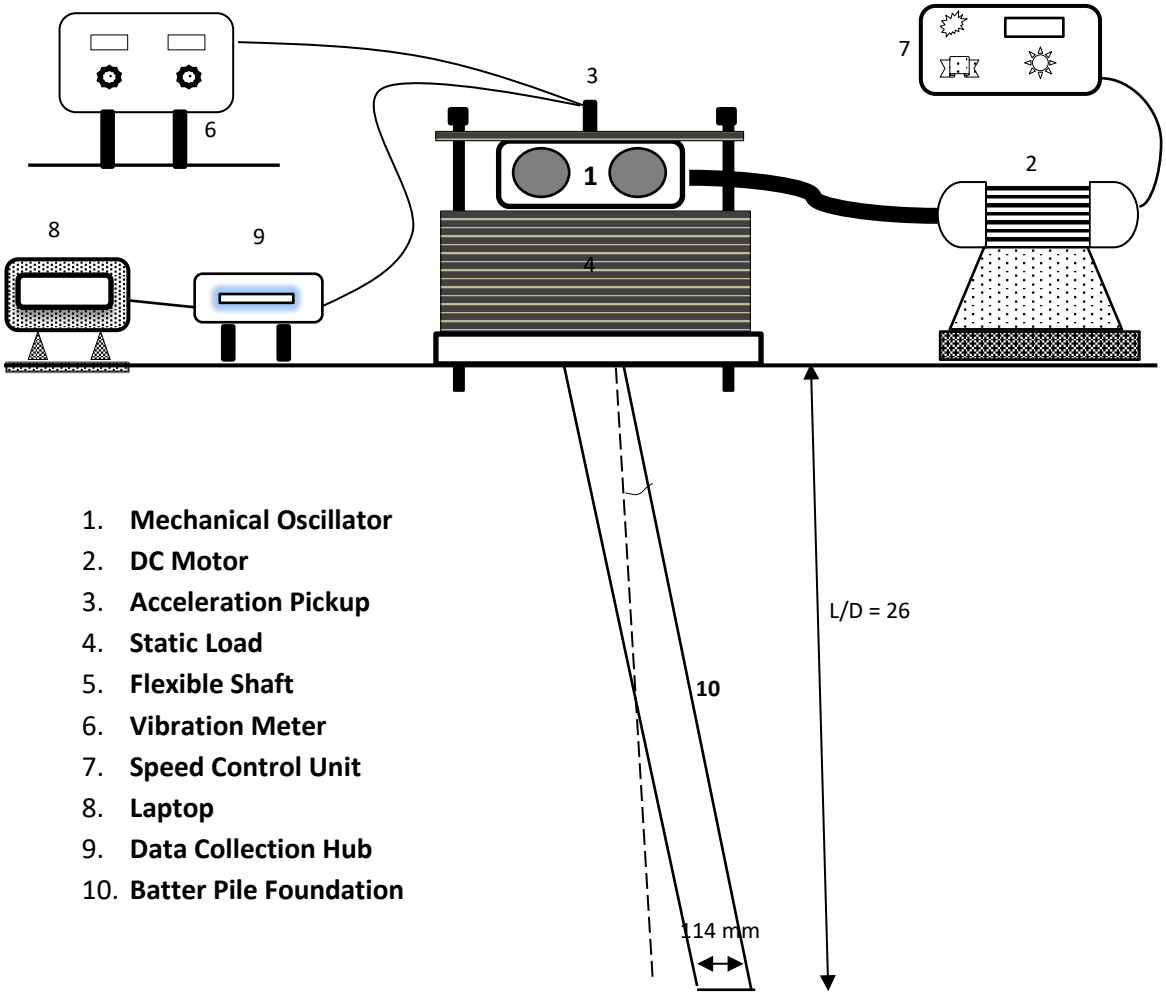

Figure 1: Schematic diagram of vertical vibration test setup in batter pile (L/D = 26, β = 10º)

desired static weight. Then the mechanical oscillator assembly was mounted on the top of the steel plates in such a way that the oscillator imposed a vertical harmonic excitation force on the pile foundation. The whole assembly was properly tightened with the pile cap using four bolts so that it could act as a single unit. The accelerometer was attached vertically on the top of the plate over the center of the pile cap. Tests were conducted for four different eccentric moments ($W_e.e$ = 0.449, 0.670, 1.664, and 1.830 N m) with the static load (*Ws*) of 12 kN. The complete vertical vibration test set up is shown in Fig. 3. The experimental frequency-amplitude response curve of single batter pile for different eccentric moment is shown in Fig.

2. It is observed from the dynamic test results that the measured frequency-amplitude response curve exhibits nonlinear behavior by showing decrement in resonant frequencies and disproportional increment in resonant amplitudes with the increase in excitation moments.

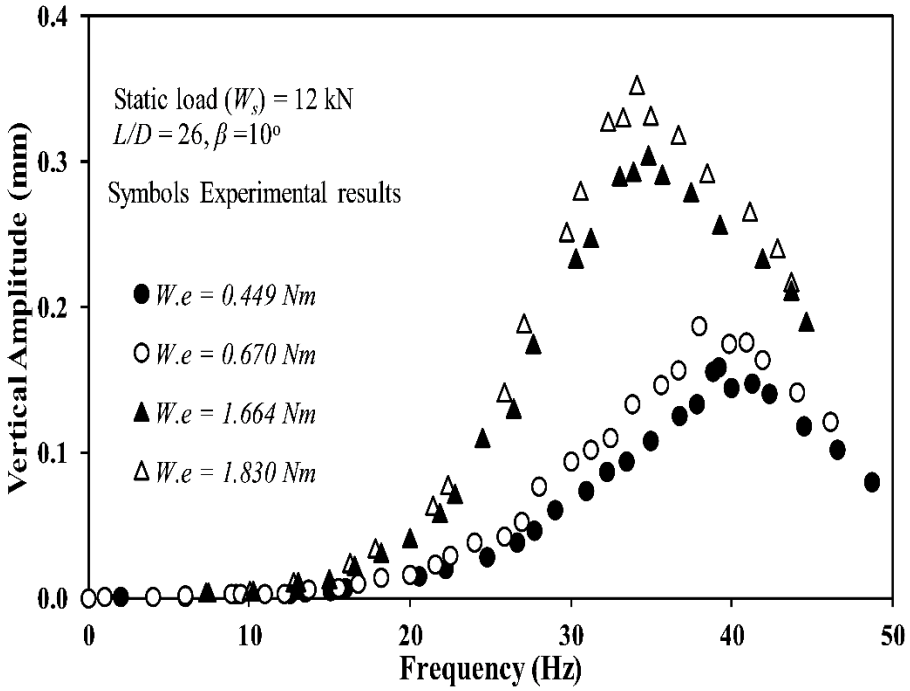

Figure 2: Experimental frequency versus vertical amplitude response of single batter pile

4. COMPARISON BETWEEN THE EXPERIMENTS AND THEORETICAL RESULTS

The test pile on the field has been analysed with all the soil models i.e. Linear Model, Nonlinear Model 1 and Nonlinear Model 2 to get the frequency-amplitude response of the batter pile-soil system. The soil material damping has been assumed 10 percent for the analysis. For different eccentric moments the weak boundary zone parameters were adjusted so that the nonlinear theoretical response curves match closely to dynamic field test data. For the current soil conditions and applied dynamic load, G_{ws}/G_s varied from 0.015 to 0.22, T_{ws}/R_i varied from 0.5 to 1, D_m varied from 0.2 to 0.35. The results obtained from the field experiments are compared with the theoretical analysis for eccentric force (*W.e =1.644 Nm*) as shown in Fig. 3.

- Linear Model: It can be well comprehended from the figure that the theoretical resonant frequency is higher and resonant amplitude are lower than the dynamic test result on the single batter pile (L/D = 26, β = 10°). This is due to the assumption that the soil is perfectly bonded to the pile and that the soil behaviour is primarily governed by laws of linear elasticity explicating no weak inner zone resulting in larger stiffness of batter pile-soil system which produces higher resonant frequency and lower resonant amplitude values.

- Nonlinear Model 1: From the comparison, it is observed that Nonlinear Model I show a well-defined match with the test results. Nonlinearity of batter pile foundation is also

exhibited from the figure with the increase in the resonant amplitude and decrease in the resonant frequency with the increase in excitation levels.

- Nonlinear Model 2: It can be observed that the Nonlinear model 2 produces high resonant frequency and high resonant amplitude when compared to dynamic test result.

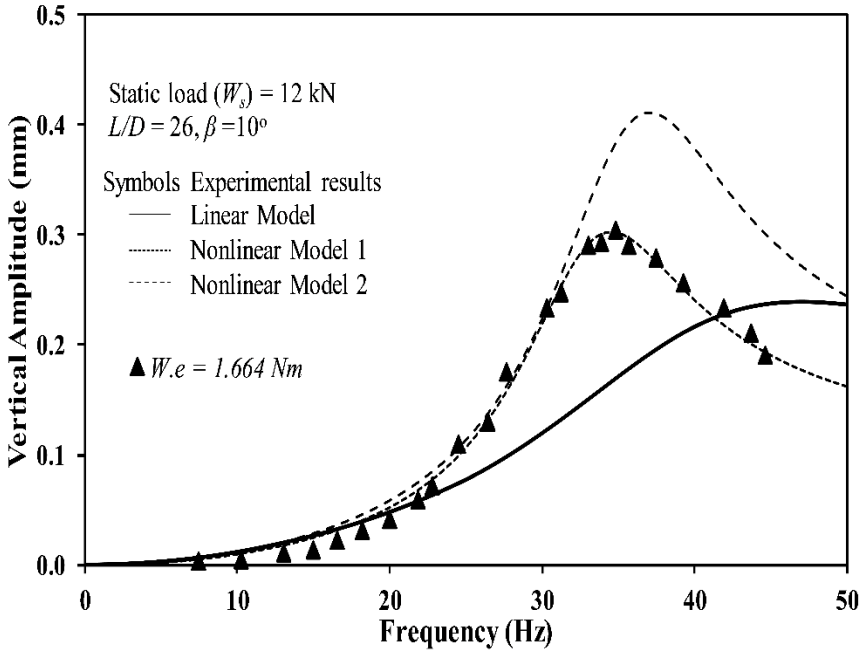

Figure 3: Comparison between the response curve obtained from vertical vibration test and Linear Model analysis

5. STIFFNESS AND DAMPING OF BATTER PILE

The vertical stiffness and damping of single batter pile ($L/d = 26, \beta = 10^o$) with frequency were determined using three models i.e. Linear model; Nonlinear model 1 and Nonlinear model 2 for all eccentric forces. The comparison of variation of stiffness and damping for different models are shown in Fig. 4a and Fig. 4b for eccentric force ($W.e = 1.664\ Nm$) respectively. It is found that Linear model highly overestimates both the stiffness and damping of single batter pile. It also shows that frequency dependent stiffness and damping of single batter pile **is** not varied with different eccentric moments showing a single stiffness and damping curves. In Nonlinear Model 1 the frequency dependent stiffness and damping values are decreased with increase of excitation force. This phenomenon occurs due to the development of weak boundary zone between pile and soil. For low frequency range, the stiffness values tend to remain linear showing the dynamic stiffness of batter pile close to static stiffness. However, the damping values of the batter pile increases rapidly as frequency approaches to zero due to the conversion of soil material damping to the frequency-dependent equivalent viscous damping. In Nonlinear model 2 the frequency dependent stiffness is

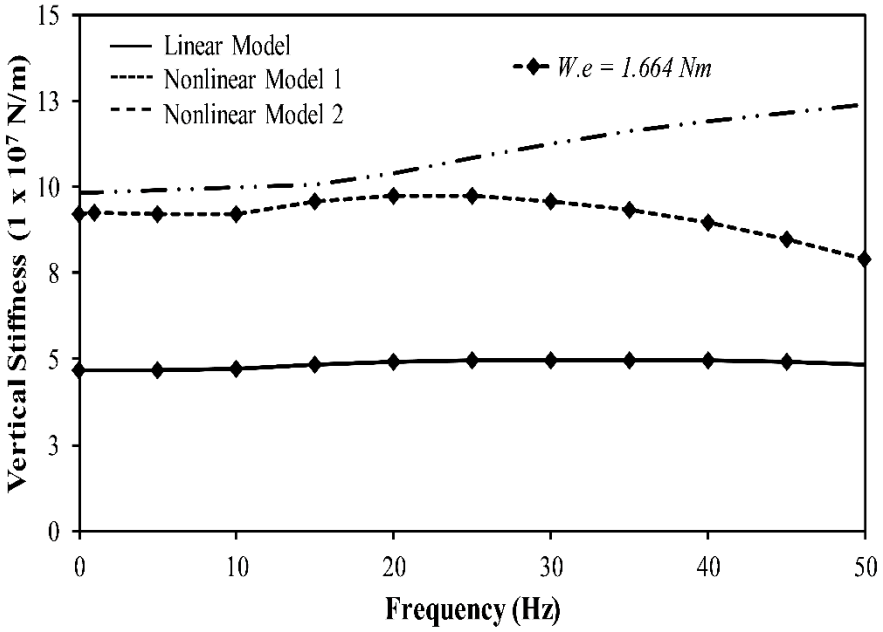

Figure 4a: Comparison of stiffness of soil-pile system obtained from Linear Model, Nonlinear Model 1 and Nonlinear Model 2b

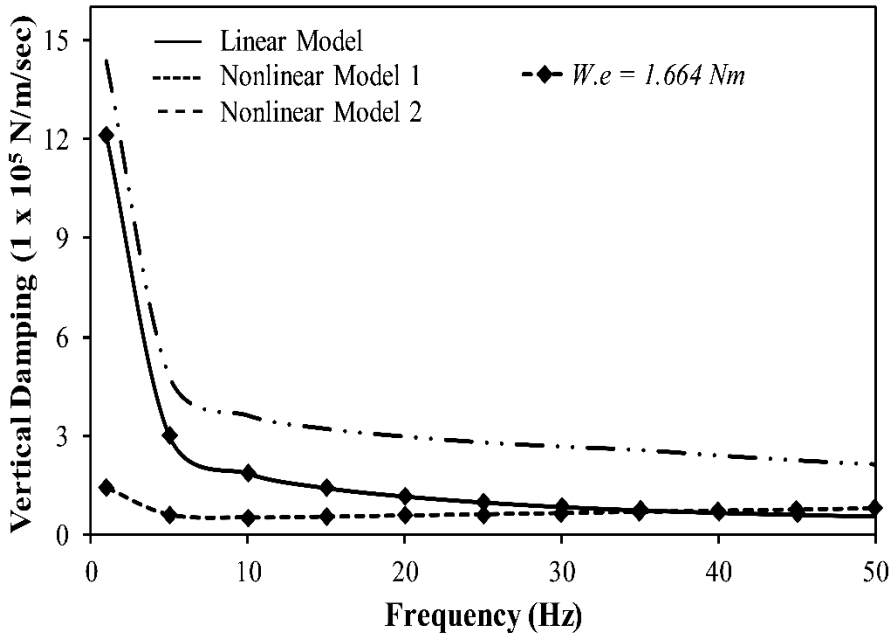

Figure 4b: Comparison of stiffness of soil-pile system obtained from Linear Model, Nonlinear Model 1 and Nonlinear Model 2b

decreased with the increase in the excitation force and the damping values tends to give a small change (overlapping) with the excitation force.

6. CONCLUSIONS

The main objective of the present study is to compare the different soil model i.e. Linear model; Nonlinear model 1 and Nonlinear model 2 to evaluate the frequency-amplitude response of the batter piles subjected to machine induced vertical vibrations. The study also includes the characterization of different soil model and variation of boundary zone parameters of the batter pile-soil system. A field vertical vibration test was also conducted on a on a single batter driven pile (L/d = 26) of inclination 10 degrees for different eccentric moments (0.449, 0.670, 1.664 and 1.830 Nm) with static load of 12 kN. On the basis of the dynamic test result, the effectiveness of different soil models is monitored. The major conclusions for the present study are as follows

- From both the dynamic test data and analysis results it is observed that the measured frequency-amplitude response curves for batter pile ($L/d = 26, \beta = 10^o$) shows marked nonlinearity which was manifested by the reduction in the resonant frequency and disproportional increment in resonant amplitudes with the increase in excitation intensity.
- Nonlinear Model 1 accurately predicts the response of the batter pile reasonably well as compared to Linear Model and Nonlinear Model 2 with dynamic test results.
- The stiffness and damping of the batter pile system are decreased for vertical mode of vibration with increase in excitation level. This reduction is primarily due to the development of weak boundary zone around the pile.
- The Nonlinear Model 1 is found capable of predicting the stiffness and damping value of single batter pile reasonably well for vertical mode of vibration with reasonable estimation of nonlinear parameters. On the other hand, the Linear Model and Nonlinear Model 2 was found to be unsatisfactory in this study.
- The nonlinear parameters like shear modulus reduction (G_m/G), damping factor (D_s), thickness ratio (t_m/R) and separation length plays a major role for actual nonlinear response of soil -pile system.

Abstract

Non-destructive testing methods are an important aspect for the structural integrity and quality assurance of reinforced concrete pile foundations which are normally built on difficult soil conditions. Hence, the structural integrity of deep foundation requires definitive and economical test procedures that can be used shortly after construction to identify the anomalies, defects and the causes of imperfections in cast-in-situ concrete pile foundations.

In the present study, an attempt has been made to detect the effect of various materials present below the pile tip by non-destructive testing. To examine the various pile tip conditions related to the construction of RCC pile, two piles of diameter 150 mm and length 4 m are constructed with two different pile tip conditions: Case 1 – pile tip at natural soil and Case 2 - pile tip at stiff material of thickness 50 cm. The weathered quartzite rock is used at the pile bottom to obtain the required stiffness as of rock. The field tests are performed on two piles using Pile Integrity Tester (PIT) to determine time velocity response for both the pile tip conditions. In case of pile with stiff material at the pile tip it was observed that the resulting velocity of the reflective wave is negative. However, the resulting velocity of the reflective wave is found positive, as the stiffness of natural soil is less than concrete.

The experimental results obtained from the field tests are simulated and examined by axisymmetric Finite Element model using PLAXIS 2D (2015). The concrete pile is modelled as linear elastic whereas; soil is modelled as Mohr Coulomb model. The jointed rock model is used to simulate the behaviour of rock at the pile tip. The dynamic impact load is applied at the top of pile and the velocity amplitude graphs are plotted as a function of time. The results obtained from the numerical analysis are compared with the field tests. It is found that the field tests and numerical results are comparable and match with good agreement. From the present study it can be concluded that non-destructive testing like PIT is useful method to determine the stiffness of the various materials present below pile tip.

1 INTRODUCTION

The quality control and quality assurance of deep foundations during the construction of cast in situ piles are an integral part of manufacturing process. As an essential requirement of engineering practice, the quality control of deep foundations is guaranteed by the acoustic methods to investigate the length and continuity of the deep foundations. Integrity testing is widely used to characterize the changes during the construction and installation of pre-cast and cast in situ piles. Hence, the structural integrity of deep foundation requires definitive and economical test procedures that can be used shortly after construction. The technological aspects of non-destructive testing (NDT) for dynamic pile integrity have seen substantial improvement in recent years. NDT of deep foundations is a complex method covering several different techniques to gain information about the integrity and quality of the deep foundation. Non-destructive testing of piles is used worldwide for various purposes e.g., quality control and quality assurance, verification of existing conditions, and quantification of dimensions. Various methods are available for checking the integrity of concrete piles after installation. Among the most widely used method, impulses or vibrations are applied to the pile and time velocity responses are measured. The commonly used testing methods such as, sonic methods, vibration methods, sonic logging techniques, etc., have been used in the last three decades in different parts of the world. The correct use of these techniques can greatly simplify and expedite investigation and be economical in addressing concerns or questions on pile conditions.

The concept of pile driving analyzer was used widely in the early 1990s. Goble and Likins [1], Teferra and Webster [2] and Likins et al. [3] used Pile Driving Analyzer for the evaluation of deep foundations workability. Hussein and Likins [4] assessed pile drivability quantitatively and evaluated the hammer-pile-soil system using Pile Driving Analyzer (PDA) based on pile force and velocity records under the impact force from a hammer. Sheahan and Hussein [5] dynamically tested 112 substructure units beneath a 5000 m long bridge. They performed dynamic pile tests to assess pile drivability and to verify design parameters for quality assurance of the structures. Morgano [6] determined the embedment depth of deep foundation using one dimensional wave propagation theory. Pile Integrity testing and Parallel Seismic testing methods were used to determine length of steel piles. Johnson and Rausche [7] used low strain integrity testing utilizing two acceleration signals. Rausche et al. [8] used non-destructive pulse echo method to determine the pile lengths under existing substructures and bridges. The method was successfully used for the evaluation of structural integrity of cast-in situ piles, drilled shafts, driven concrete and timber piles. Mullins and Winters [9] identified the presence of anomalies in both small scale and full-scale pile foundations using thermal integrity testing. Liang and Beim [10] studied numerically the effect of soil resistance distribution on the mobility and simulated the velocity and force curves for an impact force applied at the pile top surface for different soil resistance distributions. In the present study, an attempt has been made to examine the different material below the pile tip in the field using pile integrity tester. The experimental results obtained from the field tests were simulated and examined through an axisymmetric pile model fully embedded in a homogeneous soil using finite element software PLAXIS 2D [11]. The results obtained from experimental and analytical study are comparable and matches with good agreement.

2 EXPERIMENTAL STUDY

2.1 Methodology

Non-destructive testing methods used to analyze deep foundations and other structural members are either surface reflection or direct transmission methods. The most common and widely used surface reflection method include the impulse response test – pile integrity testing (PIT). The principle of integrity testing method is time-domain reflectometry of stress wave propagation through pile material acting as a one dimensional medium. In these tests, a hammer impact is used which generates compression waves at the surface of a concrete drilled shaft, pile or pier and reflected waves are received with a transducer (geophone or accelerometer) at the surface. The schematic diagram of PIT test set up is shown in Figure 1.

The generated wave travels down along the length of pile in axial direction. Downward traveling waves caused by the impulse and the reflected upward travelling waves are measured by an accelerometer held against the pile head. These reflections are stored in a small hand-held computer where they are integrated to yield a time versus velocity graph. The test equipment can amplify the signal exponentially with time to emphasis the signal reflected along the pile shaft and from the pile toe. Therefore, the effects of any signal attenuations are removed as it travels along the pile. The major components of the pile integrity testing used in the experiment are a hand-held hammer of diameter 38.1 mm, an accelerometer with high natural frequency (0.7 to 9000 Hz) and sensitivity (50 mV/g). A PIT-X tester with sampling speed of 64 kHz to record the results. The complete experimental setup with PIT equipment is shown in Figure 2.

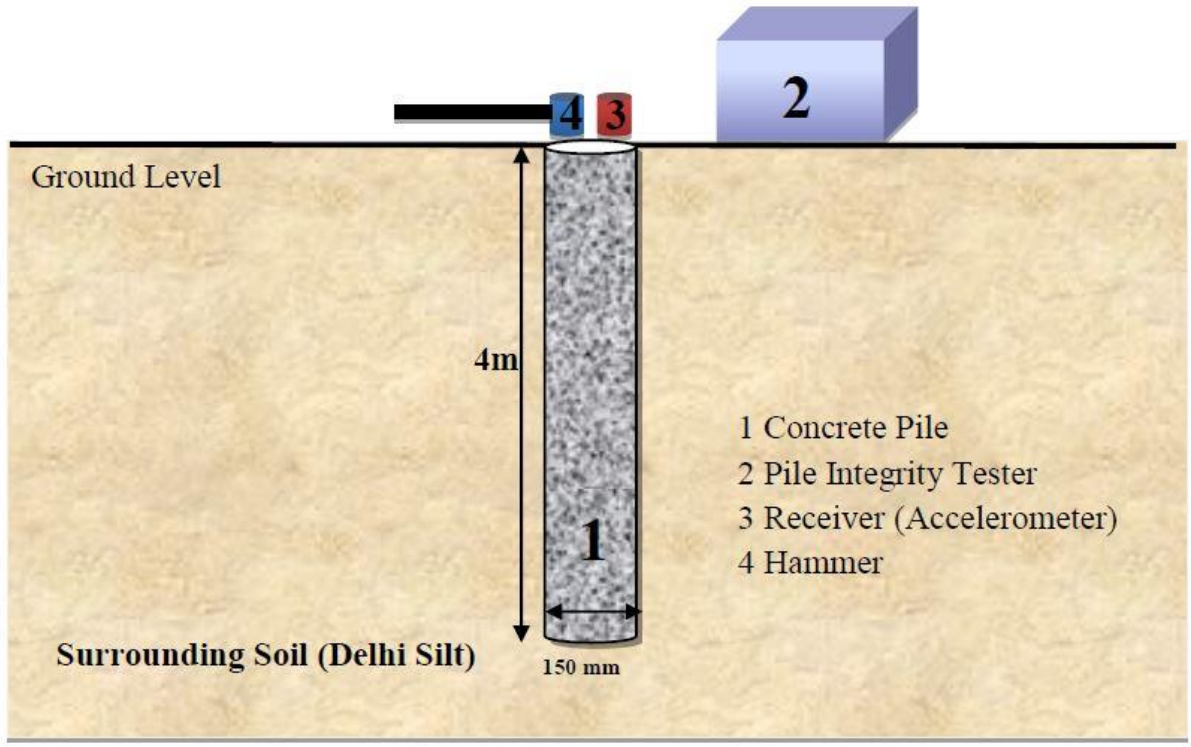

Figure 1 Schematic representation of Pile integrity test setup

Figure 2 Complete experimental setup with PIT equipment

2.2 Site Conditions

The tests are performed at the site located between Block II and III, at Indian Institute of Technology Delhi, New Delhi, India. The soil samples are collected and both laboratory and in situ tests are performed up to the depth of 5 m. It is found that the soil up to 5 m depth is predominantly sandy silt (silt = 58.8%, sand = 30.3%, clay = 10.9 %). The water table is not encountered up to the depth of exploration. The SPT test is also conducted in the field and corrected N value varies from 11 to 29.

2.3 Pile Construction

The piles are casted for two different pile tip conditions in the field. Two bore holes of diameter 150 mm and length 4 m are made with the help of hand auger. The boreholes are filled using M30 grade concrete with different arrangement at the pile tip and tested after 28 days of curing. Two different pile tip conditions are as follows:

a. Case 1 – Pile tip at natural soil
b. Case 2 – Pile tip at stiff material of thickness 50 cm. To obtain the required stiffness as of rock at the pile tip weathered Quartzite rock was put in the borehole.

3 NUMERICAL MODELLING

Numerical modeling for two different pile tip conditions is carried out using finite element software PLAXIS 2D. The pile is modelled using 15 node axisymmetric elements and the behaviour of pile is considered as linear elastic. The soil layers are modelled using Mohr-Coulomb model and behaviour of the soil is considered as drained. The soft toe below the pile tip is modelled using Mohr – Coulomb model but the behaviour is considered as drained. The quartzite rock used in the field is modelled using Jointed Rock Model. The rock properties for quartzite rock are taken from Rao K. S. et al. [12]. The properties of concrete, soil and rock considered in the analysis are tabulated in Table 1 and Table 2 respectively. The dynamic load is applied in the form of line load at the pile top surface. The absorbent boundaries are considered along the boundaries to avoid the spurious reflections. The mesh is generated with

very fine element distribution and the simulation is carried out for the actual field data. The velocity – time graphs obtained from PLAXIS 2D are compared with the PIT results obtained from the field tests.

4 RESULTS AND DISCUSSIONS

4.1 Field Test Results

The typical time velocity graph of averaged signal response for pile tip at natural soil for Case 1 is shown in Figure 3 and for pile tip at stiff material of thickness 50 cm for Case 2 is shown in Figure 4. It can be seen from Figure 3 that the peak at toe is in the same direction as of impact peak due to the presence of natural soil. However, for Case 2 the peak at toe is observed in the opposite direction of impact peak as the material below the pile tip is stiffer than the pile material as observed from Figure 4.

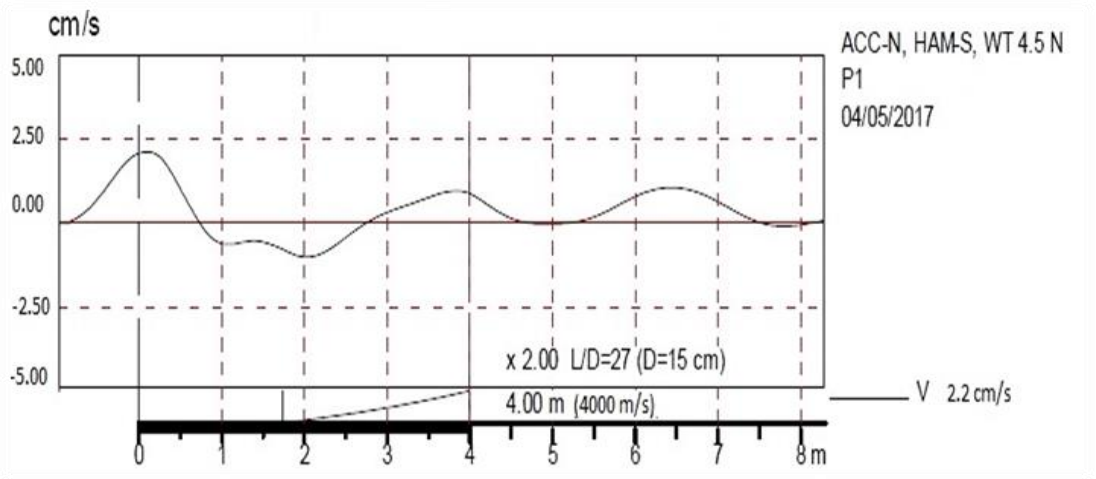

Figure 3 Signal response of Pile tip at natural soil (Case 1)

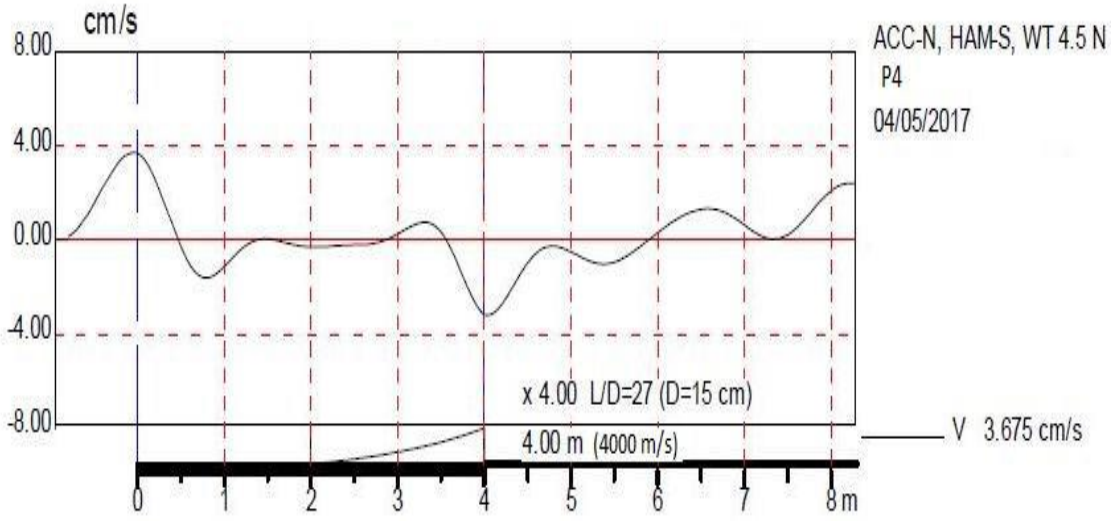

Figure 4 Signal response of Pile tip at stiff material of thickness 50 cm (Case 2)

4.2 Comparison of PIT and FE results

The field test results obtained from PIT are compared with finite element analysis results obtained using PLAXIS 2D. A typical comparison of time-velocity graph obtained from field test with FE analysis for Case 1 is shown in Figure 5. It can be seen from Figure 5 that time-velocity graphs obtained from the FE analysis matches with good agreement with the PIT results. It is also observed from Figure 5 that the toe reflection in case of PIT results is obtained prior to the PLAXIS result. This may be due to magnitude of the impact force and higher compression wave velocity in cast-in-situ pile than the velocity of the longitudinal wave considered in FE analysis.

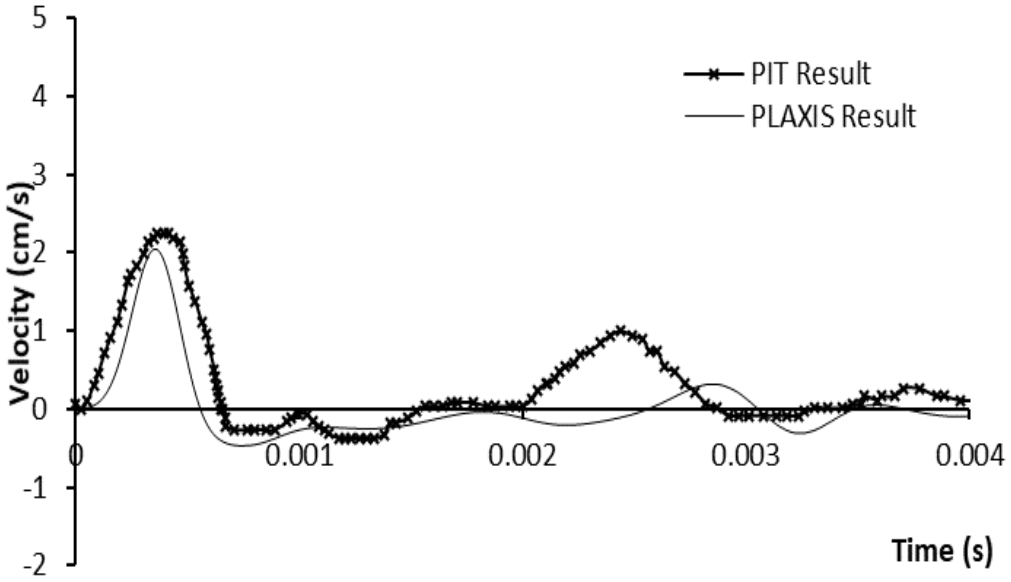

Figure 5 Comparison of PLAXIS results with PIT results for pile tip at natural soil

5 CONCLUSIONS

In the present study both field testing and finite element analysis were carried out to determine the various pile tip conditions. Based on the present study the following conclusions can be drawn:

- For Case 1 that the peak at toe is in the same direction as of the peak at the pile top surface whereas in Case 2 the peak at toe is in the opposite direction as the material below the pile tip is stiffer than the pile material.
- The time velocity graphs obtained from the FE analysis matches with good agreement with the PIT results whereas some differences occur due to the variation in the magnitude of impact force and the velocity of longitudinal wave in the pile.

Abstract

Accurate local site response analysis allows for assessing the response of sites nearby an active seismic zone, and consequently modeling the expected earthquake behavior at the surface level. However, the modeling of this non-linear behavior is always accompanied with high uncertainty and variability that could lead to either an unsafe or a very conservative design. One way to overcome these challenges is by relying on site specific instrumentation techniques. In this study a sequential data assimilation technique is employed for real time calibration of the adopted soil model by relying on a measurement data array from different soil layers in the site of interest. The dynamic model parameters are updated in an optimal probabilistic framework using Ensemble Kalman Filter and therefore minimizing the mismatch between the measured and the predicted response of the site of interest. Due to complexities associated with inverting and updating a non-linear soil model, limited number of studies used monitoring techniques to calibrate a non-linear hysteretic soil model while incorporating different sources of uncertainties. Therefore, in this study monitored data are coupled with a non-linear dynamical model in a probabilistic setting to accurately simulate the vertical wave propagation through the soil layers of a given site. This study uses simulated vertical arrays measurements to assess the validity of the framework and to determine several practical concerns such as convergence and robustness of the presented non-linear scheme.

1 INTRODUCTION

It's widely known among geotechnical engineers and researchers that the effect of strong motion earthquakes on man-made structures is largely dependent on the nature of the subsoil through which the shock waves pass [1]. Therefore, any analysis of the superstructures will require a prior knowledge on the soil properties. In getting the latter, a seismic site response analysis should be conducted through one of the following methods: frequency and time domain, equivalent linear and nonlinear analyses [2]. Depending on the numerical approach being used and the modeling of the nonlinear soil, the output of these methods may greatly vary. The nonlinear and time varying behavior of soil layers are detected using time domain methods, especially when subjected to strong ground motions [3]. Another simplified approach for site response analyses is the equivalent linear method in frequency domain which is known to be efficient and reduces computational time requirements of the site response analysis.

Although extensive efforts and advanced computational algorithms has been utilized in developing these soil response models, in practice the output of these algorithm is not always satisfactory. The main aim of geotechnical engineers is to investigate all the conditions under which predictable soil effects will be expected and to quantify uncertainties in the spatial and temporal characteristics of the predictive theoretical models [4]. However, the main hindering factor that faces practitioners and researcher is the ability to identify accurate soil parameters especially due to lack of extensive soil related data and expensive accurate experimental testing. Although some field methods are being used for evaluation of model parameters and evolution of prognosticative tools and design procedures, a high level of uncertainty and high expenses are involved [5]. As for the laboratory tests, many restrictions are applied due to the irritated samples and the complications in reproducing the site stratification and boundary conditions (Kramer 1996). Therefore, accurate implementation of soil response models is always limited to accurate identification of real site conditions. To overcome this issue, and in the light of recent advancements of geophysical instrumentations such as downhole, seismic cross hole, seismic CPT, steady state vibration and seismic reflection and refraction; application of system identification (SI) methods to dynamic soil behavior has been popular recently.

Constitutive model SI methods are divided into self-Learning simulations, parametric techniques and nonparametric techniques. The aim of SI methods is studying the behavior of existing systems, by recording input-output vibrations of soil in discrete time signals and utilizing inverse programming tools to identify or calibrate adopted system parameters. A broad range of simplified and advanced soil constitutive models have been employed in non-linear site response analysis. The aim of the prior SI techniques is to copy the observed earthquake excitation without prior knowledge on the soil parameters [5].

Parametric system identification methods enable the estimation of constitutive model parameters by solving the equation of motion [5]. Knowing that these parameters represent the characteristics of a given soil column, the prediction of its behavior under different loading conditions could be easily achieved [5]. However, the performance of the proposed framework is altered by the size of the state vector, which include the soil parameters. Therefore, a different algorithm should be adopted to account for multiple parameters in the constitutive model.

With attention to the numerous applications of system identification, some approaches that depend on time series are used to estimate the nonlinear behavior of the soil and to develop

the extended Kalman Filter algorithm and autoregressive-moving average models [7]. By coupling both, the proposed scheme and the recursive methods, an accurate estimation of the discrepancy in the approximated properties could be reached [7]. Irikura and Pavlenko suggested further idealization models to determine the stress-strain behavior of a nonlinear soil column [8,9]. Despite the simplicity of the aforementioned approach, the estimated characterizations of the soil from this linearization analysis can render significant errors due to the linearization of the highly nonlinear soil response analysis, especially when coupled with high amplitude earthquake records. Hence the model should be subjected to further calibration in order to be used in the required constitutive model [10]. Not to mention, a two dimensional site response analysis and soil-structure interaction require formulation of constitutive models and hysteretic rules for the soil profile [10].

Assimaki et al. proposed a waveform inversion algorithm, that depends on the number of parameters used, to estimate insitu soil behavior [10]. This dependency weakens the proposed algorithm, hence, a different approach should be conducted to estimate multiple parameters associated with a constitutive model. Tsai and Hashash (2007) extended the neural network based constitutive model developed by Ghaboussi [11] to include non-linear modeling of soil behavior from downhole arrays. Although this new approach was a huge jump from the known system identification methods, it was accompanied by a high level of uncertainties; mainly in the characterization of the dependency of the soil parameters. Hence, difficulties in convergence aroused, in addition to stability problems in the frame work.

To that end, this study develops a probabilistic framework for estimating dynamic soil properties using the Ensemble Kalman Filter (EnKF). Since EnKF is a non-intrusive filter, it propagates and updates the error statistics of the state vector efficiently and accurately as it does not require a linear approximation of the adopted model. The adopted data filtering technique can be easily coupled with available algorithms that simulate nonlinear soil behavior. In the study, the response of the soil is identified through the open source package, Opensees. The coupling of the non-intrusive filter, EnKF, with Opensees adds to the robustness of the framework and facilitates the application of soil identification techniques for practitioners and geotechnical engineers since the framework relies on open source and less-complicated tools. In this study a simulated vertical arrays measurements are employed to calibrate the state vector in a statistical setting. Several simulations are conducted with a main aim of investigating multiple practical concerns, such as convergence to true state and robustness of nonlinear soil identification.

2 OPENSEES

The Open System for Earthquake Engineering Simulation (OpenSees) is an open-source, object-oriented finite element software framework. The potentialities of OpenSees encompass modeling, analysis and structural reliability. Unique among software for earthquake engineering, OpenSees allows integration of models of structures and soils to investigate challenging problems in soil-structure-foundation interaction [14]. In this study Opensees is employed in the EnKF framework to integrate the dynamic response of soil layers forward in time. Details of the adopted soil modeling are presented in the next section.

2.1 Modeling features

A two-dimensional nonlinear model of the soil column was developed using OpenSees. The soil layers are modeled as four nodes plane-strain isoperimetric quadrilateral elements.

Each element node has 2 degrees of freedom. The soil material is behavior is modeled using the built-in material the "PressureDependendMultiYield" which is an elasto-plastic material. During static loading (gravity), the material behavior is linear elastic. Once dynamic loading phase is initiated, the stress-strain response is elastic-plastic. Assuming fully undrained conditions, a built-in "FluidSolidPorousMaterial" is defined to simulate the response of saturated porous media. At each layer, the nodes and coordinates are determined, and the dynamic soil properties; elastic modulus (E), bulk modulus (B), damping ratio (D), mass density (ρ), friction angle (Fang), phase angle (Pang) and Poisson's ratio (ν) are defined. The soil mass density (rho) is often estimated by a nearby subsurface sampling or using correlation methods. In this model it's important to realize that at low strain levels, the elastic theory is adopted, hence the response is linear. While at intermediate and high levels of strains (~10-2 to 5 percent), the response becomes non-linear and will experience plastic deformation continuously until failure.

3 SEQUENTIAL DATA ASSIMILATION

Sequential data assimilation techniques stem from the need to improve the model output. These techniques are based on "assimilating" observations into the model, whenever they are available; in order to correct the model, reduce parameter uncertainty and increase prediction creditability.

Among the known sequential data assimilation scheme, the Kalman filter is the best. It was developed by Kalman (1960), to solve linear problems by minimizing the mean square error between the guessed output and measurements whenever they are available. For nonlinear analysis, the extended Kalman Filter (EKF) is applied, which works by simply linearizing the predictions and measurements about their mean. The simplicity of the approach leads to an unbounded error variance where higher order moments are discarded.

To overcome this drawback, Evensen(1994b) came up with the Ensemble Kalman Filter. It states that if the dynamical model can be written in a stochastic differential equation, one can derive the Fokker-Plank equation for the time evolution of the probability density function, which contains all the information about the predicted error statistics using Monte-Carlo. Integrating an ensemble of state vector and forwarding it in time, will make the calculation of the mean and error covariance applicable. This new approach was well implemented by Slika and Nasr [15,16] in structural health monitoring applications.

3.1 Ensemble Kalman Filter

The EnKF proposed by Evensen (1994b) consists of 3 stages: the representation of error statistics using an ensemble of state vector, the alternative model for error statistics prediction, and a consistent analysis scheme. Different than the other Kalman filters, the EnKF executes multiple simulation independently, incorporates the new measurements and updates the multiple models simultaneously. After each update, the EnKF describes model parameters through mean and variance. For each time recursive process, the EnKF consists of a forecasting step based on the current state variables, and an assimilation step to update the state variables.

In this paper, the state vector (U) incorporates dynamic variables and soil parameters:

$$U=[V\ P]^T \tag{1}$$

where V consists of the displacement, velocity and acceleration at the top of each soil layer.

P is the model parameters that will be updated, at each available measurement, in the forward model. The soil density, elastic modulus friction angle and phase angle are to be updated at each iteration. A sensitivity analysis was performed to identify the correlation between the soil parameters and to determine the sensitivity of the model to a small change in those parameters.

The initial ensemble is chosen in a way that represent the statistical distribution of the initial guess of the state vector. U, the matrix holding the ensembles such that $U_i \in R^n$ as shown in (2). Where N is the number of ensemble members, and n is the size of the model state vector.

$$U = (U_1, U_2, \dots, U_N) \in R^{n \times N} \tag{2}$$

The ensemble mean is given by

$$\overline{U} = U1_N \tag{3}$$

Where $1_N \in R^{N \times N}$ is a matrix where each element is equal to equal to $1/N$.

The ensemble perturbation matrix could be defined as

$$U' = U - \overline{U} \tag{4}$$

The model error covariance matrix can be computed as follow

$$P_e = \frac{U'.(U')^T}{N-1} \tag{5}$$

As mentioned previously, the EnKF consists of a forecast step (U^f), calculated using the forward model in order to propagate the model state vector from time step (t-1) to time step (t), as shown below:

$$U^f_{t,i} = f\left(U^a_{t-1,i}\right) \qquad i = 1, \dots, N \tag{6}$$

Note that in this forward step, only dynamic parameters are updated to minimize the discrepancy between the measurements and the corresponding predictions.

Using observed measurements d, that are measured response from data array at the top of each of layer, we can define an N vectors of perturbed observations as

$$d_j = d + \epsilon_j, \qquad j = 1, \dots, N \tag{7}$$

Which can be stored in the columns of the following matrix

$$D = (d_1, d_2, \dots, d_N) \in R^{m \times N} \tag{8}$$

The ensemble perturbations are assumed to be unbiased and Gaussian, with a mean equal to zero, and can be stored in matrix such as

$$E=(\gamma_1,\gamma_{2,\ldots..},\gamma_N) \in R^{m\times N} \quad (9)$$

From which we can construct the ensemble representation of the measurement error covariance matrix

$$R_e = \frac{E.E^T}{N-1} \quad (10)$$

If the measurement errors are uncorrelated, R_e will be a diagonal matrix.

The update state is computed as follow

$$U^a_{t,i} = U^f_{t,i} + K_t(d_{t,i} - HU^f_{t,i}) \quad (11)$$

Where H is a matrix operator, depending on the number of observations, and whose elements are only ones or zeros.

$$H = [\mathbf{0} \mid \mathbf{I}] \quad (12)$$

Where I is an identity matrix.

The Kalman gain is given by

$$K_t = P_eH^T(HP_eH^T + R_e)^{-1} \quad (13)$$

When the ensemble size (N) is increased by adding random samples, Ktcwill converge toward the exact solution of eq. (11).

Therefore, at the end of time ti, the probability density function (PDF) of the state vector is known. At the end of time of ti+1, new measurements are available and the PDF up to ti+1 is regarded as the prior PDF. By using the assimilation step, the EnKF members are conditioned with these new measurements and the PDF turns into the posterior PDF. From this point of view, the solution provided by the EnKF is based on maximizing the posterior PDF of the state vector within the context of Bayesian inversion. It is equivalent to minimizing the variances of the posterior covariance matrix in probabilistic settings.

4 NUMERICAL APPLICATION AND ANALYSIS

The simulated behavior of the soil column is based on the discussed non-linear hysteretic model in opensees in the previous section. A distribution of the material parameters are assumed for each soil layer, based on conventional soil material as presented in table 1, and will be considered as the reference true parameters. The modeled deposit is subjected to the known Elcentro earthquake record at to the bottom of the soil column. The output of the computer simulation is the mechanical response at the top of each soil layer which constitutes of acceleration, velocity and displacement. A 5% perturbation error is added to the simulated output and will be assumed herein as the measured response from the accelerometers. The measured acceleration response at the top of each layer is presented in figure 1.

Layer	Soil Type	Modulus of Elasticity (kPa)	Density ton/m^3	Poisson ratio	Friction angle (degree)	Phase angle (degree)	Depth (m)
Layer 1 (bottom layer)	Dense Sand	E1=135000	2.1	0.35	40	16	4
Layer 2 (middle layer)	Medium Sand	E2=100000	2	0.32	37	20	3
Layer 3 (top layer)	Loose Sand	E3=750000	1.8	0.27	33	23	2

Table 1: True state parameters used for simulation of measured response

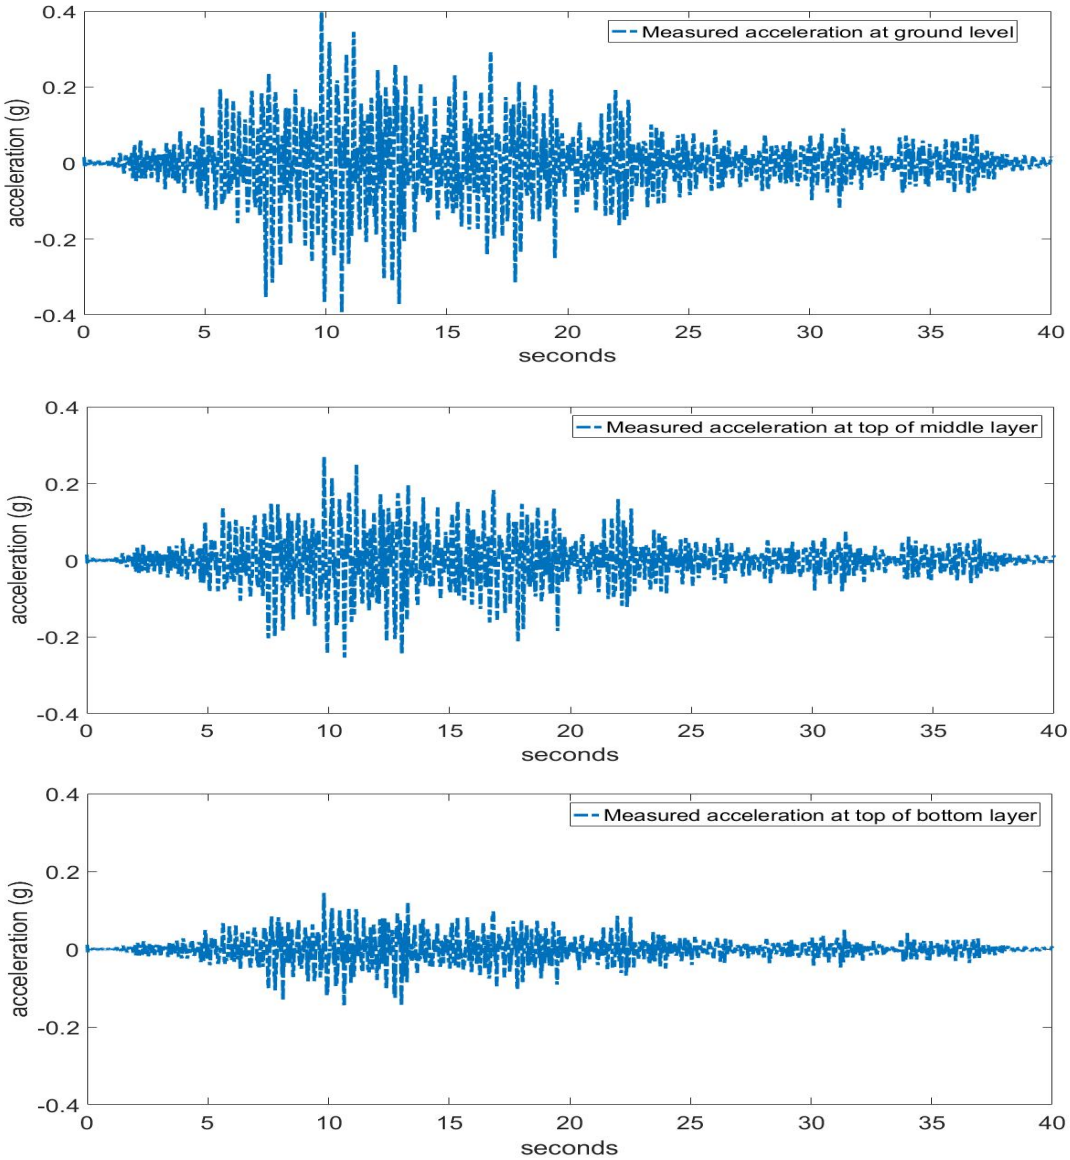

Figure 1: Measured acceleration response at the top of each layer

The main aim of the presented numerical application is to illustrate the accuracy of the suggested framework and perform sensitivity and convergence analysis. The accuracy of the framework is investigated by identifying the soil material properties starting from a probabilistic initial estimates of the soil parameters based on the "inaccurate initial knowledge". To assess the robustness and applicability of the framework different sensitivity analysis is conducted by varying several contributing factors such as, effect of initial guesses, update frequency and stability of solution as a function number of identified parameters.

4.1 Updated variable parameters

In general, a main problem in system identification is to deal with the large number of potentially necessary parameters which can lead to inefficient filtering and divergence from the optimal solution.

In nonlinear soil identification several parameters are necessary to parametrise the soil layers. However due to noisy and limited data over fitting is a common concern that requires adequate attention. A common approach to avoid divergence and handle inefficient filtering is to make the number of used parameters considerably less than the number of offered parameters. In this study, convergence analysis to optimal solution is investigated as a function of identified parameters. Four parameters are considered: Modulus of Elasticity E, soil density ρ, friction angle Fang, and phase angle Pang for each layer. In each simulation the state vector is assemble based on the assumed unknown/calibrated parameter. Summary of convergence analysis for the identified parameters is presented in table 2.

Number of Identified Parameters	Identified Parameters	Convergence of Solution
Four	E, ρ, Fang, Pang	Diverged from true state
Three	E, ρ, Fang	Diverged from true state
Three	E, ρ, Pang	Diverged from true state
Three	E, Pang, Fang	Diverged from true state
Two	E, ρ	Converged to true state
Two	E, Fang	Converged to true state
Two	ρ, Fang	Converged to true state

Table 2: Convergence of EnKF with number of identified parameters

As evident from the table above, in this nonlinear identification exercise with measurements only at the top of each layer, only two-parameters-identification guarantee a stable solution that can convergence to true state and avoids over fitting. Although capturing nonlinear response using two parameters can be a challenging task, in practice, several soil parameters are correlated and can be expressed as function of different soil types. Therefore, in practice, the number of parameters per soil layer is recommended to be limited to two guarantees efficient filtering from stability analysis point of view. In the remaining sections two parameters will be used for soil identification of each layer that are, E and ρ.

4.2 Stability of solution versus number of updates

To study the effect of the update on the accuracy of the EnKF framework, sensitivity analysis is performed to investigate the effect of the number of updates on the stability of the solution or its convergence to true state. All sources of uncertainties are incorporated in this exercise as presented in table 3.

EnKF Uncertainties	Mean	Standard deviation	Distribution
Initial estimate of E1	80,000 kPa	12% of mean value	lognormal
Initial estimate of E2	78,000 kPa	12% of mean value	lognormal
Initial estimate of E3	71,600 kPa	12% of mean value	lognormal
Initial estimate of ρ1	2.0 ton/m^3	8% of mean value	lognormal
Initial estimate of ρ2	1.8ton/m^3	8% of mean value	lognormal
Initial estimate of ρ3	1.8 ton/m^3	8% of mean value	lognormal
Model Uncertainty	0	7% of predicted mean	normal
Parametric Uncertainty	0	2% of predicted mean	normal
Measurement Error	0	3.5% of measured response	normal

Table 3 Quantified uncertainty in EnKF framework

Table 4 presents the recorded results for convergence of the calibrated parameters, E and ρ, to true state for each EnKF simulation. As evident from this table, the number of update is essential to capture the nonlinear characteristics of the soil response and guarantee convergence to true state. At higher update rate (more than 0.15 sec) the convergence to true state is not guaranteed, however at a lower update frequency, both identified parameters converged to the true state in less than 15sec. Therefore, small incremental updates are essential to guarantees convergence to the optimal solution in the neighborhood of the previous updated state, however when using less frequent updates. Divergence from true state can be attributed to the nature of the no-linear oscillating hysteretic problem that possess multiple potential local optimum solutions, therefore sequential updates shall be close enough to guide the state vector to optimum posterior solution or the true state.

Update frequency (sec)	Time needed to converge to true state
0.02	Converged after 6.5 sec
0.05	Converged after 9 sec
0.1	Converged after 15 sec
0.15	Diverged
0.2	Diverged
0.3	Diverged
0.5	Diverged

Table 4 Convergence of EnKF framework versus update frequency

To illustrate the convergence of the state vector, the identified parameters modus of elasticity E, and density ρ, are plotted versus true state values in figures 2 and 3, respectively, for an EnKF framework with 0.05 sec update frequency. These graphs confirm the convergence of all identified parameters to the true state when incorporating a frequent update strategy.

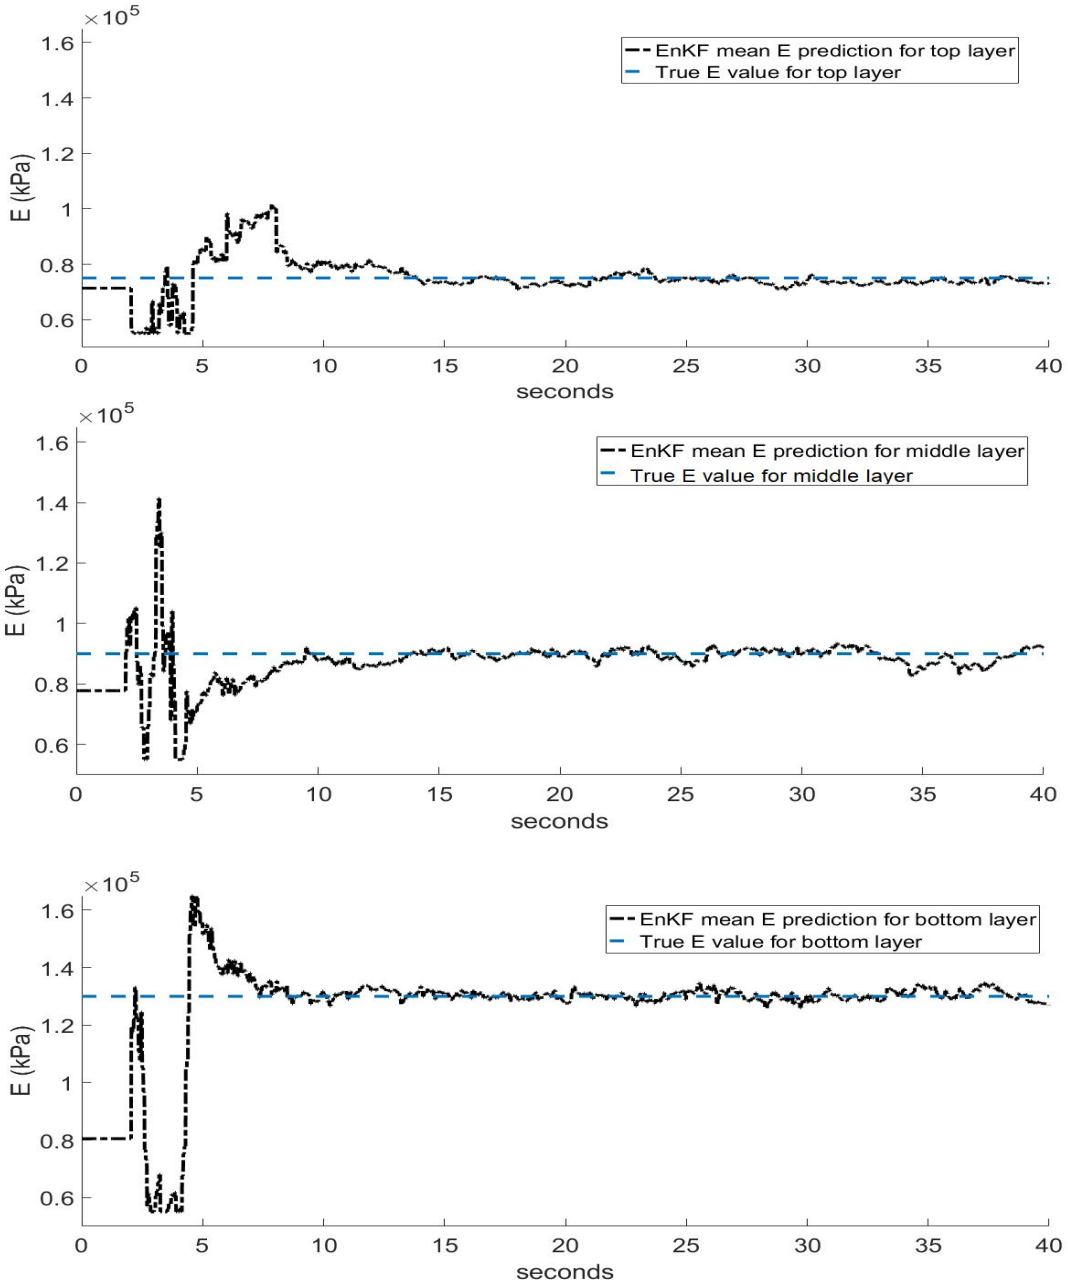

Figure 2: Identified mean modulus of elasticity for each soil layer

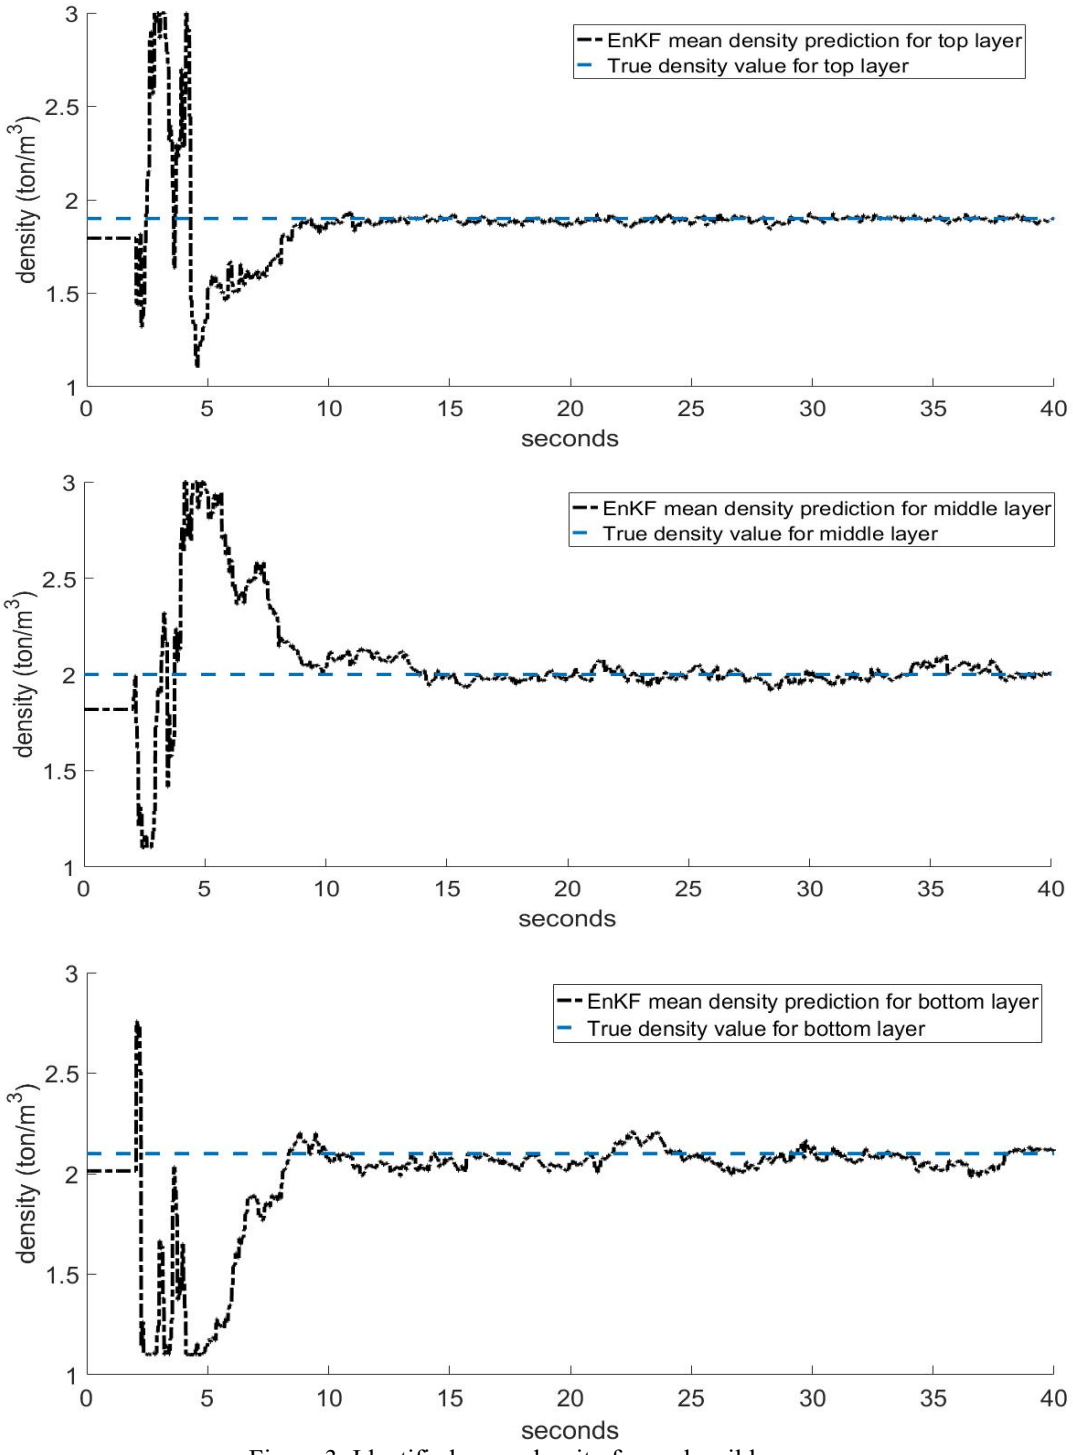

Figure 3: Identified mean density for each soil layer

4.3 Initial guess

To assess the robustness and capabilities of the presented framework to converge to the true state despite initial errors, random initial distribution for modulus of elasticity of soil and soil densities for each layers were integrated in the framework and convergence to true state were recorded in table 5. In this exercise, the update frequency is set to 0.05 sec, and the statistical uncertainties in the EnKF ate the same as assumed in table 2 except for initial mean estimate.

Mean Initial Guess set	Mean Modulus of Elasticity (kPa)	Mean Density ton/m^3	Time needed to converge
IG1	E1=110,000 E2=90,000 E3=85,000	ρ1=2.2 ρ2=2.1 ρ3=1.9	8 sec
IG2	E1=95,000 E2=95,000 E3=70,000	ρ1=2.3 ρ2=2.0 ρ3=1.7	10sec
IG3	E1=160,000 E2=120,000 E3=65,000	ρ1=2.25 ρ2=1.9 ρ3=1.65	12 sec

Table 5: Convergence of the EnKF starting from different initial guesses

As evident from table above, the presented scheme is robust and guarantees convergence within only 12 seconds even if the initial guess is far from true state by more than 30%. Therefore, the presented scheme is capable to converge to true state in some high uncertainty settings even when the soil column is subjected to a short earthquake records.

5 CONCLUSION AND REMARKS

This study presents the coupling of the widely the EnKF, with an open source soil response software package, the Opensees. The power of the suggested framework lies in its ability to identify nonlinear behavior in statistical settings based on an easy-to-implement and readily-available-tools for practitioners. Convergence analyses was conducted to investigate several concerns in nonlinear identification and to assess the robustness of the framework. Based on the presented study, several remarks were noted, (1) nonlinear identification should be mainly based on two-variable identification, (2) the frequency of update is essential for the success of a sequential nonlinear identification technique, (3) statistical nonlinear identification is successful with wide range of initial guesses even when coupled with short earthquake excitations.

Abstract

Buried natural gas pipelines are important infrastructure to connect areas of gas exploration to areas of use. In many parts of the world, pipelines cross seismic regions and varieties of soil strata, including regions of discontinuous permafrost in the Northern hemisphere. Initial studies find that the seismic response of soils can be strongly influenced by changes in underlying soil strata, hence potentially leading to greater seismic demands on buried infrastructure such as pipelines. Frozen soil deposits, in particular, can lead to a significant change in dynamic soil response to seismic excitation. To study the effect of crossing discontinuous permafrost zones on the seismic behaviour of buried natural gas pipelines, a combined modelling approach is proposed: (1) dynamic site response analysis to determine the load conditions and (2) quasi-static finite-element analysis on the pipeline and surrounding soil. In this paper, results from one-dimensional equivalent linear soil response analyses for a site of discontinuous permafrost is presented. Despite the frozen soil stratum lying at a depth of 40 m, the response of the soil at the depth of the buried pipeline is found to be significantly affected. A parametric numerical validation study on a finite element model of a typical buried natural gas pipeline is then presented to assess the influence of geometrical and mechanical parameters on the response of pipeline and surrounding soil by means of a series of incremental dynamic analyses. Outcomes of this study highlights the strong effect of the soil properties on the strain in buried pipelines.

Keywords: Pipelines, Seismic behaviour, Structural Dynamics, Earthquake Engineering, Frozen Soil, Discontinuous Permafrost.

1 INTRODUCTION

Long-distance buried pipelines often unavoidably cross terrain with different soil types as well as with variation of surface-level built-environment. For instance, the pipeline can cross highways or railways that may induce additional settlement under static loading [1]; moreover, they may also concern the boundaries between soil strata causing local stress concentrations under vertically propagating seismic waves [2].

The effect of local site conditions on the ground motions is a known phenomenon and ground response analyses are common practice in geotechnical earthquake engineering [3]. Changes in soil properties along the length of a pipeline are still considered to be an under-examined issue of importance. A variation in the seismic behaviour of soils and, hence, a variation in local stress in pipelines can be caused by discontinuous permafrost, which occurs in regions with mean annual soil surface temperature of -2 to -4°C, causing partial freezing of soil layers below ground. In the Northern Hemisphere, 24% of the ice-free land area is affected by permafrost, i.e. soil that continuously has a ground temperature below 0 °C for at least two consecutive years [4]. Still, its effect on the seismic site response for buried infrastructure has not yet been studied extensively, and in current design practice, it is ignored. As the exploration of natural resources in seismically active regions, such as Alaska, U.S., or Canada, that are also permafrost regions, is expanding, it is critical to further explore this topic [5].

Frozen soil deposits can lead to a significant change in dynamic soil response to seismic excitation. In particular, geotechnical properties, such as soil stiffness and shear wave velocities, increase in frozen soils. In a discontinuous permafrost zone, only some parts of the soil mass are in frozen conditions. This can lead to a stark contrast in soil response at their boundaries, in both lateral and vertical directions. The effect of permafrost on the ground response to transient ground motions has only sparked interest in the last decade. Some examples are given in northern Canada [6], Alaska [5], as well as in Tibetan regions of China [7], where critical infrastructure, such as railways or buried pipelines, cross seismically active zones and permafrost sites.

To study the effect of crossing discontinuous permafrost zones on the seismic behaviour of buried natural gas pipelines, a combined modelling approach is proposed: (1) dynamic site response analysis to determine the load conditions and (2) quasi-static finite-element analysis on the pipeline and surrounding soil.

In this paper, the results from one-dimensional equivalent linear analyses for soil strata in discontinuous permafrost at a site in Alaska are presented. Despite the frozen soil stratum lying at a depth of 40 m, the response of the soil at the assumed depth of the buried pipeline (5 m) is found to be significantly affected due to the large change in shear wave velocities in the frozen layer. This paper also presents the outcomes of a preliminary numerical validation study to define the influence of some geometrical and mechanical parameters on the response of pipeline and surrounding soil. A 3D finite element model of a typical buried natural gas pipeline is developed, including the soil surrounding it. By means of a series of incremental dynamic analyses (IDA), parameters, such as mesh size and geometry of the surrounding soil, are investigated to assess their effect on the response of the pipeline in soils with different geotechnical properties. Outcomes of this study highlight the significant effect of the surrounding soil properties on the strain in buried pipelines. Moreover, the study validates the use of both coarse mesh and smaller geometry of the surrounding soil to allow a computationally efficient model.

2 BACKGROUND

2.1 The effect of vertical components of ground motions

A majority of studies on the seismic resilience of buried steel pipelines considers seismic loading in the horizontal plane of the pipeline, be it in lateral or axial directions [8]. The effect of the vertical component of ground motions is not well-studied. Vertical loading is mainly considered in the case of static loading or permanent ground deformations caused by earthquakes, such as fault movements or landslides.

Lee [9] undertook a series of finite-element analyses on the combined vertical static (traffic and soil weight) and vertical seismic loading. The soil is modelled homogenously along its depth and length and traffic load is spread evenly across the surface of the soil and is not considered in the dynamic load. A number of different, albeit homogenous, soil conditions are investigated, as well as the effect of boundary conditions, corresponding to continuous and segmented pipelines. It is found that continuous pipelines behave better, and that sandy soils increase the stress in the pipelines compared to clay under static loading conditions, however only to a level that may lead to temporary serviceability issues. While no specific limit states are specified, under vertical seismic loading, it is found that for continuous boundary conditions, acceptable stress levels are obtained, while stress increases for segmented boundary conditions. A deeper analysis of the local effect of variation in soil type or built-environment is however needed.

Jeon [10] carried out incremental dynamic analyses (IDAs) to investigate the relative behaviour of buried pipelines designed to Korean and US guidelines under vertical seismic excitation. A two-dimensional model along the length of the pipeline is created, with the soil considered homogenous throughout. Maximum strains along the pipelines of up to 0.6% are observed. The range of peak ground accelerations (pga) in the study is limited to up to 1.2g and no internal pipeline pressure is assumed in the analysis.

2.2 Variations in vertical load conditions along pipelines

The effect of different vertical surface load conditions on buried high-pressure gas pipelines is the topic of a finite element study by Brückner et al [11], who applied a modular approach to look at traffic loading, water loading and railway crossings.

Manna and Duari [12] investigated the local effect of pipeline-road crossings in terms of cyclic traffic load and find that corrosion and damage is more likely underneath road-crossings. Zhou et al [1] assessed the uneven static loading conditions on a buried pipeline using finite element analysis. The authors determined that local stress concentrations in the pipeline are observed when a gas pipeline crosses a high-filling road, which may affect its operational safety. The effect of pipeline internal pressure, as well as pipeline wall-thickness are found to be significantly affecting local stress in pipeline elements under static vertical loading.

The combined effect of seismic and traffic loading has been studied by Kokavessis and Anagnostidis [2], which however focused on the soil-structure interaction in the case of soil-liquefaction.

2.3 Variations in soil conditions along pipelines

Changes in soil properties along the length of a pipeline are still considered to be an under-examined issue of importance. Local site conditions can significantly influence the response of soil to ground motions [3], [6]. A variation in soil properties may be a case of two horizontally

adjacent soil strata of different stiffness, but also the case of a pipeline crossing a soft alluvial valley [3].

In the case of pipelines crossing soil strata characterized by large temperature differences in soil layers, such as discontinuous permafrost regions, a multitude of potential issues have been studied in the literature, including uplift of the pipeline due to frozen soil around pipelines under static loading conditions [13], but also the effect of thawed layers in frozen soil on soil liquefaction [14].

However, also the dynamic properties of frozen soil are significantly different, for instance, the Young´s modulus of frozen soils can be magnitudes of 10s or 100s times larger than for the same soil in unfrozen state [4]. As ground temperatures can increase with depth below the permafrost, its stiffness will hence also decrease with depth. Similarly, the shear wave velocities are lower for unfrozen soil.

Wang et al [7] compiled wave velocities obtained from field tests along the Quinghai-Tibet railway in China for different soil types (silty clay, mudstone, marl, fine sandy soil) under frozen and unfrozen conditions. This zone is very seismically active and constitutes the largest area of permafrost at high elevations in the world. The data from ten boreholes was then used to carry out site response analyses and obtain ground motion acceleration spectra. Wave velocities are 1.2 - 1.6 times and 1.4 - 1.7 times larger in frozen soils for S-wave and P-waves, respectively.

Yang et al. [5] looked at another seismically active permafrost region, namely Alaska. One-dimensional equivalent linear analysis was carried out looking at the vertically propagating horizontal shear waves. The aim was to investigate the effect of permafrost on the seismic response of bridges in Alaska, hence looking at the response at ground level in soils with and without permafrost. Variations in permafrost depth, thickness as well as depth to bedrock were the main parameters studied.

The parametric study showed that a soil profile with a permafrost table at -20 m and the bedrock table at -66 m produces the largest surface response spectrum. This particular soil profile may produce a site response that is larger than anticipated by design codes. The authors hence concluded that the seismic design of structures should consider the presence of continuous permafrost, as it influences the site response significantly.

Dadfar et al [6] investigated the effects of discontinuous permafrost on the seismic behaviour of pipelines by modelling the 2D response of a pipeline that is crossing alternating regions of frozen and unfrozen soil. The frozen and unfrozen free-field responses in the horizontal direction of the soil are determined to be significantly different due to a large change in seismic shear wave velocities. The results from the soil free-field response study is then used as input motion along the length of the pipeline and compared to a uniform support excitation case. It is found that considering regions of frozen soils leads to a large induced moment and plastic deformation in the pipeline, which is not observed in the uniform case. Ovalisation is not found to be critical, but the pipeline is instead found to yield in bending.

In discontinuous permafrost, frozen soil deposits can lead to a significant change in soil response. In particular, the stiffness of the soil and shear wave velocities are increased in the frozen soil [15]. In a discontinuous permafrost zone, parts of the soil mass are frozen conditions while others are not. This can lead to a stark contrast in soil response at their boundaries, in both lateral and vertical directions, as frozen soils have different geotechnical properties and shear-wave velocities than unfrozen soils.

Dadfar et al [15] conducted a combined experimental and numerical study on the seismic site response of alternate blocks of frozen and unfrozen soil. Free-field spectral accelerations were

found to be larger for the frozen soil, but the increase is affected significantly by the spacing and geometry of the frozen soil blocks.

3 METHODOLOGY

An intensive study of available literature on modelling the effect of transient seismic ground motions on pipelines [3] found that the inertial soil-pipeline interaction is negligible and that the fully dynamic problem of buried pipelines can be split into a dynamic soil analysis and a quasi-static analysis of the pipeline behaviour.

In the case of vertical loading with variation in soil properties in the soil model, ovalisation of the pipeline cross-section, as well as bending failure of the pipeline are assumed the only potential failure mechanisms, the latter being less realistic due to the high ductility of steel pipelines used for natural gas transportation [8]. Excessive ovalisation of the cross-section can lead to loss of pipeline integrity or serviceability and is limited to 15% by most guidelines [6]. Buckling or fracture of the pipeline are only observed under axial loading [3].

It is hence proposed to use a similar two step approach to modelling as proposed by Psyrras and Sextos [3]. First, one-dimensional equivalent linear analysis on two different sets of soil strata, with and without permafrost layer at 40 m depth, is performed to obtain soil response spectra at different depths of the soil. Initial results from the ground response analysis step are presented in the next section, highlighting the effect of permafrost layers on the soil response at ground level.

Next, the pipeline and surrounding soil are modelled in a three-dimensional finite element model, with vertical displacement applied to the top of the soil, according to the obtained acceleration histories obtained from the ground response analysis. In this study, a parametric analysis on the various parameters affecting the finite element modelling of the pipeline-surrounding soil model is presented. The effects of different soil materials around the pipeline, different pipeline diameter and thickness of the pipeline-wall, as well as geometric parameters of the surrounding soil model, including mesh-size and depth of modelled soil stratum are assessed.

The results obtained in this study can then be used for future modelling of pipelines crossing two different soil strata, by applying two different loading histories along the length of the pipeline, obtained from ground response analyses.

4 GROUND RESPONSE ANALYSIS WITH AND WITHOUT PERMAFROST

In this section, an initial response analysis of potential vertical soil strata with and without permafrost layer is presented. Two soil profile are constructed for a site in Alaska [5], with the mechanical properties of the different layers provided in Table 1 and Table 2.

A one-dimensional equivalent linear analysis is then performed in the DEEPSOIL software [16], with two low velocity transition layers with thickness of 1.5 m assigned on the top and bottom of permafrost layer to account for the surface condition and the partially frozen layer between frozen and unfrozen soils.

Layer name	Thickness (m)	Unit weight (kN/m3)	Shear wave velocity (m/s)	Damping ratio (%)
Sandy Silt 1	14.00	20.00	200.00	0.48
Sandy Silt 2	23.00	20.00	300.00	0.48
Sandy Silt 3	14.00	20.00	400.00	0.48
Gravel	6.00	20.40	450.00	0.50
Weathered Rock (Clay)	9.00	20.40	550.00	2.60

Table 1. Soil characteristics for the stratum without permafrost

Layer name	Thickness (m)	Unit weight (kN/m3)	Shear wave velocity (m/s)	Damping ratio (%)
Sandy Silt 1	10.00	20.00	200.00	0.48
Sandy Silt 2	20.00	20.00	300.00	0.48
Sandy Silt 3	10.00	20.00	400.00	0.48
Frozen Soil	11.00	20.00	1500.00	2.20
Gravel	6.00	20.40	450.00	0.50
Weathered Rock (Clay)	9.00	20.40	550.00	2.60

Table 2. Soil characteristics for the stratum without permafrost

A dynamic analysis was performed using twelve earthquake records (Chi Chi, Coyote, Imperial Valley, Kocaeli, Loma Gilroy, Loma Gilroy (2), Mammoth Lake, Nahanni, Northridge, Northridge(2), Parkfield and Whittier Narrows). For details of the records, the reader is directed to the documentation of DEEPSOIL[16].

A comparison of the two soil profiles is hence made based on this analysis. In a first stage, the response of the soil at 5 m depth, i.e. in the first soil layer of sandy silt, is analysed. This corresponds to the buried depth of the pipeline assumed in the initial finite element analysis [9]. The results are hence compared for strain, acceleration and displacement for this depth in the presence or absence of a layer of frozen soil below.

Looking at soil acceleration at 5 m depth for soil with and without permafrost layer below, respectively, an increase between 2.7% and 22.0% with a mean of 9.2% (standard deviation = 0.08) is recorded over the twelve applied ground motions. This difference in soil acceleration at a boundary between two soil profiles could lead to a highly localised difference in demand on a buried pipeline. In Figure 1, an example of the effect of a permafrost layer at 40 m depth on the acceleration time history in the top soil layer for the Parkfield ground motion record is displayed. The figure highlights the effect on the peak acceleration in the top layer of soil due to the presence of permafrost.

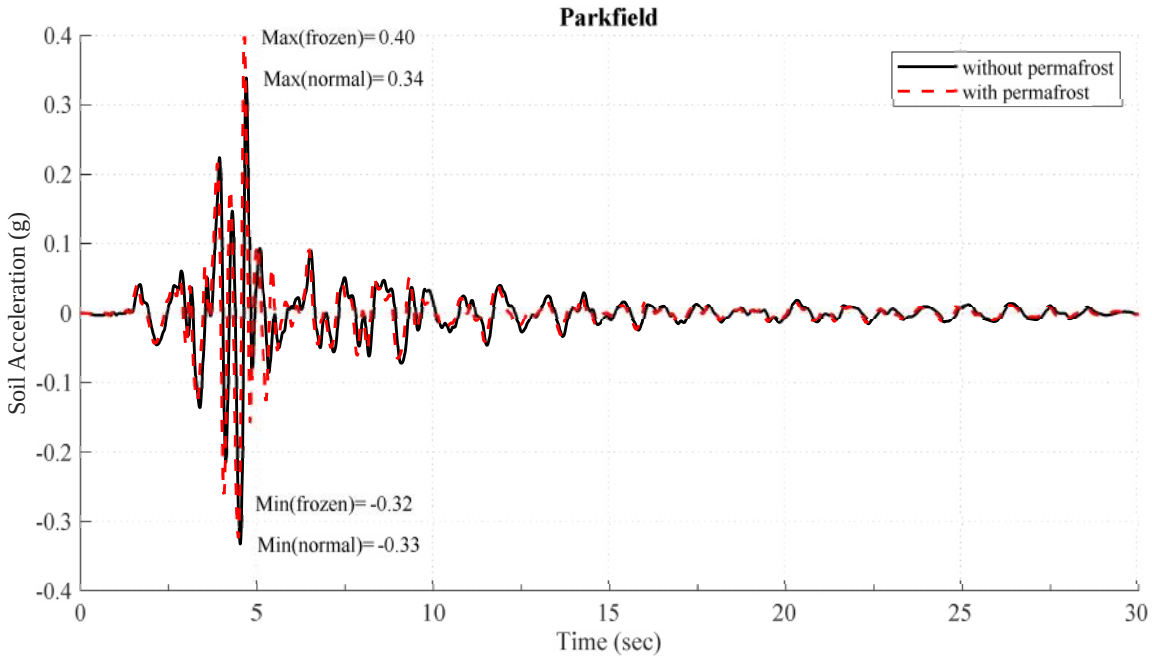

Figure 1. Acceleration - time history at 5m depth for both soil profiles for the Parkfield record

Obtained maximum strain in the top layer of soil and recorded peak ground acceleration for the soil strata are shown in Figure 2. It indicates that higher levels of strain are reached in the soil without permafrost in the strata below. It would hence seem that the presence of permafrost attenuates the strain in the top layer of soil. A similar trend, albeit with more dispersion, can be seen for the maximum soil displacements, shown in Figure 3.

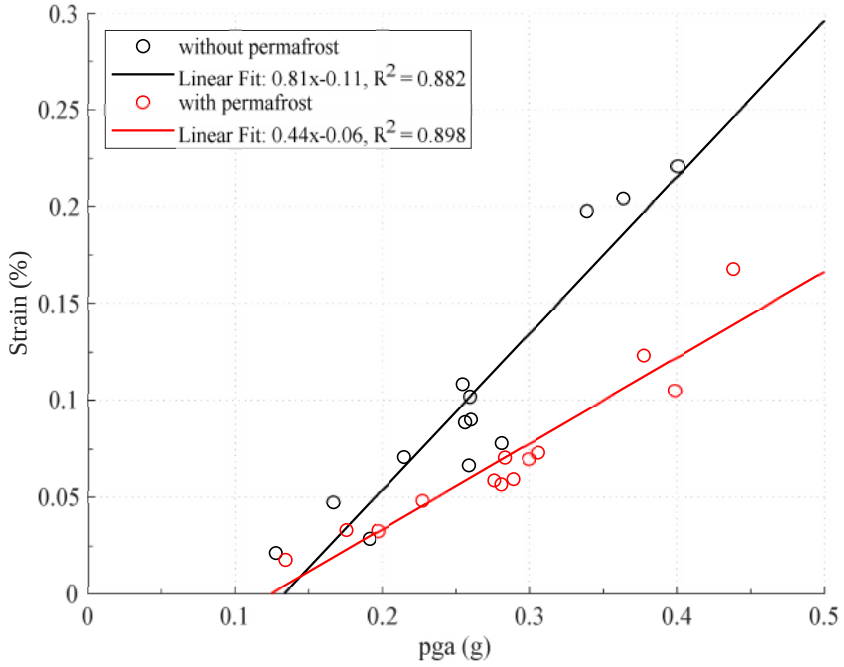

Figure 2. Strain in the first soil layer against pga for all records

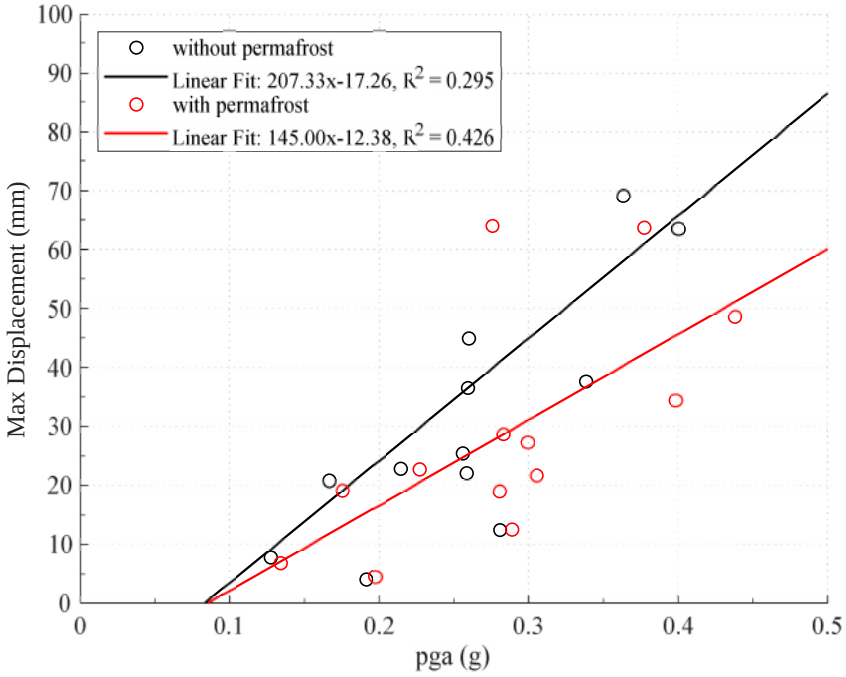

Figure 3. Maximum displacement in the first soil layer against pga for all records

To further investigate of the results, the maximum soil strain and displacement throughout the depth of the two soil profiles is analysed. The results displayed in Figure 4 highlight that in the frozen soil, due to the strong increase in stiffness, a very low maximum strain is obtained, compared to the unfrozen soil. This reduction in strain for the same ground motions is then transferred to the layers, leading to the attenuation in soil strain observed at 5 m depth.

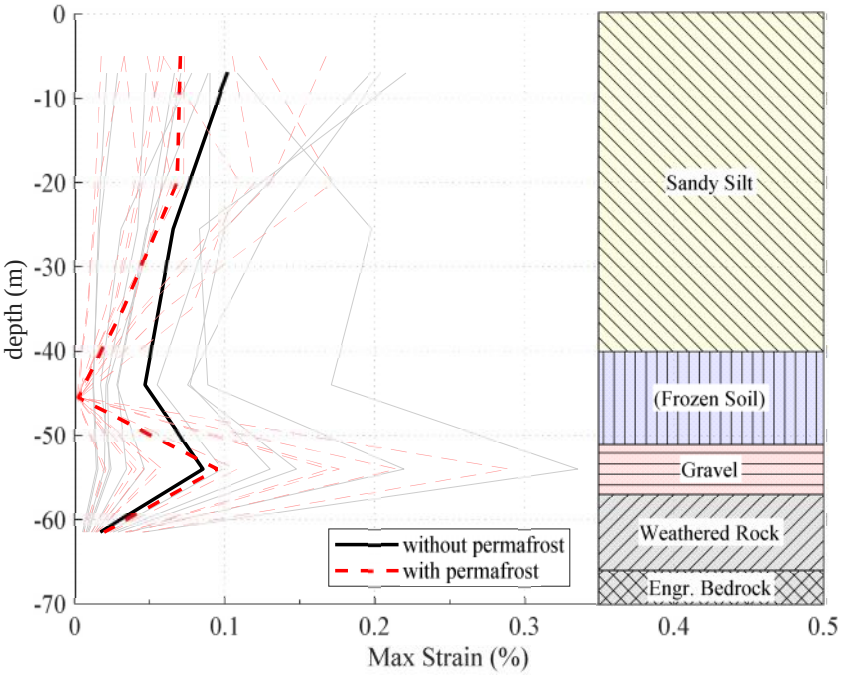

Figure 4. Maximum strain versus depth in the soil profile for all ground motions

For soil displacement, a similar observation can be made, with reduced values observed in the permafrost layer and the layers above it (Figure 5). In both cases, below the frozen soil

layer, the response of gravel and weathered bedrock are not affected by the presence of permafrost. In the top soil layer, i.e. where the pipeline is buried, a reduction of 21% in soil displacement and 31% in soil strain are observed on average for the profile including a layer of permafrost.

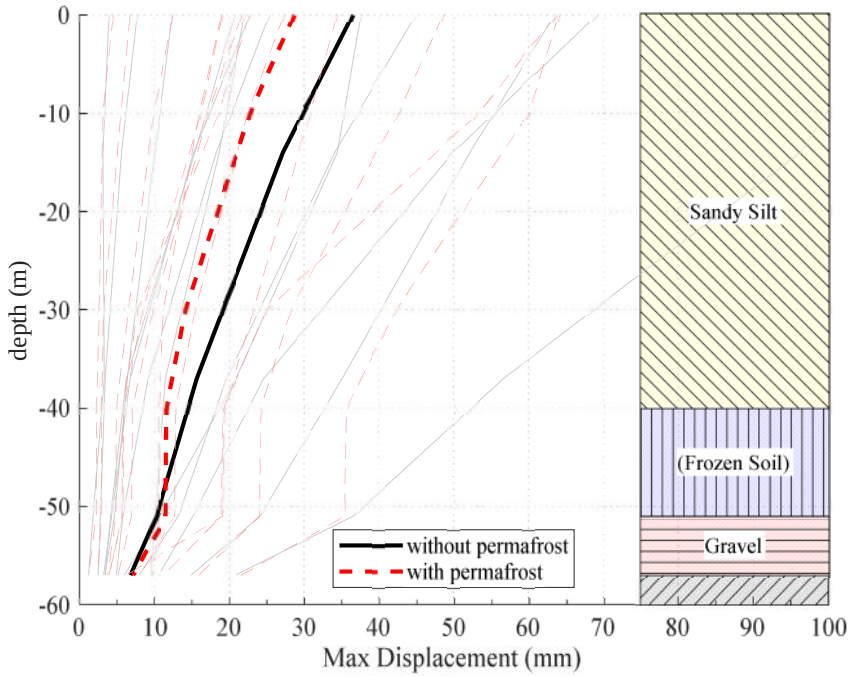

Figure 5. Maximum displacement versus depth in the soil profile for all ground motions

Overall, the results from this initial soil response study are in line with previous studies ([15], [17]) and highlight the difference in behaviour between the two soil profiles under the same earthquake loading. It is important to note, however, that the response is highly dependent on the selection of ground motions and that larger spectral acceleration will amplify this difference.

5 PARAMETRIC FINITE ELEMENT ANALYSIS

In the literature, finite element studies on the seismic behaviour of buried pipelines that assess the relative influence of modelling parameters are rare. Lee [9] undertook a parametric study concentrating on the influence of buried depth, mesh size and pipeline length. In this study, the influence of four model parameters (soil type, soil depth below pipeline, pipeline diameter and mesh size) are assessed individually. These parameters are summarised in Table 3 and are described in more detail in the following section.

Soil Type	Soil depth below pipeline, h' (m)	Pipeline diameter (m)	Mesh size (m)
Saturated sand / Silty sand	10 - 30	0.2 – 0.4	1 – 2 – 4

Table 3. Assessed parameters in the finite element model

A finite element model of a buried pipeline is created in ABAQUS [18]. The pipeline has a diameter of 0.4 m and a wall thickness of 10 mm for all models except for the parametric study of pipeline diameter for which a smaller diameter of 0.2 m and thickness of 5 mm are tested. For all models, this pipeline is buried at a depth of 5 m and has a length of 15 m. The soil surrounding the pipeline is modelled with a width of 10 m and a length of 15 m. The model dimensions are summarized and illustrated in Table 4 and Figure 6, respectively.

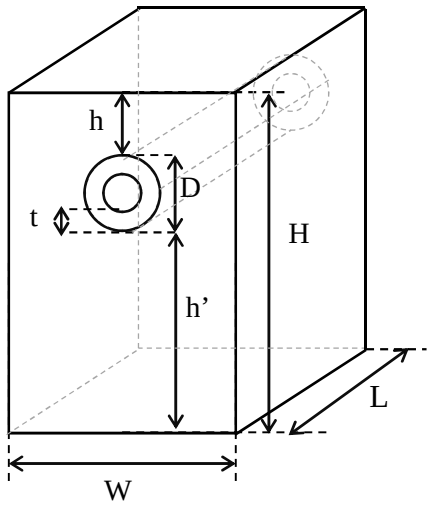

Figure 6. Finite element model dimensions

Dimension	Symbol	Value (m)
Length	L	15
Width	W	10
Total depth	H	15.4 – 35.4
Buried depth	h	5
Depth below	h'	10 – 30
Pipeline diameter	D	0.2 – 0.4
Pipeline wall thickness	t	5 – 10 (mm)

Table 4. Model dimensions summary

The material properties of the pipeline are constant in all models and represent a ductile steel pipeline. The elasto-plastic material properties [9] are shown in Table 5. To model the pipeline, second order reduced integration shell element with eight nodes (S8R) are chosen. The elements have a thickness corresponding to the pipeline wall thickness and a mesh size of 1 m for all models in the parametric study (Figure 7).

Mechanical property	Symbol	Value
Density (kg/m3)	ρ	7850
Young's modulus (GPa)	E	210.7
Poisson's ratio	ν	0.3
Shear modulus (GPa)	G	81.0
Yield strength (MPa)	f_y	490
Yield strain (%)	ε_y	0.23

Table 5. Pipeline elasto-plastic material properties

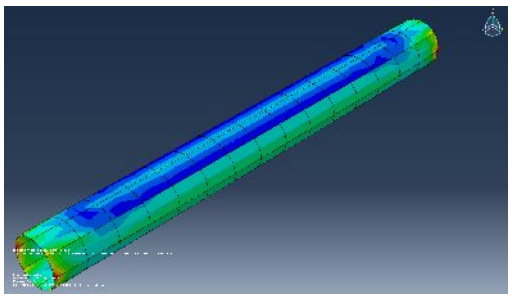

Figure 7. Pipeline finite element model and meshing.

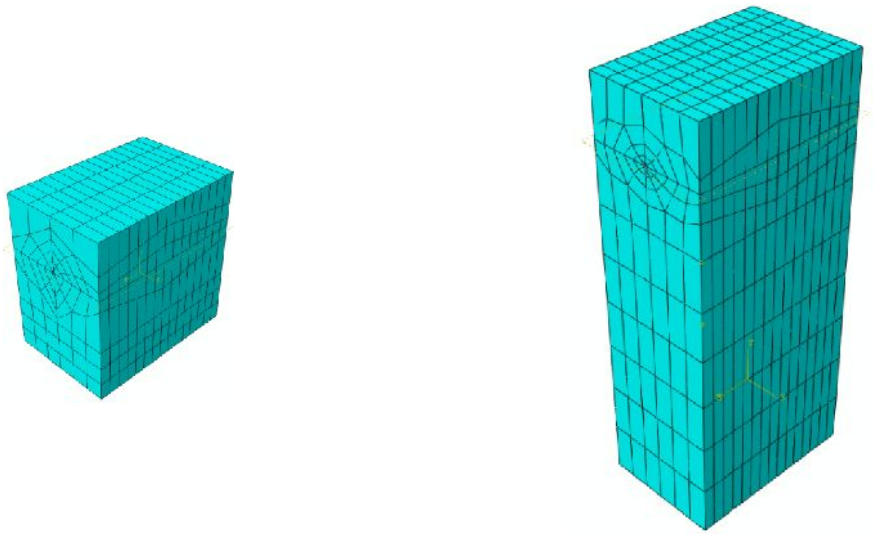
The effect of two different soil types on the seismic performance of the pipeline is assessed. As shown in Table 6, a flexible silty sand material [5], as well as a stiffer saturated sandy material [9] are defined. The materials aim to reflect the material in the top layer of the soil strata defined in the ground response study, as well as a stiffer variant of it. The soil is considered as elasto-plastic material with Mohr-Coulomb plastic properties and is modelled using three-dimensional second order reduced integration brick elements with 20 nodes (C3D20R). The material properties for the soil types are summarised in Table 6.

Type of property	Mechanical property	Symbol	Saturated sandy soil	Silty sand
Elastic	Density (kg/m3)	ρ	2160	2160
	Young's modulus (MPa)	E	96.00	5.00
	Poisson's ratio	ν	0.25	0.35
Mohr-Coulomb	Friction angle (°)	φ	40.00	20.00
	Dilation angle (°)	ψ	2.00	2.00
Cohesion	Cohesive strength (kPa)	c	17.00	10.00

Table 6. Soil properties in finite element model

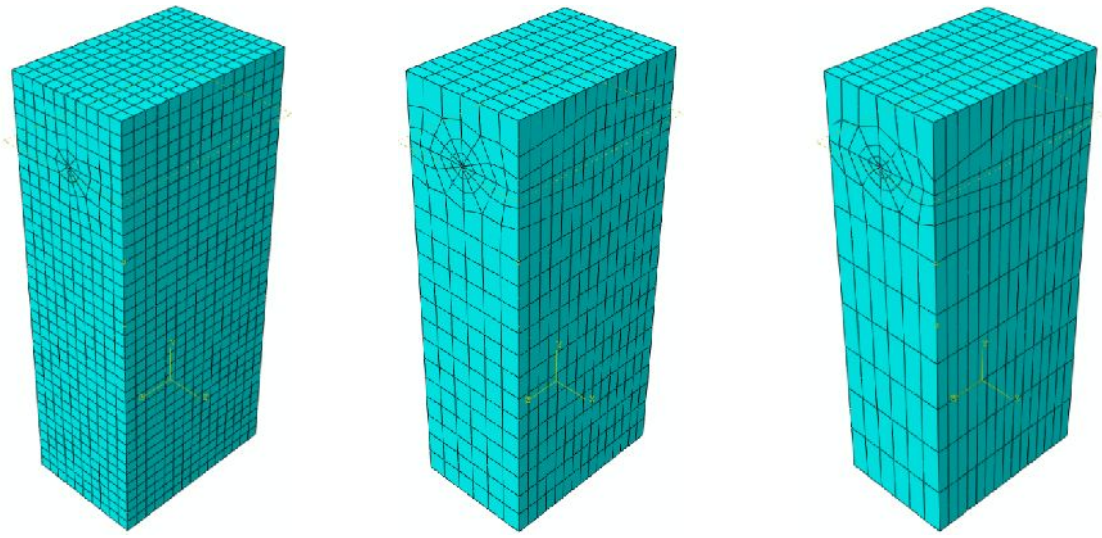
The influence of soil depth below the pipeline is assessed in the parametric study for a constant mesh size (4 m), for a pipeline buried at 5 m in sandy silt, for one earthquake record. The comparison is performed on two soil depths representative of values found in the literature. As shown in Figure 8, these correspond to 15 and 35 m total depth, for the shallow [9] and deep [10] soil models, respectively.



Shallow soil (15m total depth) Deep soil (35 m total depth)

Figure 8. Model geometry with different soil depths

While the mesh size of the pipeline is kept constant at 1 m, a mesh size sensitivity study for the soil surrounding it is conducted, testing the effect of mesh size varying from 1 m to 4 m. The mesh obtained for the three sizes, varying from fine to coarse, for the soil elements are shown for the deeper soil model in Figure 9.



Fine mesh (1 m) Medium coarse (2 m) Coarse mesh (4 m)

Figure 9. Mesh sizes for sensitivity study

The boundary conditions for the model are shown in Figure 10. The base of the soil is fully restrained, while roller supports are put on the side faces (Y-Z planes) of the soil model. The ends (Y-X planes) of the pipeline are also modelled as rollers. The nodes at the interface between soil and pipeline are fully tied.

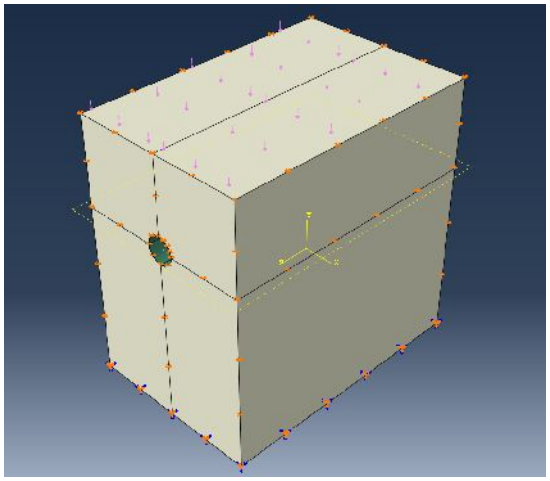


Figure 10. Boundary conditions in finite element model.

For the parametric analysis, an IDA is performed scaling the six sample records for values of pga up to 2.0 g. While this value of pga is large, it is consistent with other studies in the field (e.g.: [19]). The reader is reminded that the purpose of this initial study is the investigation of modelling parameters´ influence, rather than a vulnerability assessment of pipelines. The details of each analysis are reported within the sections focusing on the individual parameters. The seismic load is applied as body force in Abaqus [18]. Before applying the seismic load, a realistic static load is applied in the first step of the analysis. This includes the gravity load and an additional load due to traffic loading applied on the ground surface as a uniformly distributed pressure of 1100 kPa. This corresponds to a total load of 165 000 kN applied on the soil with dimensions of 10 by 15 m.

The seismic behaviour of the pipeline is then assessed by comparing the maximum absolute strain and stress in the longitudinal direction along the axis of the pipeline and the vertical displacement in the pipeline elements at midspan at each step in the IDA.

6 RESULTS

6.1 Mesh sensitivity

As an initial assessment, sensitivity to the mesh size is analysed using the larger diameter pipeline and saturated sandy soil properties. The deeper soil geometry is chosen as the difference in mesh size would be more pronounced for it. The pipeline material and pipeline element mesh size are kept constant. An IDA with pga intensities of 0.25 up to 2.0 g with a step size of 0.25 g are ran and the differences in results for the three mesh sizes are compared.

In particular, mean differences in terms of longitudinal strain ($\Delta\varepsilon$) and vertical displacement ($\Delta\delta$) to the fine mesh for the coarser mesh sizes are reported in Table 7. The differences to the fine meshed model in terms of strain are below 1.7% on average and around 1.0% in terms of displacement.

	Medium mesh	Coarse mesh
$\Delta\varepsilon$	1.68 %	0.21%
$\Delta\delta$	1.04%	1.09%

Table 7. Mesh size sensitivity in terms of strain and vertical displacement

These minor differences in results combined with the reduced computational time for the coarse mesh. On average, one step in the IDA for the coarse mesh size (ca. 1 h per run) is about four times lower than the fine mesh (ca. 4 h). The heavily reduced computational cost hence justifies the use of a 4 m mesh size.

6.2 Influence of pipeline diameter

As a parameter of pipeline geometry, the influence of the pipeline diameter is assessed. Two different diameters (0.4 m and 0.2 m) with different wall thicknesses (10 mm and 5 mm, respectively) are modelled. Note that for both geometries the diameter to thickness ratio (D/t) is kept constant at 40. The ground motions selected for the IDA are scaled with pga intensities ranging from 0.25 to 2.0 g with a step size of 0.25 g. For this comparison, the total soil depth used is 15 m (shallow soil) and the soil material corresponds to the saturated sandy soil.

The results for the applied ground motion records and the average are plotted in Figure 11. It can be observed that for the pipeline with larger diameter, the average longitudinal strain at mid-span is up to 10.8% higher. The average strain values obtained reach 0.13 % for the small diameter pipeline and 0.11% for the larger diameter. In both cases this is below the yield strain of 0.23%.

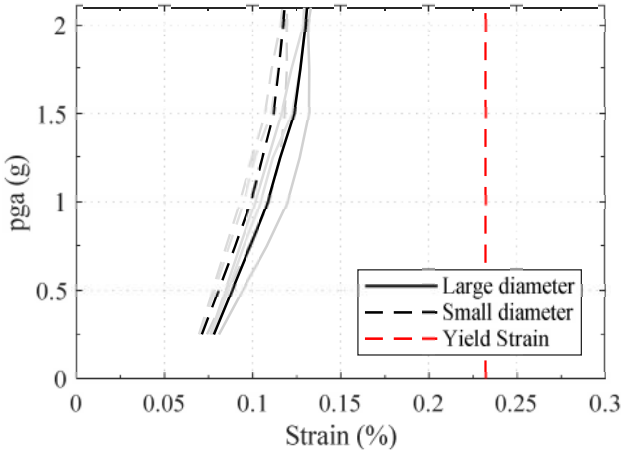

Figure 11. pga against strain comparing the influence of pipeline geometry.

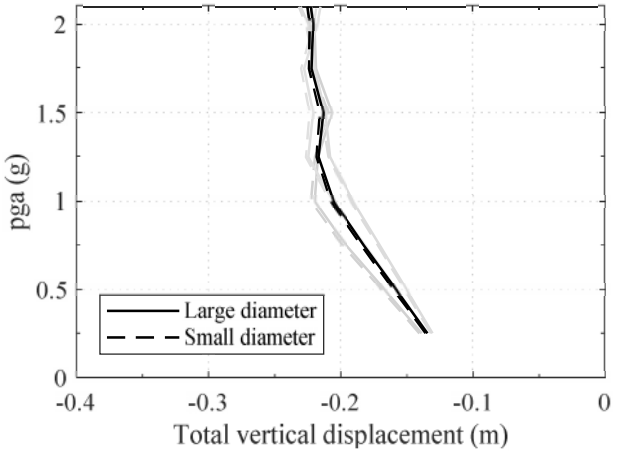

Figure 12. pga against total vertical displacement for two pipeline geometries.

In terms of maximum vertical displacement, for both relatively low values up to -0.22 m are obtained due to the stiffness of the soil (Figure 12). As it would be expected, the pipeline properties do not influence the response of the soil, instead it is expected that the soil geometry and properties, assessed in the next section, are critical parameters.

6.3 Influence of soil depth

Another important point in terms of computational cost is the total model size. This can be heavily reduced by reducing the depth of soil layers below the pipeline. In the literature for similar pipeline dimensions, 10 m to 30 m of soil below the pipeline can be found. To test the influence of this parameter, a constant mesh size of 4 m is selected. The silty soil material deposit of the site response analysis is chosen as soil material, as the influence of soil depth is expected to be highest for softer soils.

In terms of vertical displacement, large displacements for the deep soil model are observed, resulting from the significantly larger accumulated settlement under the imposed traffic load. Removing this contribution, an average difference of 14.2% is obtained between the two models, with the deeper soil presenting larger vertical displacements.

Looking at the maximum strain at mid span in Figure 13, on average there is a 20.2% higher strain in the bottom elements of the pipeline for the shallow soil model. The maximum values of strain obtained exceed the yield strain in the case of the shallow soil at 1.4 g of pga. For analysing the seismic behaviour and fragility of buried pipelines, using the shallower soil geometry seems hence appropriate as it gives more conservative results with higher strain, while simultaneously requiring less computational time (50 mins compared to 90 mins on average).

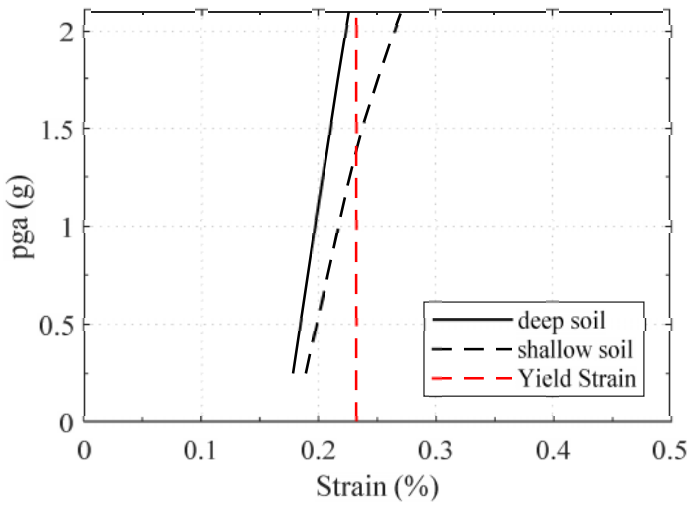

Figure 13. pga against strain comparing the influence of soil depth

6.4 Effect of soil material properties

As the model with shallow soil is deemed most appropriate and coarse mesh size is deemed appropriate for analysis, giving more conservative results and computational efficiency, the influence of material properties is also tested for the shallow geometry. The results for the same pipeline buried in soft silty soil are compared to the saturated sandy soil model.

As shown in Figure 14, the difference in strain is pronounced, with the pipeline reaching yield in the case of the soft silty sand only. The longitudinal strain is more than double the value for the pipeline buried in silty sand compared to saturated sandy soil at the extreme val-

ue of pga of 2.0 g. Strain is increased from maximum values of 0.12% to up to 0.27% in the silty sand (+125%).

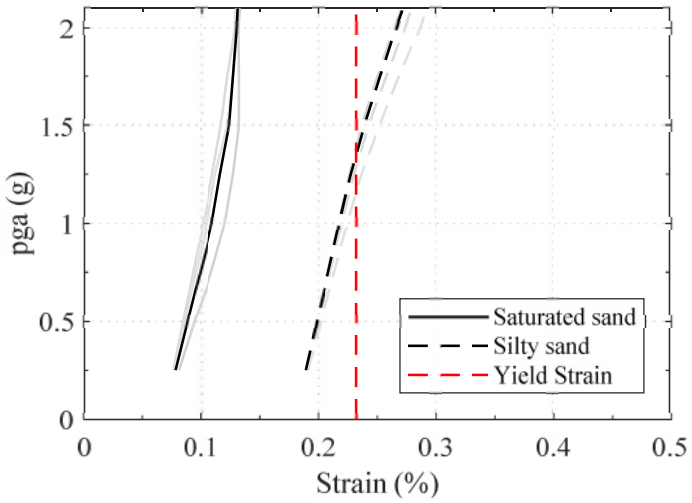

Figure 14. pga against strain comparing the influence of soil stiffness

This observation can be explained by the much larger vertical displacements observed for the softer soil. Even when the settlement under gravity loading is excluded (Figure 15), the vertical displacement is 81% lower for the saturated sand compared to soft silty sand.

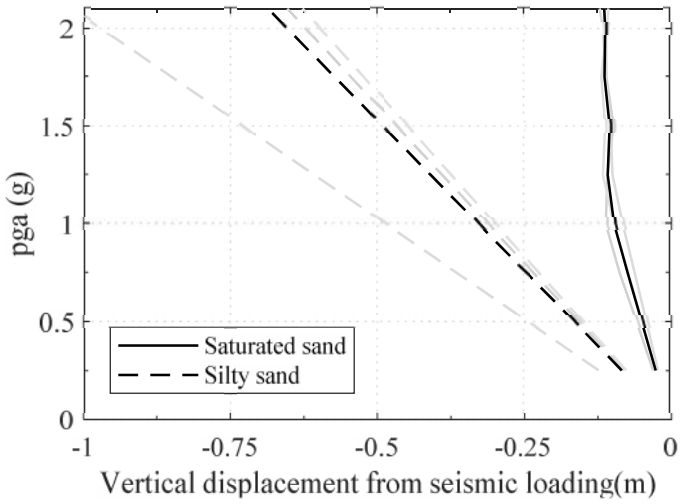

Figure 15. pga vs vertical displacement without gravity load contribution for the comparison of soil types.

Overall it can be concluded that the case of softer soils leads to higher values of strain. The sandy silt material deposit studied in the ground response study hence constitutes an important case study.

6.5 IDA of a pipeline buried in a layer of silty sand

After assessing the influence of different parameters on the behaviour of the model, an incremental dynamic analysis with six records scaled to pga values of 0.25 to 2.0 g in steps of 0.25g is undertaken for a pipeline buried in the soft silty material. This constitutes a case

study of a pipeline buried in a similar soil to the one at the location of ground response study. The effect of underlying permafrost is however not yet considered in this study.

The material properties for silty sand in Table 6 are used for the IDA. The model soil geometry is chosen to be of 15 m total depth (shallow soil), with 10 m of soil beneath pipeline and 5 m buried depth, similar to the model geometry used by Lee [9]. Based on the mesh size sensitivity analysis presented in the previous section, a 4 m mesh for the soil elements is deemed appropriate.

As shown in Figure 16, values of strain up 0.3% are reached, with an average of 0.27% at the highest pga of 2.0 g. On average, plastic strain is reached in the pipelines at a pga of 1.4 g. Plastic behaviour is hence observed for the pipeline after this level of pga, as shown in Figure 17.

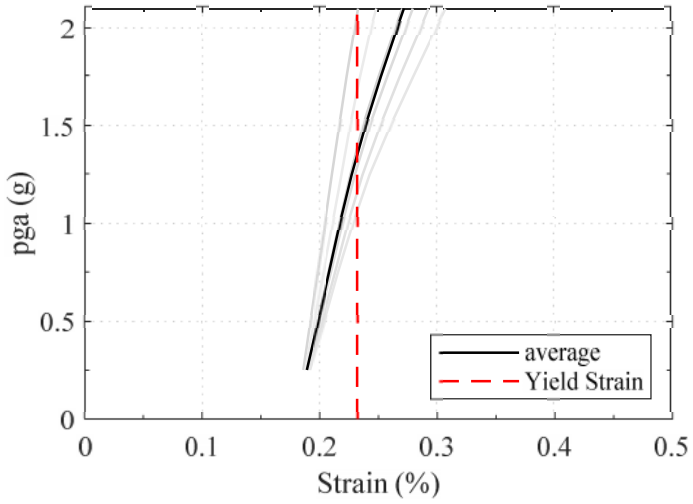

Figure 16. pga against strain for the case study pipeline buried in layer of silty sand

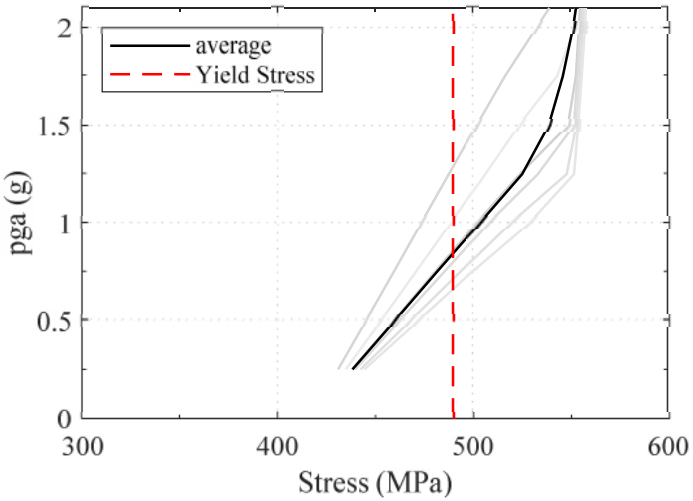

Figure 17. pga against strain for the case study pipeline buried in layer of silty sand

It is worth noting that the ground response study on the soil strata with and without underlying permafrost suggests a differential acceleration history along the length of the pipeline, which is not investigated here. Larger values of strain at the interface of the two soil strata

would be expected. In this case, which may lead to reaching yield at lower values of pga then the ones reported here. This constitutes an important factor to be analysed in future studies.

7 CONCLUSIONS

This paper discussed the modelling parameters of influence for buried natural gas pipelines crossing seismic regions with underlying irregular permafrost soil layers. An initial soil response study for a site in Alaska shows results in line with previous studies ([15], [17]). The study highlights the difference in behaviour between two soil profiles, with and without underlying permafrost, under the same earthquake records applied. The soil acceleration at 5 m depth is increased by up to 22%, resulting in a change in response of the buried pipeline. This is particularly remarkable given the depth of the permafrost layer, still influencing the relatively shallow depth of the buried pipeline. These findings are however not general and are highly dependent on the spectral accelerations of the selected ground motion at the natural frequencies of the soil strata.

A parametric finite element study is then conducted to assess the influence of various modelling parameters on the results of incremental dynamic analyses carried out on a model of the buried pipeline and the surrounding soil layer.

It is found that parameters such as mesh size and soil geometry selected to render the most computationally efficient models will render more conservative results. An increase in soil element mesh size from 1 m to 4 m is only found to affect the results in terms of maximum strain in the pipeline by 1.7%. A larger depth of surrounding soil in the model has a more pronounced effect, increasing the relative displacement in the pipeline soil layer by an average of 14.7%. The increased strain in the pipeline for the smaller soil depth, however, justifies the conservative use of the more computationally efficient parameters. The results are most influenced by the type of soil in which the pipeline is buried, as reduced stiffness of the soil will enhance the strain in the pipeline, with maximum strain results for a softer silty sand more than double of the ones obtained for a pipeline buried in a stiffer material.

The next steps of the study could hence bring interesting results when looking at the response of pipelines to vertically propagating waves at the boundary of two different soil profiles, such as the ones investigated in the ground response analysis. It is anticipated that the different soil response along the length of the pipeline would lead to higher strains in the pipeline than anticipated when only assessing the pipeline for the two soil strata individually, as it is usually done at the design stage.

Abstract

In earthquake analyses, usually the input seismic acceleration is applied at the underlying bedrock. Seismic displacement along a slip surface for given motion, depends on the dynamic response of the soil profile above the bedrock, both above and below the slip surface. In addition, the seismic displacement is affected by the rotation of the sliding mass with displacement towards a gentler configuration. Furthermore, the response of the soil profile is non-linear. Ordinary finite element methods cannot be applied in the cases where the seismic displacement along slip surfaces is larger than a few meters and no reliable cost-effective method simulating all the above effects was found in the bibliography. In the present work a new cost-effective method predicting the seismic displacement of dry slopes along a slip surface with constant shear resistance is proposed. For this purpose, state-of the-art equations modeling (a) the coupled dynamic response of soils with slippage, (b) the non-linear soil response at the dry soil medium and (c) the rotation of the sliding mass effect are combined in a unique manner. The new method implemented in an excel worksheet and applied at both the linear and non-linear cases.

Keywords: slopes, sliding-block model, dynamic response, seismic displacement, constitutive modeling, slip surface, coupled analyses, slopes.

1 INTRODUCTION

Simplified models predicting the seismic displacement of slopes [1, 2, 3] are less accurate than elaborate continuum numerical methods, but have the advantage of simplicity, which makes them usable by practicing engineers. In addition they are well-suited for extensive parametric analyses, often-needed in geotechnical earthquake engineering as soil properties and applied motions are often not known with certainty. Furthermore, they have the advantage that they can predict displacement of tens of centimeters along slip surfaces in a cost-effective numerically stable manner, something that ordinary finite element methods cannot achieve. Thus, development of simplified models predicting the seismic displacement of slopes, such as the one presented in this paper, is appropriate.

The "conventional" sliding-block model with a Mohr-Coulomb strength law [2] is the most commonly used simplified model predicting the seismic displacement of slopes for given earthquake motions [3]. As illustrated in Fig. 1a, a rigid block rests on an inclined plane. The resistance along the block-inclined plane boundary follows the Mohr-Coulomb law. Critical acceleration is the minimum horizontal acceleration which causes movement of the block. Every time where the applied horizontal acceleration is larger than the critical acceleration, the block slides. The total displacement is obtained by the addition of the partial slips. This model is used for the prediction of permanent seismic movement of slopes along a predefined slip surface, by appropriately selecting the equivalent critical and applied acceleration values of the rigid block [2, 3].

The "conventional" sliding-block model simulates the basic mechanism of the generation of seismic displacement along slip surfaces. However, it is not accurate in some cases, primarily because of (a) the dynamic response of the sliding mass and the soil profile below the sliding mass [4-7], (b) the degradation of the shear modulus along the soil profile with shear strain [6], (c) changes of the geometry of the sliding mass towards a gentler inclination [8-15], and (d) the loss of strength in the slip surface with permanent shear displacement [16,17].

Improvements have been proposed and applied in the conventional sliding-block model to simulate the effects (a)-(d), described above. In particular, regarding effect (a) above, Lin and Whitman [4] studied the dynamic response of both the sliding mass and the soil below using a lumped-mass linear system. As illustrated in Fig. 1b, only shear deformations are considered and the flexible parts of the actual system were represented by linear springs and dashpots. At one elevation, there is a sliding element, with a rigid massless plate just above it. This sliding element is rigid-plastic, and can slip in one direction only so as to simulate behavior of the conventional sliding-block model described above. On the other hand, as illustrated in Fig 1c, Rathje and Bray [5] used a generalized Single Degree of Freedom (SDOF) system with the mass and stiffness distributed along the height of the system above a sliding element. The analysis procedure proposed by Chopra and Zhang [18] who model the response of the sliding mass by considering only the fundamental vibration mode is used with a mode shape appropriate for a horizontal soil deposit.

The above formulations (a) are linear. It is well-known that soil behaves linearly only at very small shear strains, well below the typical shear strains exerted under severe earthquakes. Non-linear response has been predicted by different models, ranging form non-linear elastic to truly elasto-plastic. Elasto-plastic models which predict the response of soil at both small and large shear strains which occur under failure under general stress conditions have recently been proposed and validated [19, 20, 21]. Regarding effect (b) above, according to the definition of the problem, (i) the constitutive model must be in terms of shear stress, and not in terms of the principal stresses and (ii) along the soil profile, and not at slip element, failure does not occur and only the degradation of the shear modulus with shear strain must be mod-

eled under the dry case. Papadimitriou et al [19] proposed and validated a model simulating the pre-failure decrease of the shear modulus with shear strain.

The effect (c) above is the usual state in slides in the field, and is caused by the law of physical equilibrium where masses move towards a more stable configuration. It has been modeled in an approximate way by Stamatopoulos [8] using a chain sliding in different planes (Fig 1d), by a multi-block model [10, 13, 15], as well as by other methods [9, 11, 12, 14]. It is considerable when the seismic displacement larger than a few centimeters and when the slip surface is smaller than about 50 meters [13]. The empirical expression proposed by [8] simulating the decrease in the critical acceleration in terms of the shear displacement along the sliding mass was used in a previous dynamic sliding-block model by Jafarian and Lashgari [7].

The effect (d) above is important when considerable post-failure strain softening exists along slip surfaces, especially in saturated soils. It is beyond the present work to study it.

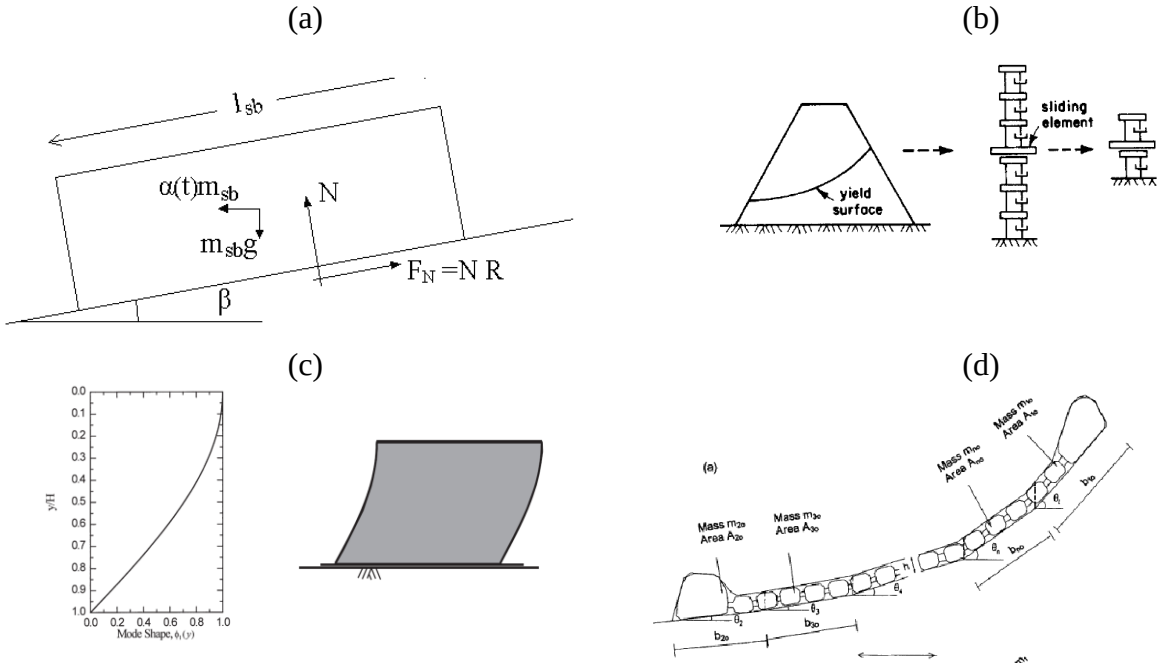

Figure 1: (a) A block sliding in an inclined plane (the "conventional" sliding-block model), (b) the discrete dynamic system considered by Lin and Whitman [4], (c) the continuous dynamic system considered by Rathje and Bray [5] and (d) the sliding system considered by Stamatopoulos [8] to simulate the effect of rotation of the sliding mass on the seismic displacement.

The purpose of the present work is to propose, derive and apply a cost-effective method predicting the seismic displacement along slip surfaces with constant shear resistance of dry slopes, by considering all the above effects (a)-(c) simultaneously. Regarding effect (a), only shear waves propagating vertically are considered. In earthquake analyses, usually the input seismic acceleration corresponds at the underlying bedrock. In addition, according to Eurocode [22] in seismic analysis the soil profile until 30m depth is considered. Furthermore, the slip surface usually is at a depth less than that of the bedrock, or the 30m depth limit of suggested by Eurocode. For these reasons, the actual dynamic soil response both above, and below the slip surface must be simulated. Thus, the applied formulation must be similar to that of Lin and Whitman [4]. Yet, unlike their formulation, the state-of-the art method predict-

ing the mass, stiffness and damping assuming the first node of a continuous mass system proposed by Rathje and Bray [5], described above, is used.

Regarding effect (b) above, an expression proposed by Papadimitriou et al [19] to simulate the pre-failure decrease of the shear modulus with shear strain in the soil profile will be used. The reason is that this relation has been validated against laboratory test results and requires a minimum number of parameters.

Regarding effect (c) above, similarly to the dynamic method of Jafarian and Lashgari [7], the empirical expression proposed by [8] is used to simulate the increase in the critical acceleration in terms of the shear displacement of the sliding mass. The reason is that this method simulates directly and cost-effectively the effect of rotation of the sliding mass in dynamic sliding-block analyses.

The paper first gives the proposed model predicting the non-linear sliding dynamic response of slopes. Following that, it discusses the proposed model and the constitutive equations associated with the model. Then, it describes the numerical implementation of the proposed model and applies it in order to illustrate the manner that different parameters affect the seismic displacement.

2 PROPOSED EQUATION SIMULATING THE NON-LINEAR SLIDING DYNAMIC RESPONSE OF SLOPES

2.1 Simulation of sliding dynamic response

As shown in Fig. 2a, the present work models a slope with a slip surface as a continuous dynamic system of height (h_1+h_2) separated by a horizontal slip element at height h_2 above its base. Only horizontal acceleration is applied at the base of the lower body and above and below the slip element different properties exist. Thus, the system is divided in two non-linear elastic bodies. The index "1" is used for the upper body and the index "2" is used for the lower body. The upper body and lower bodies have mass m_i, tangent shear modulus $G_{t\text{-}i}$, viscous material damping ratio λ_i, and density ρ_i where i takes the values 1 and 2 for bodies 1 and 2 respectively. The two bodies move a horizontal distance x_i, velocity x'_i and acceleration x''_i, where i takes the values 1 and 2 for bodies 1 and 2 respectively

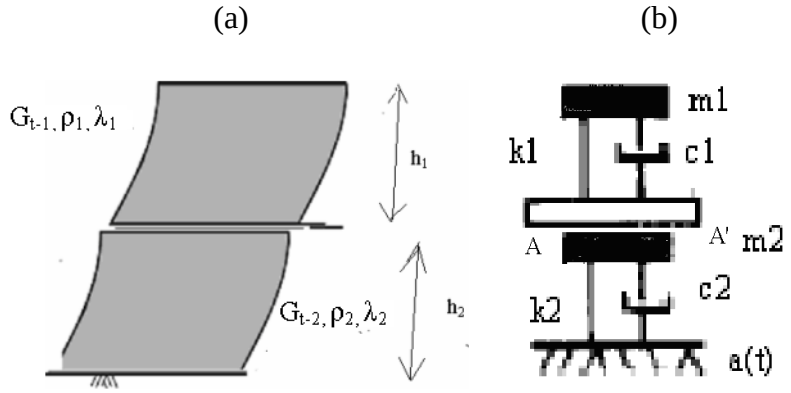

Figure 2: (a) Continuous system dynamic system considered in the present work, (c) the assumed discrete dynamic system approximation.

Fig. 2b gives the assumed equivalent discrete 2-body dynamic system with slip element approximation of the continuous system of Fig. 2a. If no slippage at the slip surface occurs, the equation of motion of the 2-body system of Fig 1b is:

$$m_1 x_1'' = m_{ef-1} \times a(t) + k_1(t)[x_1 - x_2] + c_1(t)[x_1' - x_2'] \tag{1a}$$

$$m_2 x_2'' = m_{ef-2} \times a(t) - k_1(t)[x_1 - x_2] - c_1(t)[x_1' - x_2'] - c_1(t)[x_1' - x_2'] + k_2(t)x_2 + c_2(t)x_2'$$

where

$$m_i = \frac{\rho_i \times h_i}{2} \tag{1b}$$

$$m_{ef-i} = \frac{2 \times \rho_t \times h_i}{\pi}$$

$$k_i(t) = \frac{\pi^2 \times m_i \times G_{t-i}(t)}{4 \times h_i^2 \times \rho_t}$$

$$c_i(t) = \frac{\pi \times m_i \times \lambda_i}{h_i} \sqrt{\frac{G_{t-i}(t)}{\rho_t}}$$

where a(t) is the applied acceleration in the base of the system in terms of time t, $k_i(t)$ and $c_i(t)$ are the viscous damping and spring stiffness coefficients of bodies 1 and 2, in terms of time t, m_i are the masses of bodies 1 and 2 and m_i are the equivalent masses of bodies 1 and 2 where the inertia acceleration is applied.

The above system can be expressed in matrix form as

$$\begin{bmatrix} m_1 & 0 \\ 0 & m_2 \end{bmatrix} \begin{bmatrix} x''_1 \\ x''_2 \end{bmatrix} = \begin{bmatrix} k_1(t) & -k_1(t) \\ -k_1(t) & k_1(t)+k_2(t) \end{bmatrix} \begin{bmatrix} x_1 \\ x_2 \end{bmatrix} + \begin{bmatrix} c_1(t) & -c_1(t) \\ -c_1(t) & c_1(t)+c_2(t) \end{bmatrix} \begin{bmatrix} x'_1 \\ x'_2 \end{bmatrix} - a(t) \begin{bmatrix} m_{ef-1} \\ m_{ef-2} \end{bmatrix} \tag{2}$$

Also, non-linear elasticity and the geometry of Fig. 2b predicts that for any incremental change in horizontal displacement of the two bodies (dx_1, dx_2) the corresponding incremental change in shear stress at time t ($d\tau_1$, $d\tau_2$) at the two bodies equals

$$d\tau_1 = G_{t-1}(t)\frac{dx_1 - dx_2}{h_1} \tag{3a}$$

$$d\tau_2 = G_{t-2}(t)\frac{dx_2}{h_2} \tag{3b}$$

Sliding at the slip element of Fig. 2b occurs when

$$-a_c(t) - \frac{m_{ef-1}}{m_1} x_1'' - a(t) > 0 \tag{4a}$$

where $a_c(t)$ is the horizontal acceleration for relative displacement of the slip element, in terms of time. In particular, the effect of rotation of the sliding mass above the slip surface is simulated by increasing the critical acceleration of the slip element with the distance moved along the slip element (u) as:

$$a_c(t) = a_{co} + 11\frac{u}{L} \tag{4b}$$

where a_{co} is the critical acceleration at u=0 and L is the slip length.

Sliding in only one direction is assumed and the governing equation of motion at the slip element is

$$u'' = -a_c(t) - \frac{m_{ef-1}}{m_1} x_1'' - a(t) = -a_c(t) - 0.64x_1'' - a(t) \qquad \text{for} \quad u' > 0 \qquad (5)$$

where u'' and u' is the relative acceleration and velocity along the slip element.

During sliding, the two bodies move separately. The equations of motion for the upper and lower masses become:

$$m_1 x_1'' + c_1(t)x_1' + k_1(t)x_1 = -m_{ef-1}[a(t) + u''(t)] \qquad (6)$$

$$m_2 x_2'' + c_2(t)x_2' + k_2(t)x_2 = -m_{ef-2}a(t) - u''(t)m_{ef-1} \qquad (7)$$

Sliding stops when the relative velocity of the slip element (u') becomes zero. Then, again equations (1) hold.

The above solution is, according to the terminology used by [4,5], is "coupled". On the other hand, in the approximate "decoupled" case, separation of the two bodies is not simulated and equations (6), (7) are not applied. Furthermore, for the rigid conventional sliding-block case, the above equations do not hold: sliding occurs when

$$-a_c(t) - a(t) > 0 \qquad (8a)$$

and the governing equation of motion at the slip element is

$$u'' = -a_c(t) - a(t) \qquad \text{for} \quad u' > 0 \qquad (8b)$$

It should be noted that in equations (7) the critical acceleration for relative motion is expressed in terms of $a_c(t)$, and thus the effect of rotation of the sliding mass above the slip surface is simulated by equation (3b).

2.2 Constitutive modeling of the soil profile in the non-linear case

For the non-linear case, at the soil profile bodies i (i=1,2), the tangent shear modulus G_{t-i} is estimated as:

$$G_{t-i}(t) = \frac{G_{o-i}}{T_i(t)} \qquad (9a)$$

where

$$G_{o-i} = Vs_i^{\,2}\rho_t \qquad (9b)$$

$$T_i(t) = 1 + \left(\frac{1}{a_i} - 1\right)\left|\frac{\tau_t(t) - \tau_{o-t}(t)}{b_i}\right| \qquad (9c)$$

where $G_{o\text{-}i}$ and Vs_i are the shear modulus and shear wave velocity respectively at very small shear strain, a_i and b_i are model parameters and $\tau_i(t)$ and $\tau_{o\text{-}i}(t)$ is the shear stress and the shear stress of the last stress reversal at time t of body i.

3 DISCUSSION OF THE PROPOSED EQUATIONS

Based on the discussion in section 1 above, equations (1b), (4a), (5) are identical to those used by Rathje and Bray [5] and the form of equations (1a), (6) and (7) is similar to those used by Lin and Whitman [4]. In addition, equation (4b) has been used by Jafarian and Lashgari [7].

The constitutive model equations (9) predicting shear modulus degradation along of the body above and below the slip element are similar to those proposed by Papadimitriou et al. [19], but adjusted for the dry simpler case. The state-of-art work by Vucetic and Dobry [23], indicates that the decrease of the shear modulus with the shear strain depends as a first approximation only on the Plastisity Index (PI) of the soil, as illustrated in Fig. 2a. In equations (8), the model parameters a_i specifies the Gs/Gmax ratio where the shear stress-degradation response is fitted, and the model parameter b_i fits the value of the actual response at a_i. A typical value of a_i for the problem considered is 0.5. Assuming ηa=0.5, for the simulation of Fig. 3a, β_i must vary in terms of only Go and PI. Assuming that ρ=2T/m^3, numerical simulations illustrated that typical values for sands are 1, 0.1, 0.02 for Vs = 100, 250, 500 m/s.

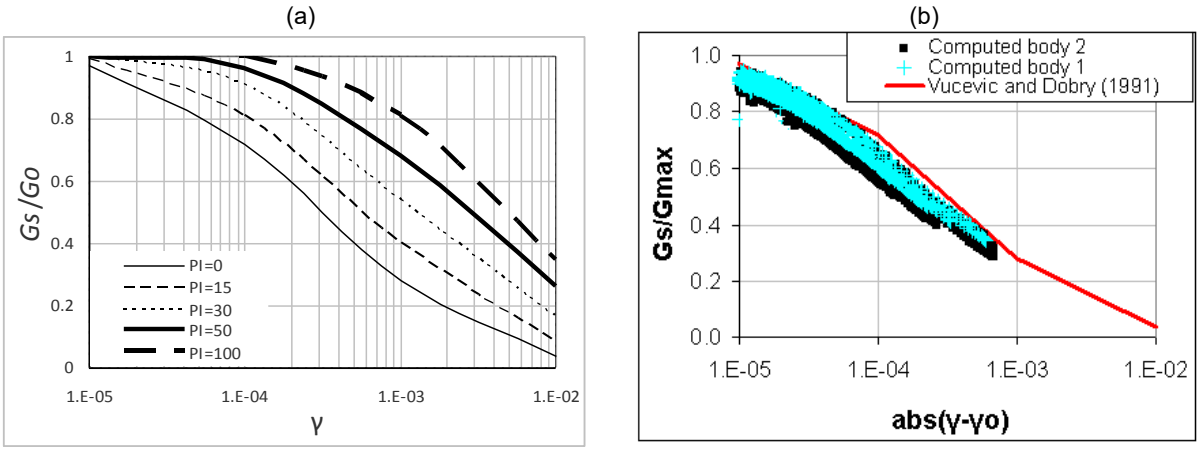

Figure 3: (a) State-of the art shear modulus degradation in terms of shear strain (γ) and Plasticity Index (PI) [23]. (b) simulation for this degradation for the case studied in section 4.1.

4 NUMERICAL IMPLEMENTATION AND APPLICATION

4.1 Numerical implementation

Equations (1)-(6), (8) and (9) simulating the non-linear dynamic response of a 2-body system with a slip element with constant strength were solved numerically using the Newmark method with its parameters β and γ taking the values of 0.25 and 0.50 respectively.

The linear case corresponds to a_1=a_2=1. For the linear case, input at the numerical code is the seismic acceleration history, the critical acceleration a_{co} and the variables h_i, Vs_i, ρ_i, λ_i. Output includes the acceleration time history of the two bodies for the coupled and decoupled cases and the acceleration, velocity and displacement history along the slip element for the coupled, decoupled and rigid cases. For the non-linear dry case, additionally, the val-

ues of the parameters a_i and b_i are needed. Additional output of the program in this case is (a) the tangent shear moduli of bodies 1 and 2 versus time, (b) the shear stress-strain response of the two bodies and the (c) the secant modulus degradation with shear strain of the two bodies.

Figures 4 and 3b give typical output results of the proposed method. The case of non-linear sandy soil with $h_1=h_2=15$m, $Vs_1=200$m/s, $Vs_2=300$m/s, $\rho_1=\rho_2=2$t/m^3, $\lambda_1=\lambda_2=0.15$, under the Aegion 1995 earthquake input motion and slip surface with $a_{c0}=0.5$m/s^2 and, L=100m and model parameters $a_1=\alpha_2=0.5$, $\beta_1=\beta_2=1$ is presented.

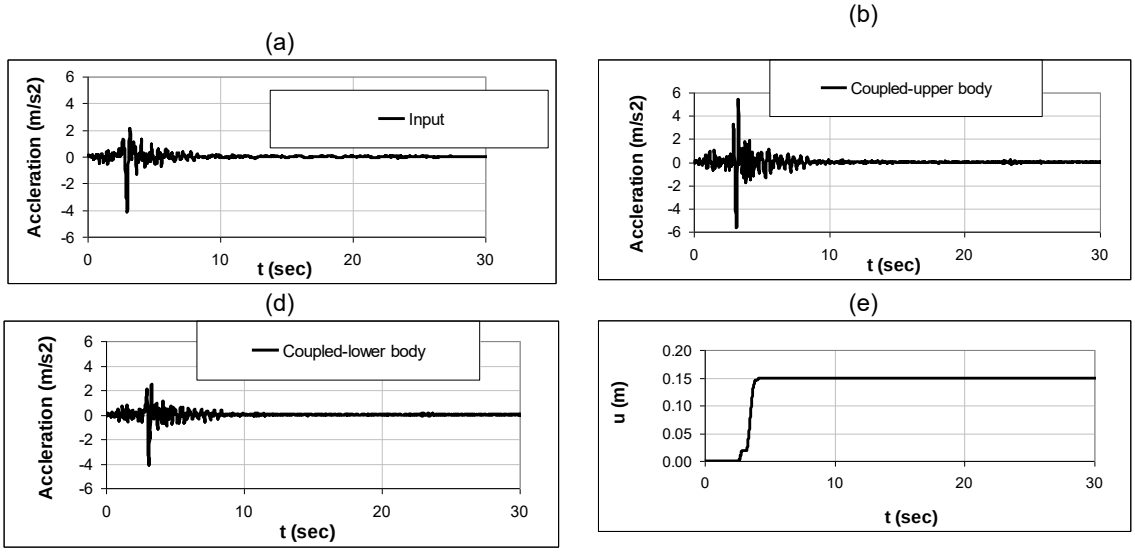

Figure 4: Typical results of the proposed method. The case of non-linear sandy soil with $h_1=h_2=15$m, $Vs_1=200$m/s, $Vs_2=300$m/s, $\rho_1=\rho_2=2$t/m^3, $\lambda_1=\lambda_2=0.15$, under the Aegion 1995 earthquake input motion and slip surface with $a_{c0}=0.5$m/s^2, L=100m and model parameters $a_1=\alpha_2=0.5$, $\beta_1=\beta_2=1$. (a) input acceleration history, (b),(c) acceleration histories of bodies 1 and 2, (d) seismic displacement along the slip surface versus time.

4.2 Example applications

Limited parametric analyses of the new model were performed to investigate critical factors affecting the final seismic displacement along the slip surface (u_f). In these analyses, the depth of rock (h_1+h_2) was taken as 30m, because this is the maximum depth which affects the results according to Eurocode [22]. In addition, for the density value, which does not affect considerably the dynamic soil response, the typical value of $\rho_1=\rho_2=2$t/m^3 was selected. Furthermore, the damping $\lambda_1=\lambda_2$ was taken as 15%, similarly to analyses by [5, 7]. Regarding the applied input motions, the Aegion 1995 earthquake input motion was used. Its characteristics are: Maximum acceleration (a_{max})=2.1(m/s^2), Predominant Period=0.42s, Mean Period (Tm)=0.62s, Magnitude (Ms)=6.1. It was selected because it is a typical European medium-magnitude motion.

In linear analyses, in order to define the proposed dynamic system, in addition to the parameters specified in the above paragraph, a_{co}, Vs_1, Vs_2, h_1 (or h_2) and L must be specified. The critical acceleration a_{co} was selected as 0.5m/s^2, because it corresponds for a rigid system to a seismic displacement of about 10cm, which is the tolerable displacement value for typical structures. Regarding the slip length L, first the case L=1000m was selected, because it corresponds to a large landslide where the effect of the rotation of the sliding mass does not play an important role. Then, the case of L=10m, because it corresponds to a landslide of very small slip length where the effect of the rotation of the sliding is critical even when the seismic displacement is a few centimeters. Similarly to the previous works [5, 7], the seismic displace-

ment is presented in terms of a_{co} and the Ts_1/Tm ratio, where Tm was defined above and Ts_1 is the fundamental period of the upper body of the system which slides, which equals

$$T_{S1} = \frac{4h_1}{Vs_i} \tag{10}$$

Figs 5a-c present the results of elastic parametric dynamic analyses described above. In particular, in Fig 4a the case with $Vs_2=Vs_1$ and $h_2=15$m is given. The rigid and decoupled case solutions, as well as the case of L=10m are given for comparison. In Fig 5b the case with $Vs_2=Vs_1$ and $h_2=1$m, 15m, 25m is presented. In Fig 5c the case with $Vs_2=150$, 300 or 500m/s and $h_1=h_2=15$m is presented. Fig. 6 presents the seismic displacement in terms of a_{co} for the case of $h_2=15$m, $Vs_1=Vs_2=200$m/s for L=1000m and L=10m for the Aegion 1995 earthquake. Fig. 6 also presents the seismic displacement in terms of L for $a_{co}=0.1$m/s^2 for the Aegion 1995 earthquake. In Fig. 6, in all cases the decoupled and rigid cases are also given for comparison.

The cases above do not simulate the decrease of shear modulus with shear strain, which is considerable, especially for sandy loose soils and high intensity input motions. Fig. 4d illustrates the effect of non-linearity of the soil profile on seismic displacement versus Ts_1/Tm for the case of Fig. 5d with $h_2=15$m, $Vs_1=Vs_2=$ 200m/s, $\rho_1=\rho_2=2$t/m^3, $\lambda_1=\lambda_2=0.15$, L=1000m, $a_1=\alpha_2=0.5$, $\beta_1=\beta_2=1$.

5 DISCUSSION

5.1 Interpretation

First the results of the linear analyses of section 4 are considered and the following can be observed:

(a) Regarding the response of u_f versus Ts_1/Tm, similarly to [5, 7]: (i) for $Ts_1/Tm=0$, u_f corresponds to the seismic displacement of the rigid case, (ii) as Ts_1/Tm increases, u_f increases until a peak value is reached, (iii) as Ts_1/Tm increases further, u_f decreases until if becomes zero and (iv), the coupled (and correct) solution gives u_f values less than the decoupled solution for most Ts_1/Tm values and, especially for Ts_1/Tm values, near unity.

(b) Regarding the effect of the stiffness soil layer below the slip surface, which has not been studied in detail by previous researchers, it changes significantly uf: For example Fig 5c illustrates that for $Vs_1=Vs_2$ and $Ts_1/Tm=1$, as h_2 varies, u_f changes from 0 to 0.20m and Fig 5b illustrates that for $h_1=h_2=15$m and $Ts_1/Tm=0.5$, as Vs_2 varies, u_f changes from 0.15 to 0.25m.

(c) Regarding the response of u_f versus a_{co}, similarly to [3] u_f decreases as aco increases, approximately, in a logarithmic manner. The dynamic response plays an important role for small seismic displacement and diminishes for very large seismic displacement (>1m).

Regarding the effect of rotation of the slip surface on u_f, similarly to [8], it is considerable for L values less than about 100m and uf values larger than about 0.1m.

Regarding the effects of non-linearity, Fig. 5d illustrates that the u_f versus Ts_1/Tm results are shifted to the left. This can be interpreted by the fact that as shear strain increases, the shear modulus decreases, and thus the effective Ts_1/Tm increases.

5.2 Possible applications and improvements/extensions

The parametric analyses illustrated that the proposed method simulates all critical factors affecting the seismic displacement of dry slopes, where the shear resistance along the slip surface does not change considerably with shear displacement. A typical case where this occurs

is the case of dry loose sandy soils. It would be interest to validate the model predictions against well-documented landslides on this type. Furthermore, the proposed method may be extended for the cases of (a) saturated soil profiles and (b) saturated surfaces which lose a considerable part their strength along the slip surface in terms of shear displacement, by implementing models predicting pore pressure build up (a) at the soil profile and (b) at the slip surface at the proposed method.

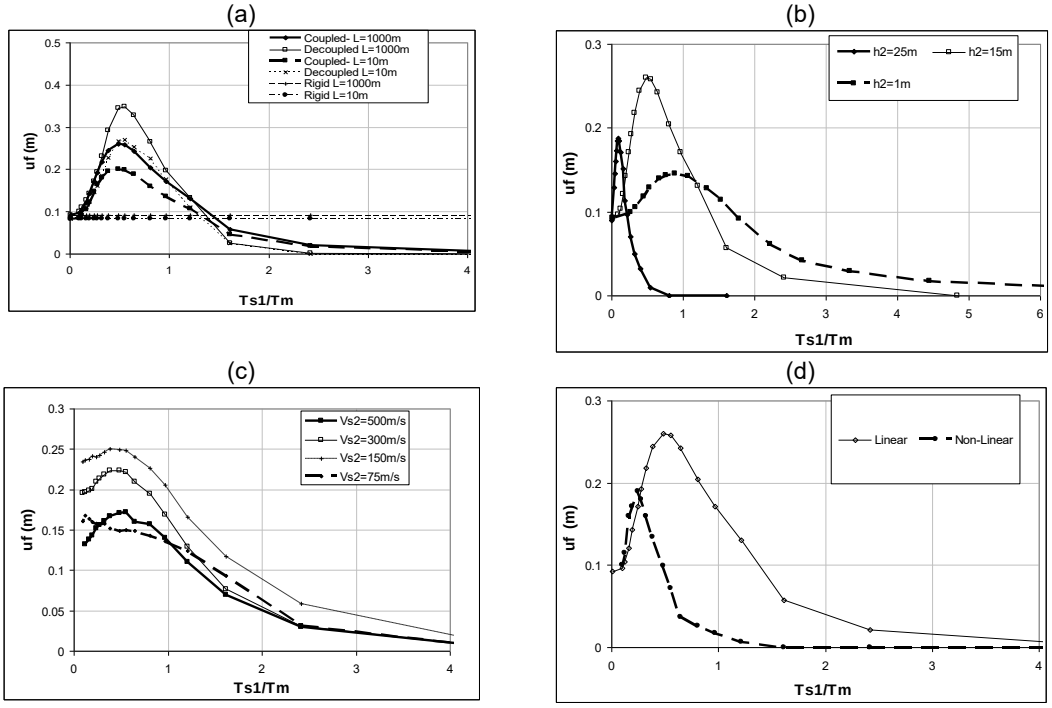

Figure 5: Results of dynamic parametric analyses The seismic displacement u_f for the coupled case versus Ts_1/T_m for the Aegion 1995 earthquake case with a_{co}=0.5m/s2, h_1+h_2=30m, $\rho_1=\rho_2$=2t/m3, $\lambda_1=\lambda_2$=0.15 for (a) elastic analyses if $Vs_2=Vs_1$ with h_2=15m and L=1000m and L=10m, (b) for elastic analyses if $Vs_2=Vs_1$, L=1000m, in terms of h_2 and (c) for elastic analyses if h_2=15m, in terms of Vs_2, L=1000m. (d) the linear and non-linear soil profile with $a_1=\alpha_2$=0.5, $\beta_1=\beta_2$=1 in the case of Fig. b, with h_2=15m. In (a) the rigid and decoupled cases are also given for comparison.

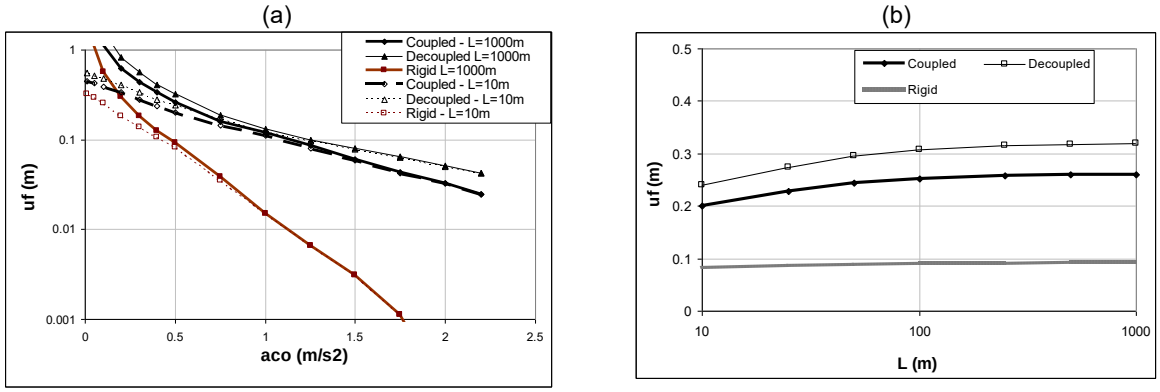

Figure 6: Results of dynamic parametric linear coupled, decoupled and rigid analyses. The seismic displacement u_f (a) in terms of a_{co} for L=1000m and L=10m and (b) in terms of L for a_{co}=0.5m/s^2.

6 CONCLUSIONS

- A new cost-effective method, given by equations (1)-(7) and (9), is proposed predicting the seismic sliding movement of dry slopes along slip surfaces with resistance that does not change considerably with shear displacement. The method models (a) the coupled dynamic response of soils both above and below the slip surface, (b) the rotation of the sliding mass effect and (c) the non-linear soil response at the soil medium, by combining previous work in a unique manner.
- The new method was solved numerically and applied at both the linear and non-linear cases. In the linear case the effects of the stiffness of the soil layer both above and below the slip surface on the seismic displacement are illustrated and interpreted. The effect of the rotation of the sliding mass is also illustrated. In the non-linear case, the effect of the shear modulus degradation in the soil profile was illustrated and interpreted.

Abstract

Settlement is the vital issue for analysis of a tunnel in any conditions of soils such as sand, clay etc. Many researches have been carried out to predict surface settlement above a tunnel but some technique needs further research to be established. In this paper, analysis of EPB-TBM (Earth Pressure Balanced Tunnel Boring Machine) tunnel has been considered along a straight line through homogeneous sand layer which has been observed in the Chittagong Coastal area, Bangladesh. Circular type tunnel is considered for analysis. Direct effect of seismic fault has been neglected. Phased construction method has been incorporated to analyze this event. Important parameters for surface settlement of tunnel are tunnel depth, tunnel diameter, tunnel construction technique, different relative densities of sand etc. In this paper, the variation of tunnel depth and tunnel diameter has been considered and analyzed. Analysis has been performed through finite element based software PLAXIS 3D. Surface settlement along transverse and longitudinal to the tunnel axis has been predicted. Variation of depth (distance between free surfaces to top surface of the tunnel), tunnel diameter and length (phased excavation) have been considered to evaluate surface settlement for static and dynamic cases in sands.

Keywords: Settlement, PLAXIS 3D, Sand, EPB – TBM, Seismic, etc.

1 INTRODUCTION

Developing of underground space, tunneling is the most important issue in civil engineering. Tunnel is being constructed to densely populated areas as well as for long transportation infrastructures. Construction of tunnel induces ground movements which may affect existing structures. Ground movement is related with damage rate of tunnel. Generally, damage rate of tunnels are lower than surface structures under seismic loading. To prevent damages of tunnels, accurate assessment is necessary to predict tunneling-induced ground movements. Ground movement above a tunnel in sand has been reported by Mair and Taylor (1997), Vorster et al. (2005), Marshall et al. (2012) etc. Tunneling effects on pipelines and buildings have been investigated in sand by several authors (Klar et al., 2007, 2015; Farrell et al., 2014; Giardina et al., 2015; Franza & Marshall, 2017; Ritter et al., 2017). Relative depth of tunnel (A_n/D_n) and diameter of tunnel (D_n) are main factor to handle ground movement above a tunnel in sand with proper construction technique and relative density. The goal of this paper is to predict ground movement above a tunnel in sand in Patenga, Chittagong, Bangladesh. In this paper, circular type tunnel has been considered which moves along a straight line in sand layer. Variable parameters in these paper are relative depth of tunnel, diameter of tunnel and tunnel length with constant relative density and construction method (EPB – TBM). Numerically, ground settlements are observed with the variation of variable parameters under static as well as seismic loading. Linear analysis has been performed to predict ground movement above a tunnel. Finally, appropriate placement of tunnel in sand layer has been performed through numerical analysis.

Figure 1: Under construction of tunnel at Potenga, Chittagong, Bangladesh

2 LOCAL GEOLOGY AND GEOTECHNICAL PARAMETERS

According to GSB (1990), the local geology consists of mainly beach and dune sand. This sand contains light to whitish-grey sand which is medium to fine, well sorted, and

subrounded; this also contains concretions, shell fragments, heavy minerals, and rare clasts which include small mud-flat deposits. Unconformably overlies Late Tertiary formations. Several bore logs have been carried out at the project site. A typical bore log has been presented in Figure 2. The soil profile mainly consists of softy silty clay up to a depth of 3 to 5 m, which is underlain by fine sand.

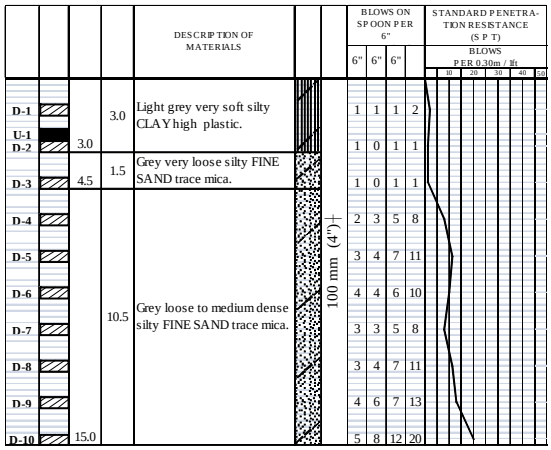

Figure 2: Typical borehole log at Potenga, Chittagong, Bangladesh

3 MODIFIED EMPIRICAL AND ANALYTICAL FORMULAS

Underground space technology such as tunneling has become very popular and demanding. In urban areas, people wants alternative mode of transportation for excellent facilities. Engineer must take note and gain high knowledge about tunneling technology. Protection needs of surface structures as well as underground facilities from ground movements due to construction of tunneling as well as seismic shaking after construction exist.

3.1 Modified Empirical Formula of Vertical Settlement

Vertical ground settlement is the major important issue during tunneling as well as seismic shaking and also long term behavior of tunnel. For practical purpose, important issue is the maximum settlement due to tunneling. The authors have modified Mair's (1993) maximum ground settlement formula with the consideration of 0.5 percent uniform volume loss (Mair and Taylor, 1997) for sand and 35 percent of *K* factor (Mair and Taylor, 1997) as shown below.

$$V_{(z),max.} = 0.0045 \frac{D^2}{(H - z)} \quad (1)$$

Where, *D, H, z,* $V_{(z),max.}$ are represented by inner diameter of tunnel (m), vertical distance (m) from free surface to tunnel center line, any vertical distance (m) from free surface and maximum vertical settlement (m). For surface settlement, z is equal to zero.

3.2 Modified Empirical Formula of Lateral Settlement

Lateral ground settlement affects surface structures and underground facilities similar to vertical settlement of ground. Maximum lateral settlement of ground has great role in professional field. O'Reilly and New (1981) gives an empirical formula to predict lateral surface settlement. The authors have modified this formula with the consideration of Atkinson and

Potts (1977) equation from the centrifuge tests for tunneling in dry sands which is shown below:

$$U_{(x),max.} = V_{(z),max.} \frac{A + D}{4(H - z)} \tag{2}$$

Maximum lateral ground settlement (m) and distance (m) from free surface to tunnel crown are expressed as $U_{(x),max.}$ and A in equation (2).

3.3 Modified Empirical Formula of Longitudinal Settlement

Most of tunneling analysis (Franza et al., 2018, Pescara et al., 2011, Franza and Marshall 2015) has been carried out based on plain strain consideration which has not included longitudinal settlement profile of tunnel. A few researches have been expressed in longitudinal settlement above a tunnel based on field observations. Attewell and Woodman (1982) gives an empirical relation to predict longitudinal ground settlement above a tunnel. Authors have modified this relation as shown below:

$$U_{(y),max.} = \frac{V_{(z),max.}}{(H - z)} \tag{3}$$

Where $U_{(y),max.}$ is expressed as maximum longitudinal ground settlement (m) and unit length consider along the longitudinal direction of tunnel due to plain strain consideration.

3.4 Modified Empirical Formula of Lateral Settlement Under Seismic Loading (USL)

A lot of seismic analysis has been performed for surface structures. A few data are available to express damage of tunnels after an earthquake before 1970's. Pescara, (2011) gives an empirical relation to predict lateral displacement above a tunnel under seismic shaking by using Eurocode 8. The authors have modified Pescara, (2011) formulae as shown below:

$$\Delta_{(x),max.} = f \frac{a_1 g S C k}{C_s} \left(C_d - (H - z)\right) \tag{4}$$

Where $\Delta_{(x),max.}$, a_1, g, S, C, k, C_d, f and C_s are represented as maximum lateral settlement (mm), seismic coefficient such as 0.15 (Bangladesh National Building Code (BNBC) 2006), gravitational acceleration (9.81m/s^2), soil factor (1.15) based on Eurocode 8 which equivalent to BNBC 2006, factor of ground motion (0.9) (Power et.al 1996), ratio of peak ground velocity to peak ground acceleration (142) (Power et.al 1996), total depth (27.5m) of upper layer and tunnel layer, modified factor (10) based on present author modified analytical formulae and apparent propagation velocity of S-wave: several authors [O'Rourke and Liu, 1999; Power et al., 1996; Paolucci and Pitilakis, 2007] have suggested values between 1 and 5 km/s.

3.5 Modified Analytical Formula of Vertical Settlement

Verruijt and Booker (1996) have showed a closed form general solutions for the calculation of the vertical ground settlement under uniform radial ground loss. Authors have modified these formula for long term as well as seismic loading. Long term ground deformation has been taken as 1mm based on observations by Rankin, (1988) and Loganathan et.al (1998). Maximum ground settlement for long term and seismic loading has been expressed by equations (5) and (6) which have been provided below, respectively.

$$V_{(z)max.} = -0.005R^2\left(\frac{z_1}{r_1^2}+\frac{z_2}{r_2^2}\right)+0.001R^2\left[\frac{z_1(-z_2^2)}{r_1^4}+\frac{z_2(-z_2^2)}{r_2^4}\right] + \frac{0.01R^2}{m}\left[\frac{(m+1)z_2}{r_2^2}+\frac{mz(-z_2^2)}{r_2^4}\right] - 0.002R^2H\left[\frac{-z_2^2}{r_2^4}+\frac{m}{m+1}\frac{2zz_2(-z_2^2)}{r_2^6}\right] \quad (5)$$

$$V_{(z)max.} = -0.005R^2\left(\frac{z_1}{r_1^2}+\frac{z_2}{r_2^2}\right)+\frac{0.01R^2}{m}\left[\frac{(m+1)z_2}{r_2^2}+\frac{mz(-z_2^2)}{r_2^4}\right] \quad (6)$$

Where, $z_1 = z - H$, $z_2 = z + H$, $r_1^2 = z_1^2$, $r_2^2 = z_2^2$, $R = D/2$, $m = 1/(1 - 2\upsilon)$, $k = \upsilon(1 - \upsilon)$. υ is the Poisson's ratio of soil. Long term ground deformation due to ovalization is equal to zero under seismic loading.

3.6 Modified Analytical Formula of Lateral Settlement

Verruijt and Booker (1996) have also showed a closed form general solutions for the calculation of the lateral ground settlement under uniform radial ground loss. Authors have also modified these formula based on Hunt (2004) and Zhou (2014) considering lateral distance from tunnel axis for long term and seismic loading which is shown below:

$$U_{(x),max.} = 0.00125R^2\left(\frac{(A+D)}{r_1^2}+\frac{(A+D)}{r_2^2}\right) - 0.0000625R^2\left[\frac{z_1((A+D)^2-16kz_1^2)}{r_1^4}+\frac{((A+D)^3-(A+D)16kz_2^2)}{4r_2^4}\right] + \frac{0.0025(A+D)R^2}{m}\left(\frac{1}{r_2^2}-\frac{2mzz_2}{r_2^4}\right) + \frac{0.001R^2(A+D)H}{(m+1)}\left[\frac{z_2}{r_2^4}+\frac{mz((A+D)^2-48z_2^2)}{16r_2^6}\right] \quad (7)$$

$$U_{(x),max.} = 0.00125R^2\left(\frac{(A+D)}{r_1^2}+\frac{(A+D)}{r_2^2}\right)+\frac{0.0025(A+D)R^2}{m}\left(\frac{1}{r_2^2}-\frac{2mzz_2}{r_2^4}\right) \quad (8)$$

Where, equation (7) represents as the maximum lateral settlement for long term loading and equation (8) represents as the maximum lateral settlement for seismic loading.

4 NUMERICAL ANALYSIS

Numerical analysis is necessary to evaluate behavior of underground structures under seismic loading. Material properties have been determined from two types of tri-axial tests such as consolidated drained and consolidated un-drained. Models have been created for analysis in software PLAXIS 3D based on the Potenga, Chittagong site conditions. Two types of parameters are used in this model such as fixed and variable. Fixed parameters are soil volume, material properties of soil and tunnel lining, borehole location etc. Variable parameters are tunnel length, diameter and relative depth. Mohr-Coulomb material model has been con-

sidered for soil and linear elastic model consider for tunnel lining in long and short term behavior. Non-porous drainage type has been considered for lining segment. Bulk unit weight of silty clay, fine sand and lining segments are 16.4 kN/m^3, 18.6 kN/m^3 and 24 kN/m^3 for long term behavior and for short term behavior these values are 17 kN/m^3, 19.03 kN/m^3. Saturated unit weight of short and long term behavior of sands, clays are 20 kN/m^3, 20 kN/m^3, 19 kN/m^3 and 18.90 kN/m^3. Modulus of elasticity of clay, sand and lining segments are 14.4 MPa, 26.1 MPa and 28 GPa for long term behavior and 22.5 MPa, 40.8 MPa for short term loading. Cohesion of clay has 30 kPa for both long as well as short term loading. Internal friction angle of sands and clays are 29^0, 23^0 for short term loading and 36^0, 23^0 for short term behavior. Dilatancy angle of sand is 6^0 for long term behavior only. Poisson's ratio of sands, precast segment and clays are 0.25, 0.20 and 0.31 for both cases. Face pressure, grouting pressure and jacking force of tunnel are 90 kN/m^2 with axial increment 14 kN/m^2/m, 100 kN/m^2 with axial increments of 20 kN/m^2/m and 600 kN/m^2. 0.5% uniform surface contraction has to be taken with axial increment of 0.05%.

In seismic analysis, free field boundary conditions have been taken along lateral direction because of seismic loading has to be applied in this direction. Software automatically considers other values which are necessary to analyze this model. Most of the earthquakes have a frequency range such as 8 to 12 Hz. Material damping has been considered as 5%. Length of Earth Pressure Balance Tunnel Boring Machine (EPB-TBM) considered is 12m. Maximum number of steps and maximum number of iteration are 250 and 60 in analysis for long and short term loading. Initial length of tunnel is 25m and tunnel advancement of 2m along its own axis is considered. Three stage of advancement of tunnel have been considered for analysis. Variable diameters of tunnel are 10.5m, 10.8m and 11.0m. Depths from free surface to top surface of tunnel are 4.5m, 5.5m, 6.5m, 7.5m, 8.5m. Thickness of pre-cast segment considered is 0.5m. The finite element model is shown in Figure 3.

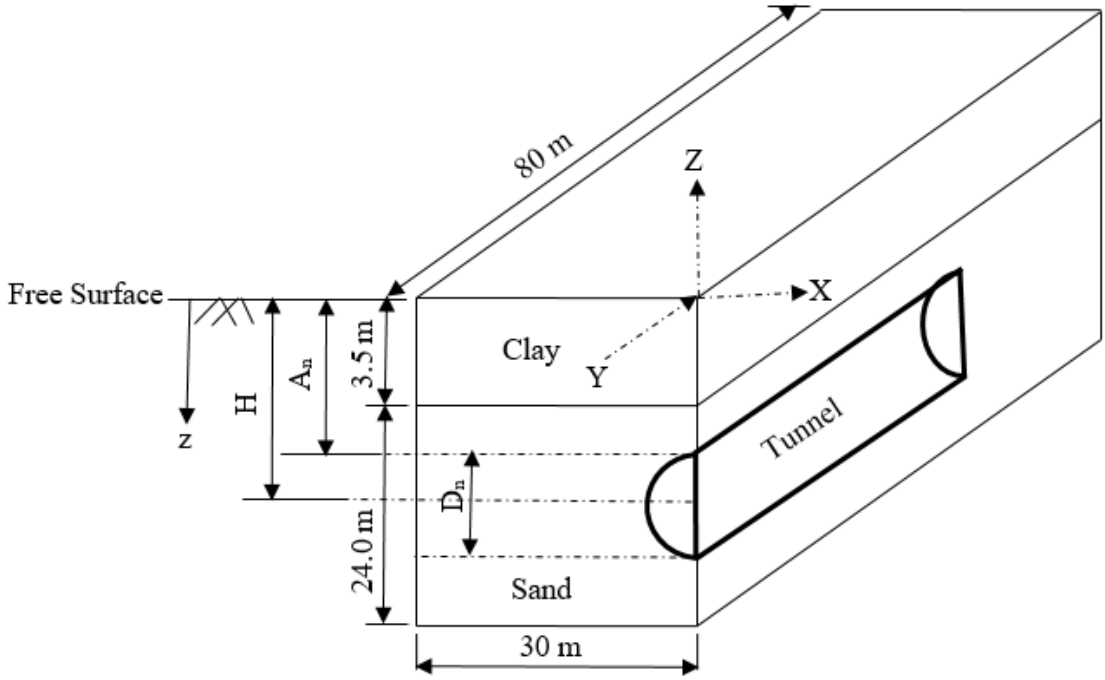

Figure 3: Finite element model based on Potenga soil conditions at Chittagong

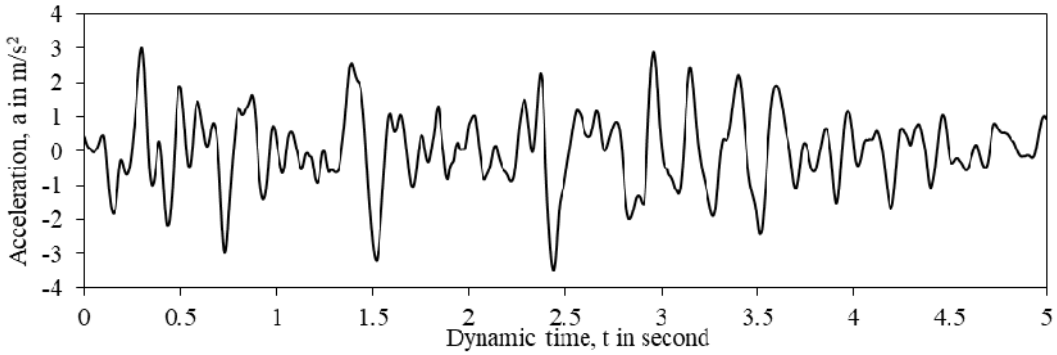

Figure 4: Seismic data at Potenga, Chittagong.

When model geometry, material properties and other relevant data are fully defined then model has to be divided into finite elements in order to perform finite element calculations. This type of composition of finite element method is called mesh. Fine mesh will be used to obtain accurate numerical results. Half portion of the tunnel has been considered because of symmetry. 10-node tetrahedrons soil element have been taken for analysis. Every phase consists of a particular loading or construction stage. Analysis phases are initial, plastic and seismic. In plastic phase of calculation, drained behavior has been taken and un-drained (A) option has been taken for seismic loading. Seismic data has been input in the software based on a real seismic event in Chittagong as shown in Figure 4. Plastic calculation is related with the elastic-plastic deformation analysis. In a normal plastic calculation, the stiffness matrix is based on the original un-deformed geometry. Loading can be defined in various sense during plastic calculation mode such as changing the load combination, stress state, weight, strength or stiffness of elements, activated by the changing the load and geometry configuration or pore pressure distribution by means of staged construction. For meshing, the number of cores is set to 256 for this model. Software performs seismic analysis after the completion of modeling and static analysis. Seismic analysis is the complex type of dynamic analysis which contains non-periodic loading history. The applied seismic load is the product of the input value of the defined seismic load and corresponding seismic load multiplier. Activation of the seismic load or seismic prescribed displacement, free field boundary conditions can be defined for a seismic analysis. Meshing of the model is presented in Figure 5. Meshing effect on model has been shown in Table 1.

Table 1: Meshing effect on model due to tunneling

Tunnel Length, y_1 (m)	Ratio, A_1/D_1	Maximum total vertical settlement, V_{zt} in mm		
		Coarse	Medium	Fine
27	0.4286	44.7	44.5	44.5

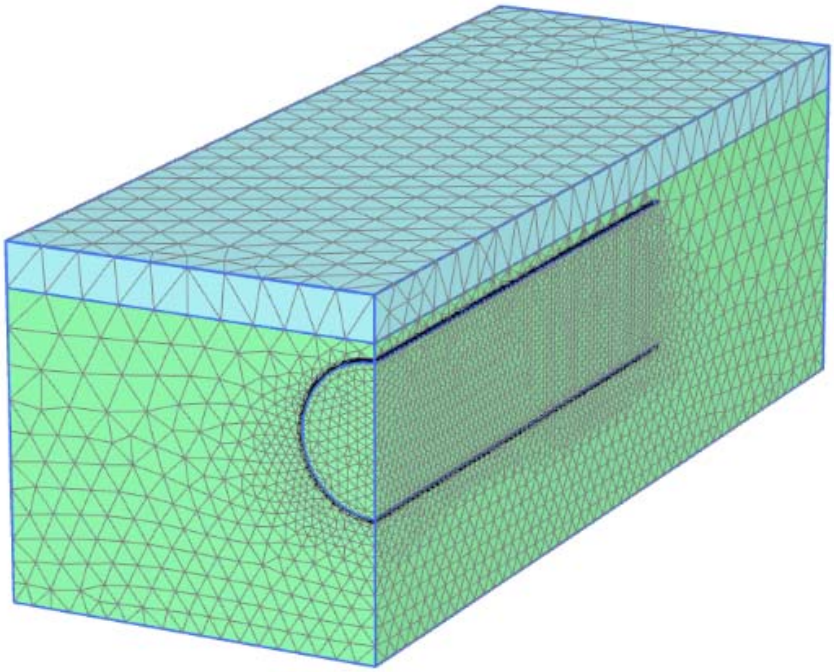

Figure 5: Un-deformed fine meshing of the research model

Seismic loadings are imposed for a short time but its impact upon the structures or soil is high. High frequency of seismic loading can easily pass through the small elements of these model. Fine meshing which yields best analysis is applied under seismic loading.

5 RESULTS AND DISCUSSIONS

Maximum surface settlement in vertical, lateral and longitudinal directions above a tunnel has been discussed here. Variation of surface acceleration in lateral direction is also presented. Seismic loading has been applied in the model for five seconds in lateral direction. Some terms used to express results are MEF-LTL (Modified Empirical Formulae Long Term Loading), MEF-SL (Modified Empirical Formulae Seismic Loading), MAF-LTL (Modified Analytical Formulae Long Term Loading), MAF-SL (Modified Analytical Formulae Seismic Loading) etc. Following parameters are varied: diameter – 10.5m (D_1), 10.8m (D_2), 11.0m (D_3), length – 27m (y_1), 29m (y_2), 31m (y_3) and relative depth – 4.5m (A_1), 5.5m (A_2), 6.5m (A_3), 7.5m (A_4), 8.5m (A_5).

5.1 Vertical Surface Settlement Above a Tunnel

Vertical surface settlement consists of stability of structures which stands on the ground surface. Vertical surface settlement depends on the variation of relative depth, tunnel length and tunnel diameter. These settlements are calculated based on previously mentioned equations and are shown in Figure 6. Three diameters represent almost similar results during seismic and long term loading based on modified formula. Results of modified analytical and empirical formulae are very close for long term loading. Settlement gradually decreases with the increase in relative depth based on author modified formulae. Minimum settlement is 30mm at A_5/D_1 location using MAF-SL formula.

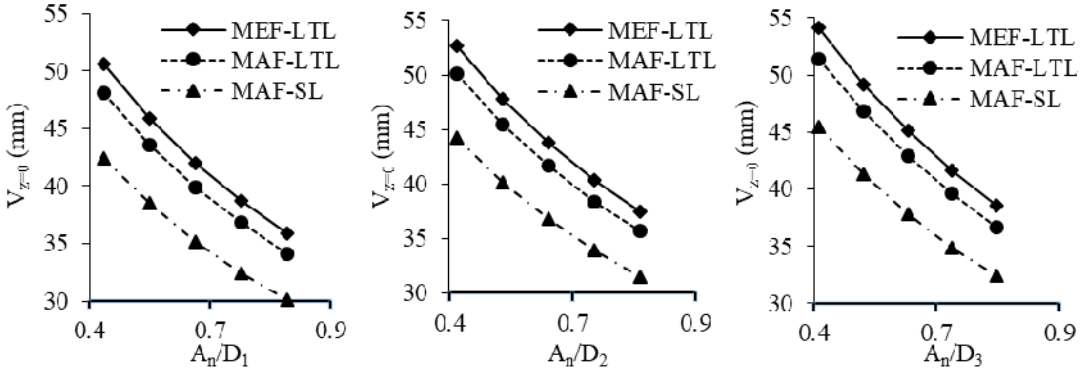

Figure 6: Vertical surface settlement for long term and seismic loading based on modified formulae.

Figure 7 and Figure 8 present the vertical surface settlement for long term and seismic loading based on numerical analysis using PLAXIS 3D. Uplift has been observed for each loading types, longitudinal length and diameter. Three construction stages of tunnel coincide at a point A_5 for long term loading which represents minimum settlement, apparently 7 mm at A_5/D_1 location. Third construction stage of tunnel fully represents uplift under seismic loading for three diameters. Minimum settlement is nearly 2 mm at A_5/D_1 location under seismic loading.

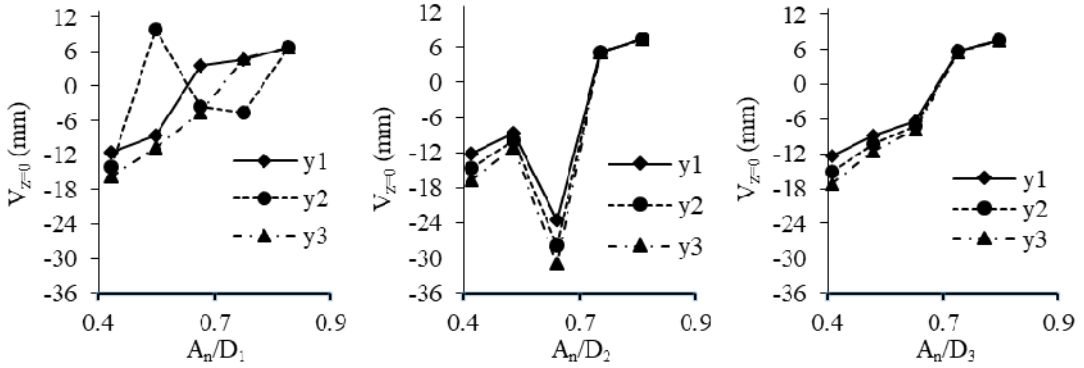

Figure 7: Vertical surface settlement for long term loading based on finite element method.

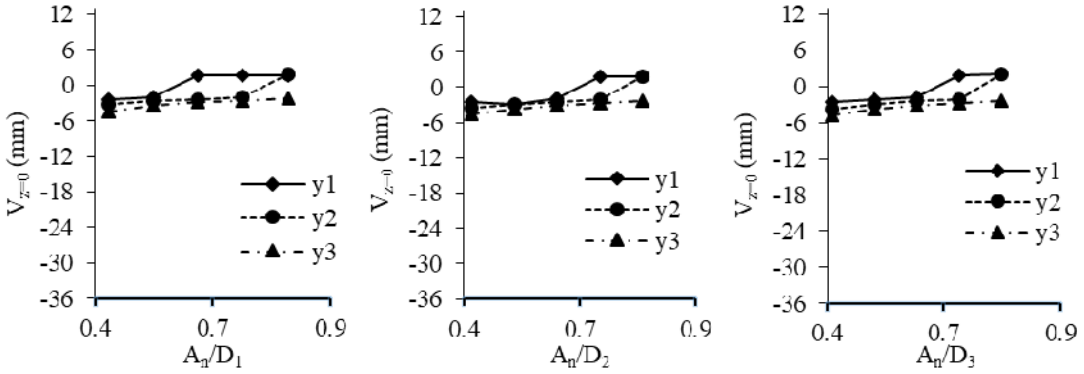

Figure 8: Vertical surface settlement for seismic loading based on finite element method.

5.2 Lateral Surface Displacement Above a Tunnel

Lateral surface settlement consists of lateral stability of super structures under long term (Figure 9) and under seismic (Figure 10) loading effect. Change of these settlements is made based on variation of depth of tunnel crown, length of tunnel and diameter of tunnel. Modified

and numerical methods have been used to calculate these settlements. At A_5 location, lateral settlement is nearly 9mm of diameter D_1 for long term loading based on modified formulae in Figure 9.

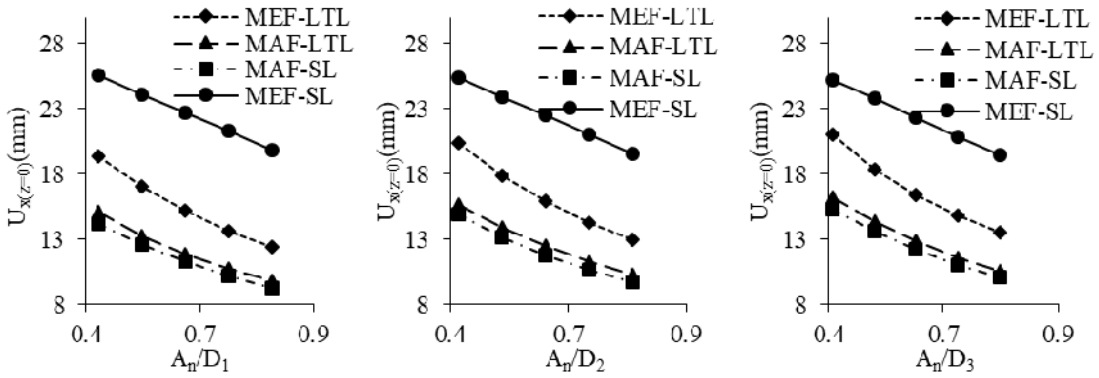

Figure 9: Lateral surface settlement for long term and seismic loading based on modified formulae.

At A_5 location, lateral settlement is nearly 3mm of diameter D_1 for long term loading based on finite element method in Figure 10. According to Figure 11, uplift is observed during seismic loading at A_5 location which indicates the minimum value.

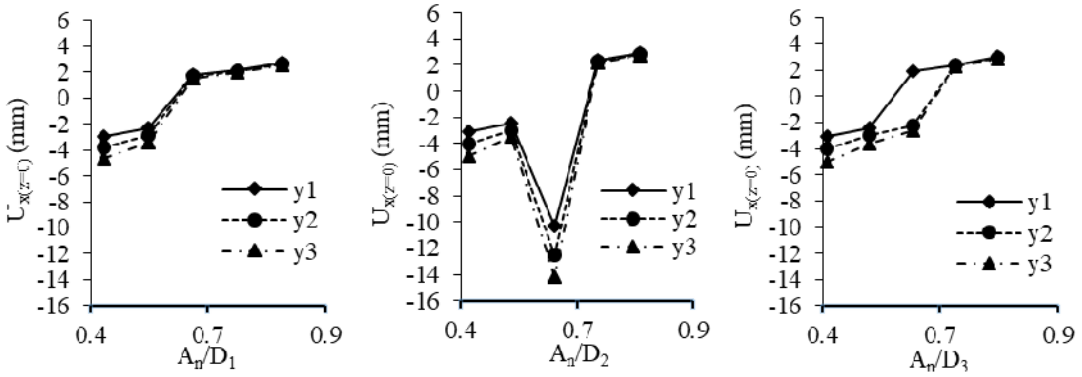

Figure 10: Lateral surface settlement for long term loading based on finite element method.

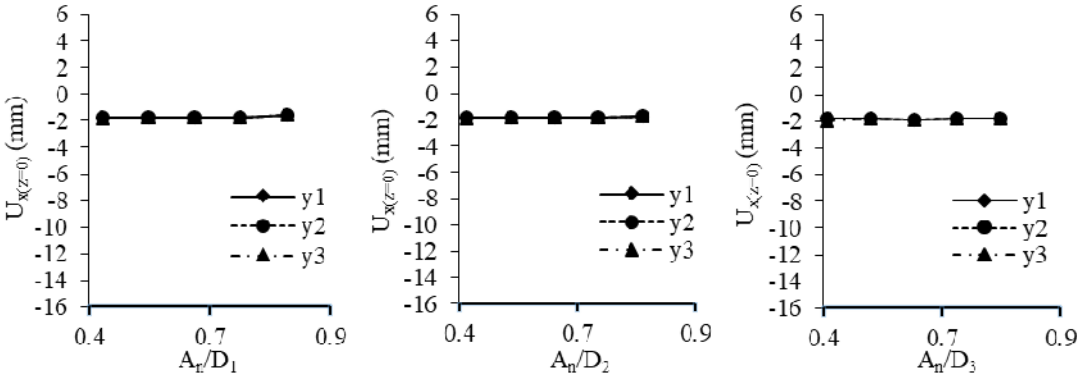

Figure 11: Lateral surface settlement for seismic loading based on finite element method.

5.3 Longitudinal Surface Displacement Above a Tunnel

Longitudinal ground movement along length of the tunnel can be seen in Figure 12. These settlement profile also express that the effect of phased construction of tunnel. Minimum val-

ue of settlement is 2.6mm due to extension at A_5/D_1 location based on author modified formulae as can be seen in Figure 12.

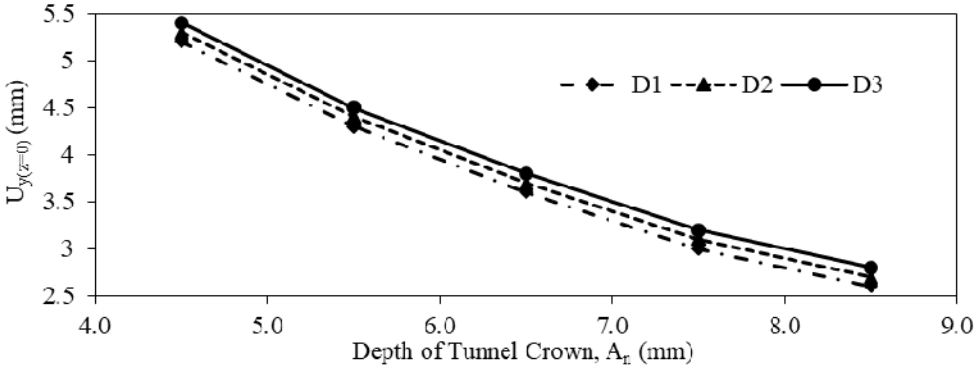

Figure 12: Longitudinal surface settlement for long term loading based on modified formulae.

Figures 13 and Figure 14 show negative value of settlement which indicates the contraction of ground due to tunneling and positive settlement express that the extension of tunnel along its length. Settlement gradually decreases with the increase of depth of tunnel crown for modified and numerical formulae. Minimum settlement is 3mm due to contraction at A_5/D_1 locations for long term loading based on numerical analysis. Longitudinal settlement is very low during seismic analysis which is nearly 0.3mm at A_5/D_1 location. Figure 15 shows longitudinal surface settlement profile based on finite element method PLAXIS 3D.

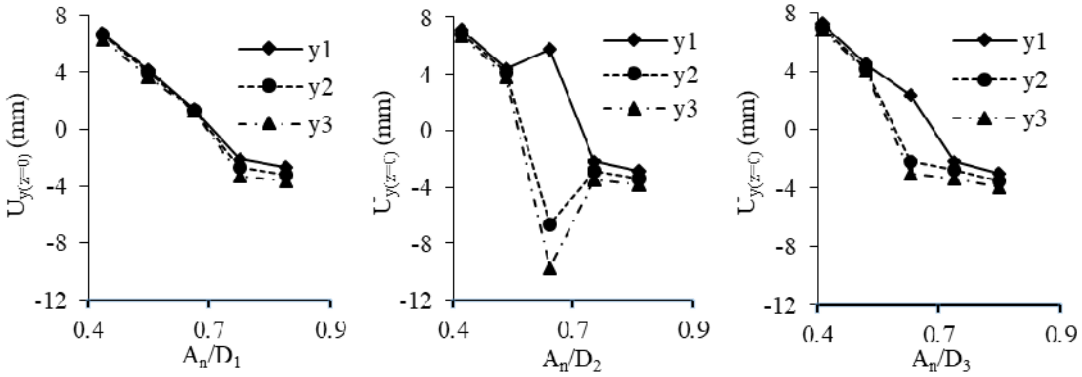

Figure 13: Longitudinal surface settlement for long term loading based on finite element method.

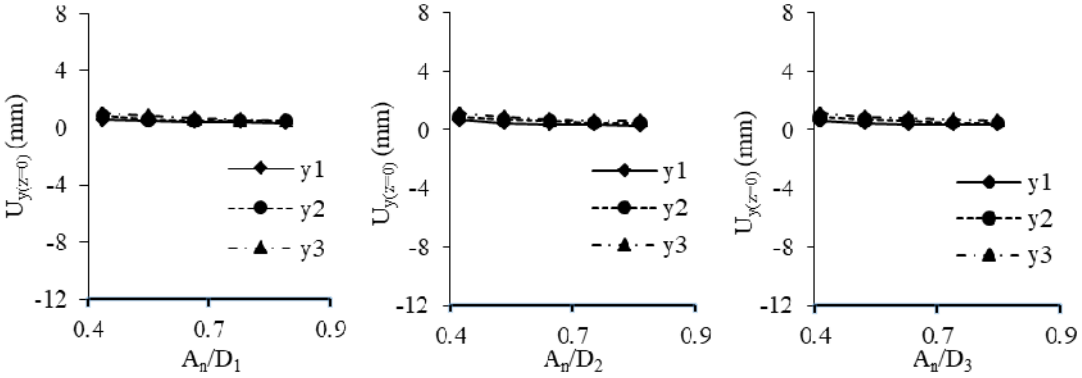

Figure 14: Longitudinal surface settlement for seismic loading based on finite element method.

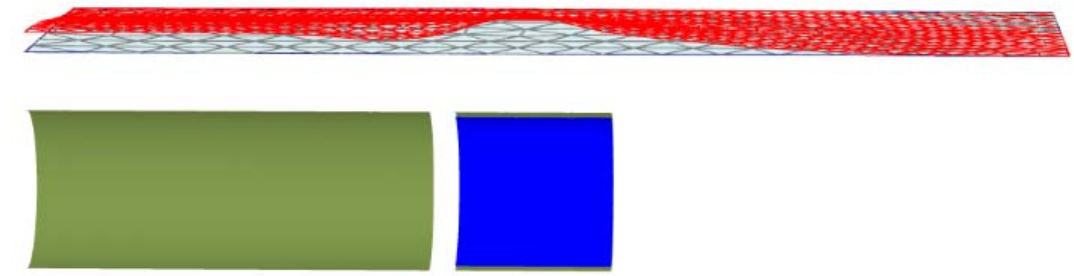
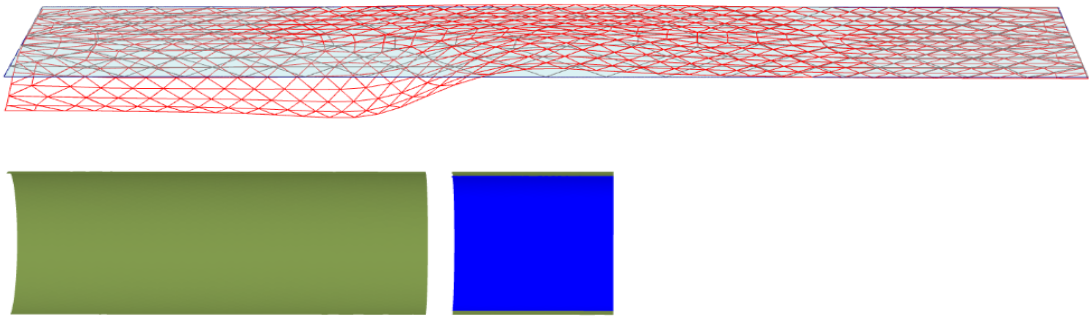


(a) Upward settlement due to tunneling



(b) Downward settlement due to tunneling

Figure 15: Longitudinal surface settlement profile based on finite element method.

5.4 Surface Accelerations Above a Tunnel Under Seismic Loading (USL)

Ground movement above a tunnel has been produced by surface acceleration. Lateral acceleration of tunnel is critical than other two directions. A lot of points are present on the surface. One point (-3, 15.5, -0.1) has been used here to express surface acceleration. Surface acceleration gradually decreases with the increase in depth of tunnel crown for diameter, D_1 as shown in Figure 16. Line A_5 shows the minimum acceleration for diameter, D_1 at 0.25s. The acceleration value is nearly 0.24 m/s^2. The value of acceleration for diameter, D_2 and D_3 is higher than diameter, D_1. Acceration values are -0.5 m/s^2 for diameter D_2 and nearly 0.8 m/s^2 for diameter D_3 at 0.25s.

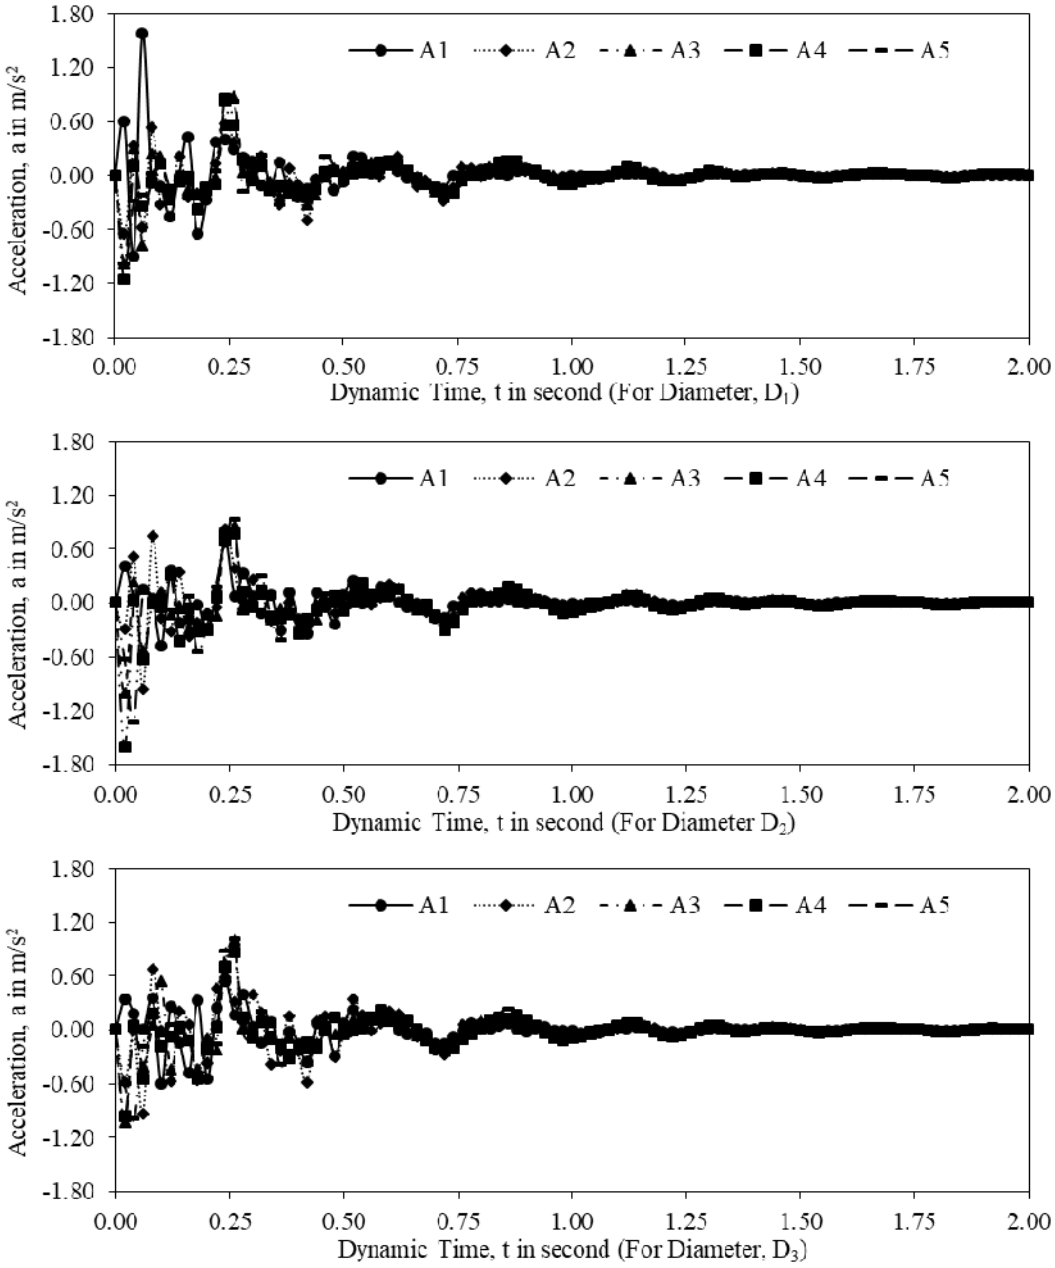


Figure 16: Lateral surface acceleration during seismic loading based on numerical analysis.

6 CONCLUSIONS

Movement of tunnel in homogeneous sand layer has been studied for ground structures in Chittagong coastal area. Upward surface settlement occur because of soft upper clay layer. Another reason of upward settlement is the shallow depth of tunnel placement. The results obtained from author modified empirical and analytical formula apparently match well. Surface settlement is more important than the total settlement for tunneling. Results of these research deals with maximum value. Minimum values of maximum vertical surface settlements are 7 mm for long term loading and 2 mm for seismic loading. Minimum values of maximum lateral surface settlements are 3 mm for long term as well as seismic loading and

9 mm for modified formulae. Similarly, minimum values of maximum longitudinal surface settlements are 3 mm due to contraction for long term loading and 0.3 mm for seismic loading. Settlement obtained from the author modified formula are greater or nearly equal to the finite element methods. Minimum value of acceleration is 0.24 m/s^2 under seismic loading. In these research, value of seismic loading is lower than the long term loading because of seismic source is located far away from the tunneling project. Two major conclusions are:

(1) Author modified formula may be used for practical purpose for all types of underground tunnel which passes through the sand layers.
(2) Suitable depth of the tunnel for this analysis is 8.5 m and suitable diameter is 10.5 m.

Future studies may be conducted such as replacement of homogeneous layer with the heterogeneous layers, considering strong seismic loading, inclination of tunnel, two or more tunnel, tunnel passes through the active seismic fault reason etc.

ACKNOWLEDGEMENTS

This work has been carried out in the Department of Civil Engineering, BUET. The authors gratefully acknowledge the support and facilities provided by BUET.

Abstract

In earthquake analyses, usually the seismic displacement along slip surfaces is estimated by the sliding-block model, where a rigid block rests on an inclined plane and every time that the applied horizontal acceleration is larger than the critical horizontal acceleration value for relative motion, the block slides. Different empirical expressions have been proposed predicting the seismic displacement of the sliding-block model, in terms of characteristics of the applied seismic motion and the critical horizontal acceleration for sliding. However, the seismic displacement along a slip surface depends on the dynamic characteristics of the soil profile both above and below the slip surface. Eurocode classifies the soil profiles into at least 4 distinct categories. The present work proposes empirical expressions relating the seismic displacement along slip surfaces in Greece, in terms of not only to characteristics of the acceleration history and the critical horizontal acceleration for sliding, but also to the soil type category according to Eurocode, as well as, the depth of the slip surface. For this purpose, extensive parametric analyses using a recently developed dynamic coupled numerical code which predicts the seismic displacement along slip surfaces at some of depth of elastic soil profiles. An extensive data base of seismic motions recorded in Greece is used and applied for typical soil profiles according to Eurocode with varying critical acceleration value and slip surface depth. The results are analyzed statistically and related to the conventional sliding-block permanent seismic displacement predictions.

Keywords: slopes, sliding-block model, dynamic response, seismic displacement, Greece, empirical equations.

SEISMIC SLIDING DISPLACEMENT OF SLOPES IN TERMS OF SOIL PROFILE TYPE

1 INTRODUCTION

Damage of natural and man-made slopes usually occurs as a result of excessive movement along slip surfaces. Engineers usually assess the seismic safety of slopes using the dynamic factor of safety calculated along slip surfaces by comparing the applied forces to the soil strength [1]. However, evaluations based on the dynamic factor of safety have the serious drawback that they do not consider the seismic displacement, which is directly related to damage [2].

The "conventional" sliding-block model [3] is the most commonly used simplified model predicting the seismic displacement of slopes for given earthquake motions [4]. A rigid block rests on an inclined plane. The resistance along the block-inclined plane boundary follows the Mohr-Coulomb law. Critical acceleration is defined as the minimum horizontal acceleration which causes movement of the block. Every time where the applied horizontal acceleration is larger than the critical acceleration, the block slides. The total displacement is obtained by the addition of the partial slips. It depends on the critical acceleration of the block and the applied seismic motion. This model is used for the prediction of permanent seismic movement of slopes along a predefined slip surface, by appropriately selecting the equivalent critical and applied acceleration values of the "conventional" sliding-block model [2, 3, 4].

Different empirical expressions have been proposed predicting the seismic displacement of the sliding-block model, in terms, primarily, of the ratio of the maximum acceleration of the applied seismic motion divided by the critical horizontal acceleration for sliding [4-9]. Some of these expressions use other than the maximum acceleration parameters of the seismic motion, such as the maximum velocity or the Arias Intensity, or parameters of the earthquake that produced the seismic motion, such as its earthquake magnitude or its earthquake fault distance [5, 9]. In addition, region-specific empirical expressions have been proposed predicting the seismic displacement of the sliding-block model, as different regions have different earthquake faults and geological profiles conditions, and thus potentially different applied seismic motions characteristics. Region-specific empirical expressions predicting the seismic displacement with the "conventional" sliding-block model for seismic motions in Greece has been proposed by [9].

The conventional sliding-block model described above assumes rigid motion and thus it does not consider the dynamic response of the soil both above and below the slip surface, which affects the seismic displacement along the slip surface. Based on results of simplified dynamic models, expressions have been proposed predicting the seismic displacement along the slip surface in terms of not only the critical acceleration for sliding and characteristics of the applied seismic motion described above, but also characteristics affecting the dynamic response of the sliding mass such as its height and shear wave velocity [10-12]. However, the seismic displacement along a slip surfaces depends not only on the dynamic characteristics of the sliding mass, but also on the dynamic characteristics of the soil profile below [13, 14]. On the other hand, recently, a new cost-effective method, is proposed predicting the seismic sliding movement of dry slopes in soil profiles along slip surfaces with resistance following the Mohr-Coulomb law. The method models the coupled dynamic response of soils both above and below the slip surface [13]. An advantage of this method is simplicity, which makes it ideal in performing dynamic parametric analyses.

Depending on the geographical locations, National Codes specify the characteristics of the design typical seismic motion, such as the maximum seismic acceleration [15]. This seismic

motion typically corresponds at bedrock sites. Furthermore, Eurocode [1] classifies the soil profiles into distinct categories, presumably exhibiting similar dynamic response. Based on the above, it is of interest for practicing engineers, to relate the seismic displacement along slip surfaces, not only to characteristics of the seismic motion and the critical horizontal acceleration for sliding, but also to the soil type category according to Eurocode, as well as, possibly, the depth of the slip surface.

The purpose of the present work is to propose empirical expressions relating the seismic displacement along slip surfaces in Greece, in terms of not only characteristics of the acceleration history and the critical horizontal acceleration for sliding, but also to the soil type category according to Eurocode, as well as, the depth of the slip surface. In particular, it proposes and validates equations correcting the predictions of the conventional sliding-block model for typical seismic motions of Greece in terms of the soil profile type according to Eurocode and the depth of the slip surface. For this purpose, the following are performed below: (a) ground profile types are described according to Eurocode, (b) a data base of seismic motions in Greece is collected, (c) typical ground profile types according to Eurocode are selected and numerical analyses are performed using the recently developed numerical code by [13], (d) based on the analyses performed and statistical analysis an empirical equation correcting the seismic displacement predictions of the sliding-block model based on the soil type category according to Eurocode, as well as the depth of the slip surface is derived and validated, (e) the results are discussed and an example practical application of the proposed expression for the prediction of the seismic displacement of an actual slope in Greece is given.

2 GROUND TYPES ACCORDING TO EUROCODE

Eurocode [1] defines ground types A-E, as given in table 1, based on observations by the earthquake engineering community that (a) only the first 30m depth of a soil profile play a critical role in the dynamic response, (b) for given soil type, the only soil property that affects the dynamic response is the shear wave velocity and (c) for similar dynamic response, a non-uniform soil profile with n layers may be simplified by an uniform one, with shear velocity Vs_{30}, defined as :

$$Vs_{30} = \frac{30\text{m}}{\sum_{i=1}^{n} \frac{h_i}{Vs_i}} \tag{1}$$

where h_i and Vs_i is the thickness in m and elastic shear wave velocity of layer i of the n layers of the soil profile.

Ground type	Description	Vs_{30} (m/s)
A	Rock or other rock-like geological formation	>800
B	Deposits of very dense or medium-dense sand, gravel or stiff clay	360-800
C	Deep deposits of dense or medium-dense sand, gravel or stiff clay	180-360
D	Deposits of loose-to-medium cohesionless soil or of soft-to-firm cohesive soil	<180
E	Soil profile consisting of a surface alluvium layer with Vs values of type C or D and thickness varying between 5-20m, underlain by type A soil	

Table 1: Ground type according to Eurocode [1].

3 DATA BASE OF SEISMIC MOTIONS IN GREECE

For the present work, real-time acceleration histories from the most significant recorded seismic events that took place in Greece between 1970 and 2014 were used as a database. Data were obtained from the Internet Site for European Strong-Motion Data (www.isesd.hi.is/). In addition, the seismic recording from the recent earthquake that occurred in Kefalonia on 03/02/2014 of size M≥6.10 [Argostoli, Lixuri, Chavriata], which were not included until recently in the European Strong-Motion Database (ESD) was used. In particular, the filtered acceleration time histories for the horizontal seismic component xx were obtained. The criteria used to select the Database are the magnitude of the earthquake and the maximum acceleration α max≥0.04g.. A total of 50 seismic motions were selected in this manner. Table A1 of the Appendix presents the number of the seismic motion, its name, its station, its date, and its magnitude (Mw). The time histories were analyzed with the seismosignal program [16] the to extract the spectral and temporal parameters. Table A2 of the Appendix presents for each seismic motion, its mean period, its predominant period, its peak acceleration and velocity value (a_{max} and V_{max}), its Arias intensity and its Epicentral distance.

4 NUMERICAL ANALYSES PERFORMED AND TYPICAL RESULTS

The analyses were performed using the coupled sliding dynamic model and associated numerical code proposed by Katsenis et al [13]. The model, illustrated in Fig. 1, considers the 1-dimensional dynamic response of a horizontal soil profile of depth (h_1+h_2) with a slip element at depth h_1. Different shear wave velocities (Vs_1, Vs_2), densities (ρ_1, ρ_2) and damping (λ_1, λ_2) may exist above and below the slip element. The resistance along the slip element is defined by the critical horizontal value at the initial configuration (a_{co}), for which relative movement in only one direction occurs. Thus, the horizontal slip element simulates the seismic displacement of the conventional sliding-block model. The model also simulates the rotation of the slip surface with displacement by adjusting the critical acceleration value (a_c) in terms of the accumulated seismic displacement. For seismic displacement less than about 1m, this effect diminishes when the length of the slip surface is larger than about 1000m. An option also exists where the model also simulates the non-linear shear stress-stain response of the soil profile. The numerical code associated with the numerical model above predicts the final seismic displacement along the slip element (u_f). Furthermore the numerical code predicts the corresponding seismic displacement for the given applied acceleration history and critical acceleration value that the conventional sliding-block model predicts ($u_{f\text{-}rigid}$).

In the present application, the elastic soil profile option of the model [13] was used. In addition a very long slip surface option (10000m) of the model [13] was used and thus a_{co}=a_c. According to Eurocode ground types of table 1, the soil profiles of table 2 were selected. The Vs_1,Vs_2 values correspond to the average ones of each soil profile of table 1, while the density value does not affect considerably the dynamic soil response and the typical value of ρ=2t/m^3 was selected. The damping was taken as λ_1=λ_2=15%, similarly to analyses by [5, 7, 13]. The critical acceleration value a_c was selected in such a way that computed final seismic displacement of the conventional sliding-block case ($u_{f\text{-}sl}$) varies from about 0.05m to about 0.5m. The reason is these are tolerable displacement values for typical structures.

At least five (5) a_c values were selected for each seismic motion and Vs_1,Vs_2 soil profile. For all these cases of soil profiles and a_c values, the 50 seismic motions described in section 2 above were applied and the seismic displacement (u_f) was computed. For comparison

reasons, the seismic displacement for a rigid block for the same applied motion and critical acceleration value ($u_{f\text{-}sb}$) was also estimated. Typical obtained result for seismic motions with high and low a_{max} values for the 4 seismic profiles considered are given in Fig. 2.

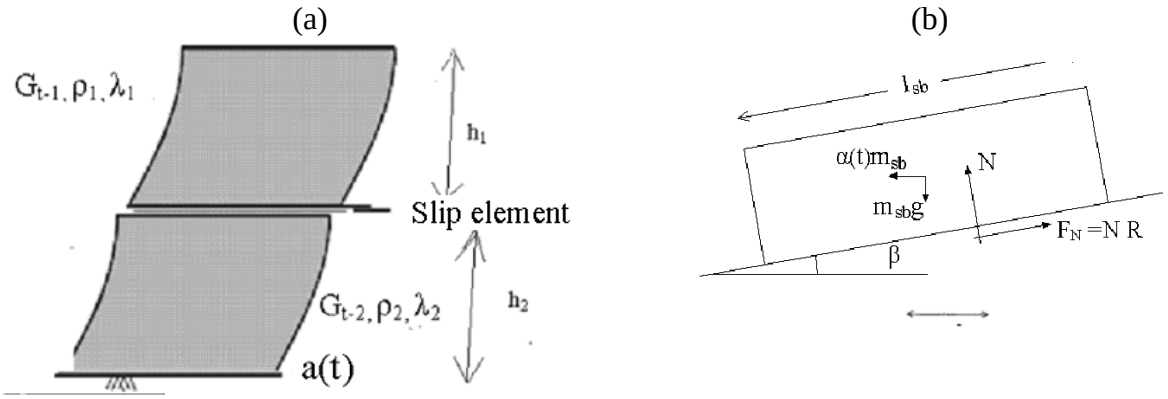

Fig. 1: (a) The dynamic system considered in the present work. The slip element simulates the response of the conventional sliding block model, given in (b).

Ground type	Vs (m/s)	h_1	h_1+h_2	$\rho_1=\rho_2$	$\lambda_1=\lambda_2$	a_{co}
S-B	$Vs_1=Vs_2=580$	5, 10, 20m	30m	2t/m3	0.15	In such a way that computed final seismic displacement along the slip surface (uf) varied from a few mm to tens of cm
S-C	$Vs_1=Vs_2=270$					
S-D	$Vs_1=Vs_2=100$					
S-E	Vs_1=200m/s, Vs_2=1000m/s					

Table 2: Soil profiles assumed in the analysis

5 EMPIRICAL EQUATION: FORM AND DERIVATION AND VALIDATION PROCEDURE

As described in the introduction section, different empirical expressions have been proposed predicting the seismic displacement of the conventional sliding-block model ($u_{f\text{-}rigid}$) in terms of factors such as a_c, a_{max}, Arias intensity, earthquake magnitude etc. In addition, some of these expressions are region-specific. As described above, as different regions have unique earthquake faults and geological profiles characteristic conditions, they have seismic motions of different characteristics and thus different empirical expressions predicting seismic displacement. Region-specific empirical expressions predicting ($u_{f\text{-}rigid}$) in Greece has been proposed by [9].

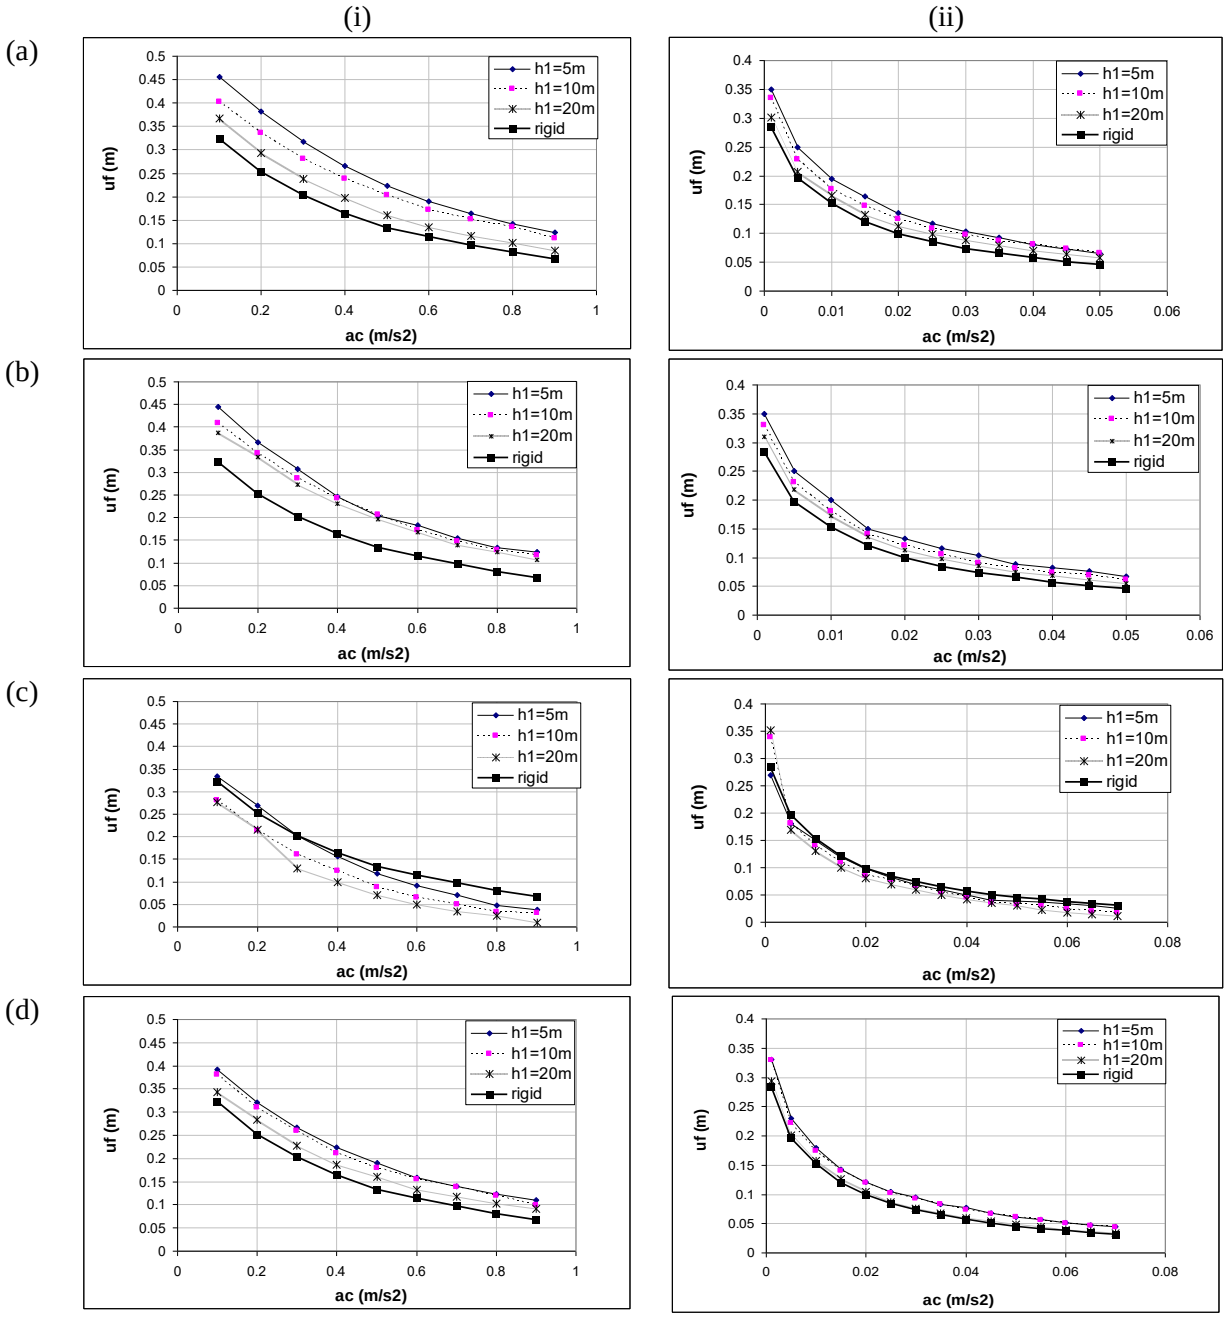

Fig. 2: Typical results for a seismic motion of high and low a_{max} value. Seismic displacement u_f in terms of the critical acceleration value for soil profiles (a) S-B, (b) S-C, (c) S-D, (d) S-E of table 2 for seismic motion (i) S3 and (b) S29 of table A1. The corresponding sliding-block displacement ($\mathbf{u_{f\text{-}rigid}}$) is given in all cases.

For this reason, in order, possibly to omit predicting the effect of factor such as a_c, a_{max}, Arias intensity, earthquake magnitude etc on u_f , we propose just to relate u_f on $u_{f\text{- rigid}}$, where $u_{f\text{- rigid}}$,is predicted with previously proposed equations and the u_f incorporates, additional the dynamic effects of the soil profile both above and below the slip surface. More specifically, we propose the following equation to predict $u_{f.}$:

$$u_f = R\, u_{f\text{-rigid}} \tag{2}$$

Thus,

$$R = u_f / u_{f\text{-rigid}} \tag{3}$$

It is of interest to establish the factors of the soil profile affecting the value of R based on the numerical analyses performed. Fig. 3 gives the ratio R in terms of ($u_{f\text{-rigid}}$) of soil profiles (a) S-B, (b) S-C, (c) S-D, (d) S-E of the analyses of Fig. 2. Preliminary inspections of the obtained results illustrates that R increases or decreases as a_c decreases, and at small a_c value it tends to 1. However, a_c for the design seismic displacement value varies a lot for different seismic motions. For example, according to Fig. 2, for the typical results for a seismic motion of high and low a_{max} value, a_c varies between 0.1-0.9g and 0.002-0.05g This variation is eliminated if the factor R is related to $u_{f\text{-rigid.}}$ Fig. 3 presents the ratio R in terms of ($u_{f\text{-rigid}}$) of soil profiles (a) S-B, (b) S-C, (c) S-D, (d) S-E of table 2 for seismic motion (i) S3 and (b) S29. It can be observed that: R increases or decreases as $u_{f\text{-sb}}$ increases, and at large $u_{f\text{-rigid}}$ value it tends to 1. Furthermore, from Fig 3 we observe that the response depends considerably on the soil type and the height of the depth of slip surface (h1): R takes a considerably less value for soil profile S-D than the other soil profiles and as h_1 increases, R generally decreases.

Based on the above we propose the following equation:

$$R = 1 + a1\, (0.1 / u_{f\text{-rigid}})^{a2} \tag{4}$$

where a1, a2 are model parameters. In particular, a1 gives the factor (R-1) at $u_{f\text{-rigid}}$=0.1m and a2 gives the manner that the factor R changes in terms of $u_{f\text{-sb}}$

Furthermore, based on the observations described above, we propose to relate the parameters a1, a2 of equation (4) with the soil profile type and h_1. For this purpose, the following procedure was followed:

- (a) First, the data base was divided in two parts, one to determine the model parameters (DB1), and the other to validate it (DB2). The data base DB1 is the odd number earthquakes and DB2 is the even number of earthquakes.

- (b) The model parameters n1 and n2 fitting best the results of the numerical analyses are obtained for each numerical analysis case of the data base DB1. Thus, 14 values for each seismic motion, and 12*25=300 in total. The best-fitting is performed under the conditions that the error has zero mean value and minimum standard deviation value. The error of the predictions is defined in the present work as

$$Er = 1 - \text{Predicted/Computed} \tag{5}$$

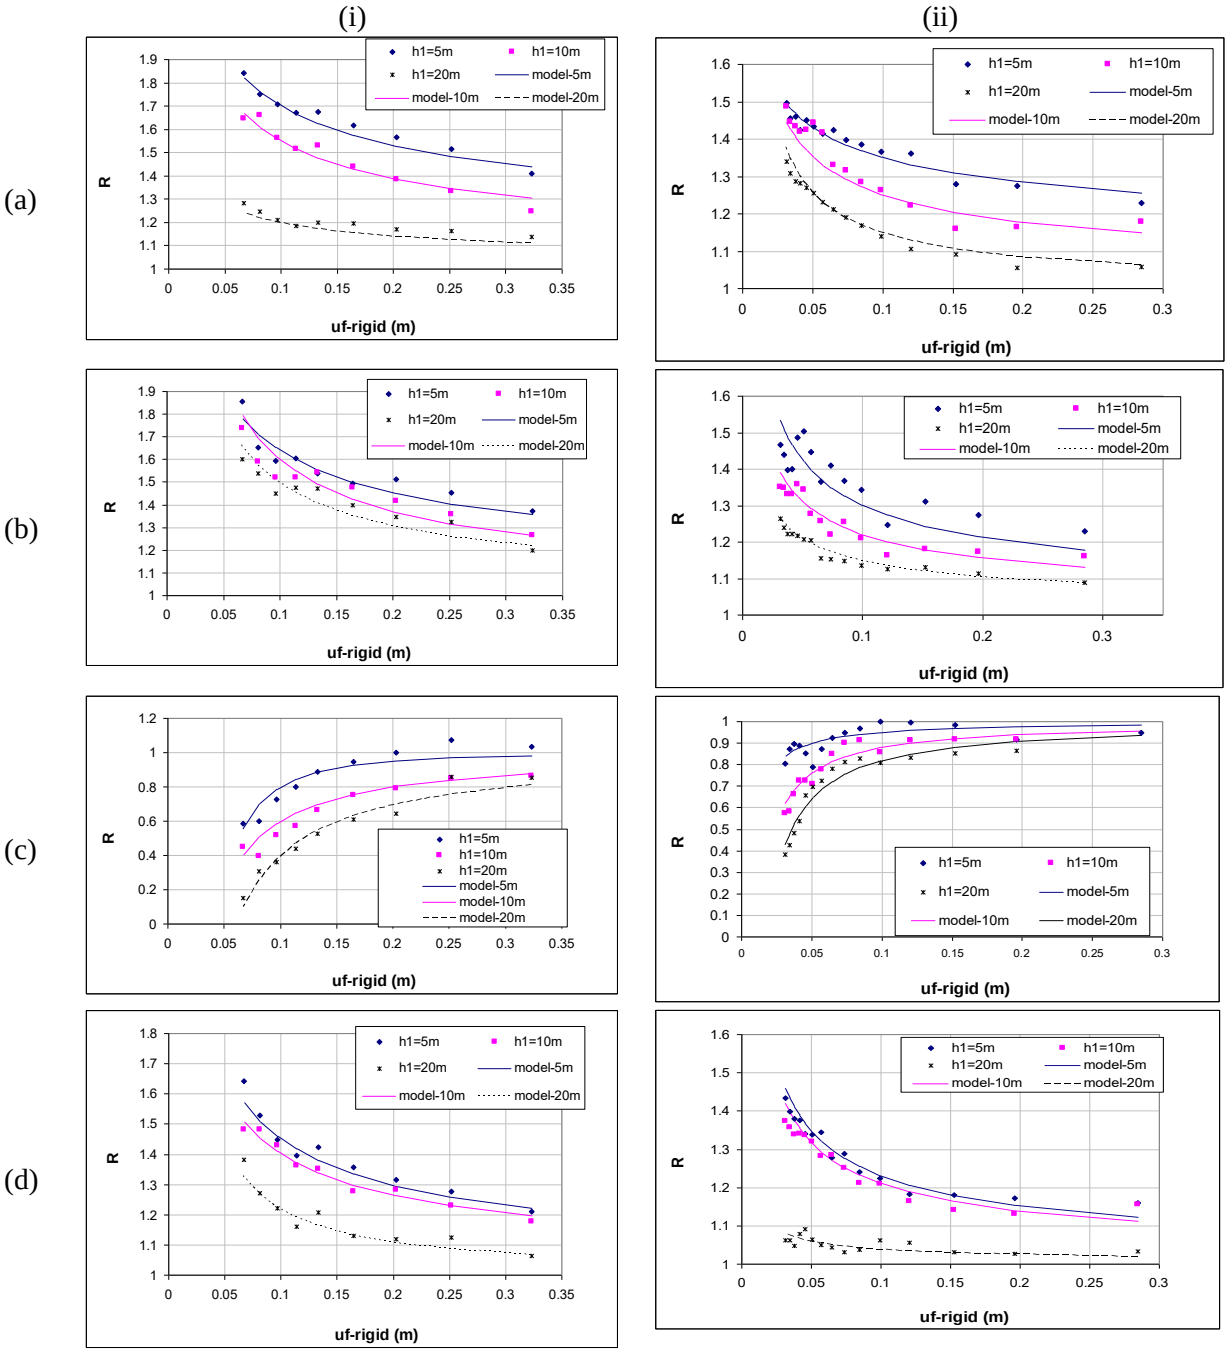

Fig. 3: Ratio R in terms of ($u_{f\text{-}rigid}$) of soil profiles (a) S-B, (b) S-C, (c) S-D, (d) S-E of the analyses of Fig. 2.

- (c) The obtained average parameters a1 and a2 for all earthquakes were statistically analyzed in terms of soil profile and h_1 value (12 cases) in order to derive the effect of soil profile and h_1 on them and propose the empirical expressions predicting R.

- (d) Once these empirical expressions were derived, the database DB2 described above was used to validate the proposed equation. The Error was measured in all 12 cases of the 25 input motions, thus in 12*25=300 cases in total and the mean and standard deviation of the error was established. If the mean and standard deviation values are close to zero, the error is small.

Furthermore, the obtained error for all earthquakes was obtained in terms of soil type and h1 (for 12 cases each time) in order to establish if the accuracy depends on soil type and h1.

6 EMPIRICAL EQUATION: PROPOSAL AND VALIDATION

Based on the procedure described in section 5, Fig. 4 gives the average factors (a) a1, (b) a2 in terms of h1 and the soil profile for the database DB1. It can be observed that, as a first approximation a1 depends on both the soil profile and h1, while a2 depends only on the soil profile. More specifically, regarding the effect of h1 on a1, Fig 5 plots the average factor $\{a1\text{-}a1_{10m}\}$, where $a1_{10m}$ is the a1 value when h1=10m, versus {h1-10m} in terms of the soil profile type. It can be observed that an approximately linear response is observed. Thus, equation (4) can be adjusted as

$$R= 1+ [n1 - n2 (h_1\text{-}10m)] (0.1/ u_{f\text{-}rigid})^{a2} \quad (6)$$

where n1, n2, a2 are parameters which depend on soil type. Finally, Table 3 gives the factors n1, n2, a2 according to Figs 4, 5.

Once the empirical equation (6) with the model parameters of table 3 was established using the database DB1, its error in the predictions of this equation was established using DB2. Considering all the data of DB2, the absolute value mean and standard deviation of the error (equation 5) were estimated as 0.05 and 0.05 respectively. As these values are close to zero, the error is small and acceptable. Furthermore, the obtained error for all earthquakes was obtained in terms of soil type and h_1 as given in table 4. It can be observed that accuracy is less in soil profile S-D.

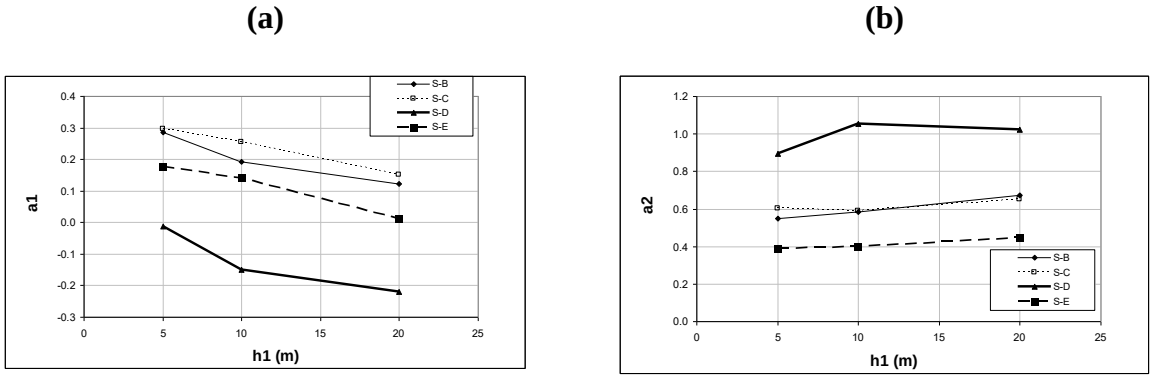

Fig. 4: The average factors (a) a1, (b) a2 in terms of the soil profile type and h1 for DB1.

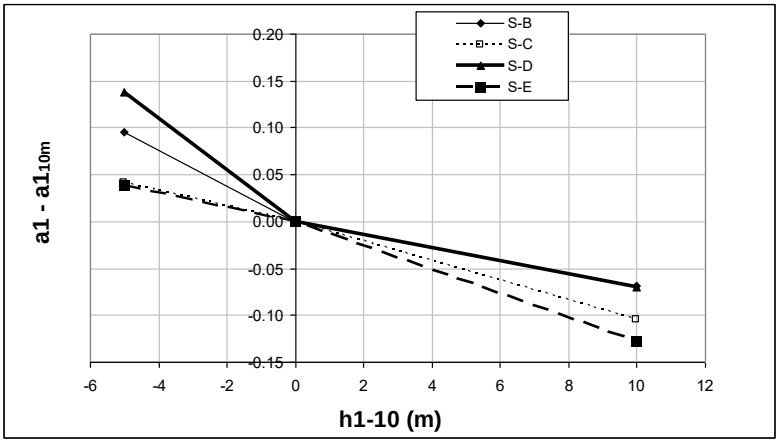

Fig. 5: The average factor a1-a1$_{10m}$ versus (h1-10m) in terms of the soil profile type

Soil type	n1	n2	a2

7 DISCUSSION AND EXAMPLE APPLICATION

The present work proposes the empirical expressions (2) and (6) with the parameters of table 3 relating the seismic displacement along slip surfaces in Greece, in terms of (a) the conventional sliding-block predictions, (b) soil type category according to Eurocode and (c) the depth of the slip surface. As an example application, we consider a site of soil category S-E where the slip surface is at average depth 5m and geotechnical and seismic analysis for bedrock seismic motion characteristics of the site gave ac=0.02g, and design earthquake of magnitude Mw=7.0 at distance R=2km. Equation (13) by [9] predicts an Arias Intensity Ia=17m/s and equation (21) by [9] predicts a corresponding maximum value of seismic displacement with "conventional" sliding-block model $u_{f\text{-}rigid}$=5.1cm. Application of the empirical expressions (6) with the parameters of table 4 would predict that when considering dynamic effects, R=1.26 and the seismic displacement u_f would increase to 6.4cm.

The proposed empirical expressions (2) and (6) assume elastic response of the soil profile and a slip surface with very large length. The proposed expression may be extended to include (a) non-linear response of the soil profile and (b) the effect of the rotation of the slip surface with shear displacement, which is considerable for slip surfaces of small length. Effect (a) may be simulated using for example shear modulus degradation expressions proposed by [17] and effect (b) may be simulated using for example the chain model proposed by [18] . In order to achieve this, numerical analyses of the method [13] should be used considering the above effects. Furthermore, the empirical expressions may be extended for regions other than Greece, by using data bases of seismic motions from these different regions.

8 CONCLUSIONS

- The present work proposes the empirical expressions (4) and (6) with the parameters of table 3 relating the seismic displacement along slip surfaces in Greece, in terms of (a) the conventional sliding-block predictions, (b) soil type category according to Eurocode and (c) the depth of the slip surface.
- These equations were obtained by extensive parametric analyses using a recently developed dynamic coupled numerical code which predicts the seismic displacement of an elastic soil profile along a slip surface at some depth. An extensive data base of seismic motions recorded in Greece was applied below typical soil layers according to Eurocode category type with slip surface at different depths and varying the resistance (as defined by the critical acceleration value) in such a way that computed final seismic displacement of the conventional sliding-block case varies from about 0.05m to 0.5m. The results were analyzed statistically.

Abstract

The dynamic response of composite structures under impact loading conditions is a complex problem which is attracting substantial attention. The case of hailstone impacts introduces additional challenges. Hence, the main goal of this paper is to present recent work towards the development of a computationally efficient impact model that combines a novel phenomenological viscoplastic contact law with a new time domain spectral shear plate finite element including nonlinear effects due to large displacements and rotations. The new viscoplastic contact law, which provides the coupling between the hailstone impactor and the target composite plate, is derived from analytical expressions and observations based on experiments and numerical results. The proposed model simulations are compared with a 3-D continuum explicit FEA model and experimental results from high-velocity spherical hailstone impacts on woven glass/epoxy composite plates, which are conducted in our impact facility. The results demonstrate the efficiency and accuracy of the proposed model.

Keywords: Composite Structures, Hailstone, High-velocity Impact, Time domain spectral elements, Contact Law

1 INTRODUCTION

Composite materials technology is of fundamental importance to current and future aircraft structures where high strength, high stiffness, and integration of multiple functionalities are essential to improve weight, fuel efficiency, CO_2 emissions and safety, and to reduce component complexity and manufacturing costs. However, an issue of particular concern is the vulnerability of composite structures to foreign object damage by small objects, such as hail and tool drop, which may result in unpredictable complex localized damage and a loss of post-impact residual strength [1, 2]

The impact behavior of composite structures is even more complicated at high velocity impacts, which is generally more detrimental to the integrity of composite structures [3], thus setting new challenges for constituent models, computational structural dynamic models and experimental studies. One case of high-velocity impact, which is the driver for the present research, encompasses hailstone impact on composite wing leading edge structures with integrated deicing heating layers, which may create localized, visible or barely visible damage in both composite and heating layers.

A major step in gaining an understanding of the impact problem is the accurate knowledge of impact/contact force. The most typical approach employs detailed 3-D continuum finite element models for the composite structure and the impactor, which results in computationally intense explicit time integration solutions. Though, hailstones are not common materials that can be easily modelled by the use of commercial finite element software. Various FE models that have been developed so far, which are based on material algorithms of Lagrangian FE, ALE or SPH [4–6], have given significantly different predictions [7,8].

In order to address these difficulties, a number of lumped-parameters models have been proposed [9]. This approach employs simplified models for the target structure usually assuming a single-layer laminate theory in the context of a global Ritz, or finite element discretization, and treats the impactor as a concentrated mass with one degree of freedom. The interaction between the impactor and target structure is based on a contact law in the form of force-indentation relationship [10].

The Hertz contact law, developed for perfectly elastic contact between compact bodies, was one of the first models used for impacts at low velocities. However, this model is not adequate for most impacts in practice, as some energy is dissipated due to plastic deformation, wave propagation, and other effects. As an alternative, an elastoplastic contact law was proposed [11] to account for energy losses due to local plastic deformation during impact. One drawback of this model is the fact that it does not account for energy loss duo to wave propagation. To encounter this problem, a number of contact models have been developed with the addition of a damping element, in order to account for energy dissipation during impact [12]. The Hunt-Crossley model gained popularity in recent years and has been used in number of studies [13]. However, the contact parameters are difficult to determine and are usually adjusted on experimental results [14].

This present study moves a step forward and aims to cover a void between numerical, analytical and simplified impact models for hailstone impact in composite structures. This is accomplished by integrating a viscoplastic modified Hunt-Crossley model with well defined parameters that are based on analytical solutions and physical observations, into a novel time domain spectral finite element for the structural dynamics of composite plate structures. In the following sections, the theoretical framework and governing equations of the developed impact model is outlined. The contact law is formulated and its performance is validated with measured data from impact tests on a rigid target [15], and subsequently simulated with 3-D solid explicit finite element models [4].The development and basic features of a time domain spectral finite

element (TDSFE) based on first order shear theory (FSDT) and geometric nonlinearities are presented. The proposed contact law and the TDSFE are integrated in the framework of an explicit time integration scheme, to provide the rapid impact simulation model. Numerical predictions of the model are presented and compared in terms of accuracy and computational speed, with results obtained by explicit 3-D FEA analysis models for impact cases on glass/epoxy plate, and also with experimental results from our impact facility.

2 VISCOPLASTIC CONTACT LAW FOR HAILSTONE

2.1 Ice Material Model

A 3-D continuum finite element model was constructed using the commercial code Abaqus/Explicit to gain deeper and broader insight into the experiments and to establish the capability to conduct virtual testing for various impactor's diameters and velocities. The model of the hailstone projectile and rigid target was built using a Lagrangian mesh. The ice was modeled with solid, reduced integration elements (C3D8R) and the element size was 1 mm. The material model, which was previously developed by Tippmann [4], incorporates a strain rate dependent elastic-plastic yield strength with element failure based on a tensile hydrostatic stress failure criterion (Table 1). The target was modeled as rigid (R3D4) and the contact between the target and the impactor was hard and frictionless (Figure 1).

Material Property	Value
Young's modulus, E (GPa)	9.38
Poisson ratio, ν	0.33
Density, ρ (kg/m^3)	836
Tensile failure pressure (MPa)	0.517
Quasi-static yield strength, σ_{yo} (MPa)	5.2
Rate dependent yield strength	See Table 2

Table 1: Summary of ice material model properties

Stress ratio (σ_y/σ_{y0})	Strain rate (s^{-1})
1	0
1.50	0.5
2.20	5
2.91	50
3.62	500
4.33	5000
5.04	50000
5.75	500000
5.96	1000000

Table 2: Strain rate dependent yield strength

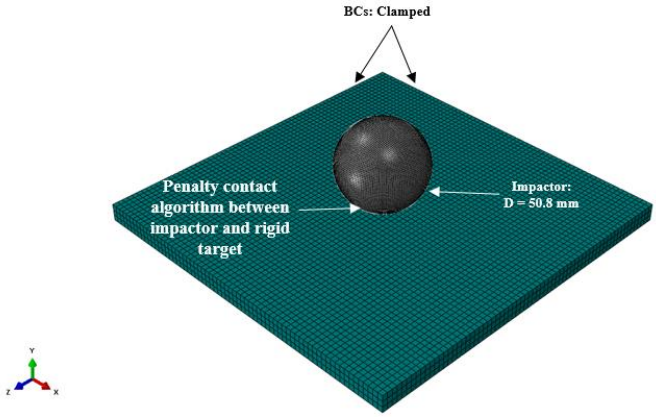

Figure 1: 3-D continuum FE model of hailstone and rigid target.

Simulations were conducted in Abaqus/Explicit and were compared to experimental tests of simulated hail ice impacts on a force measurement bar apparatus for four different velocities [15]. The simulated force-time history results during the ice impact event are in agreement with the experimental data, as shown in Figure 2, ensuring the validity of the ice material model for further virtual testing and physical observation.

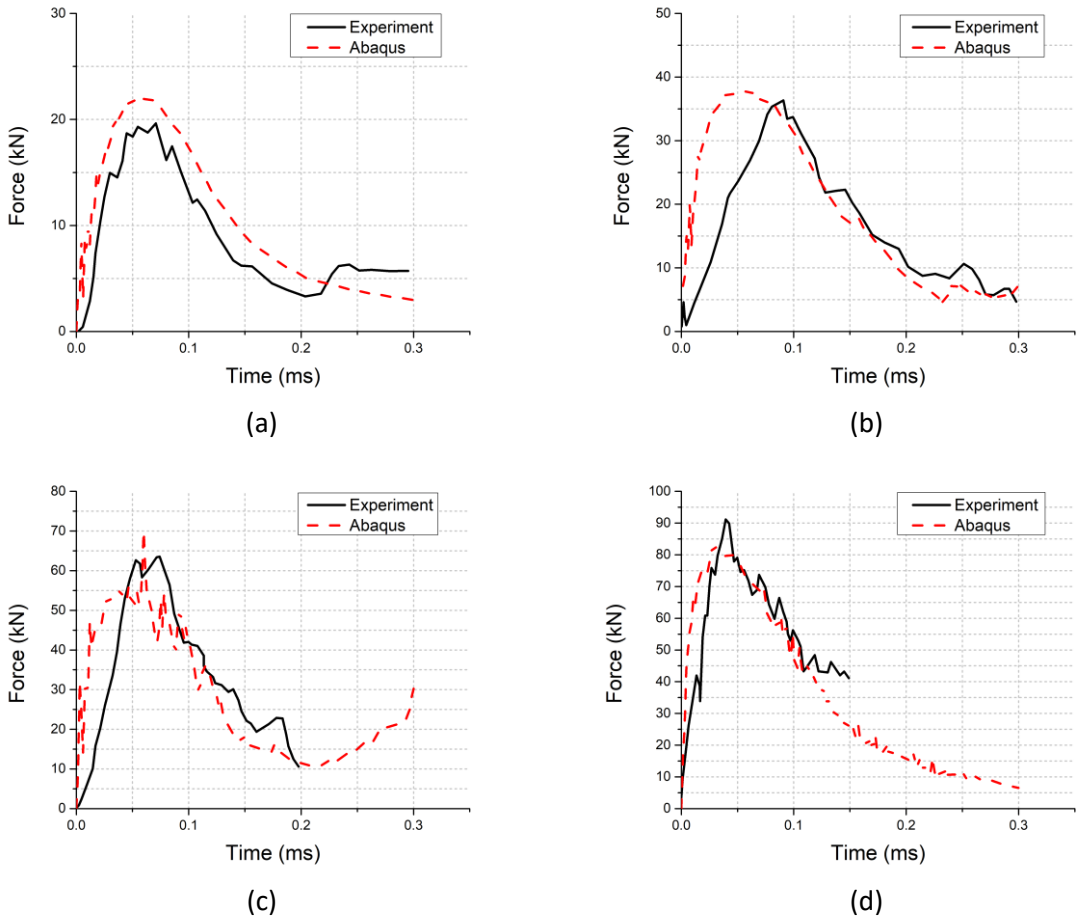

Figure 2: Force-time history for ice-impactor with diameter 50.8 mm at various impact velocities (a) v = 60.6 m/s, (b) v = 107.3 m/s, (c) v = 144.1 m/s, (d) v = 190 m/s.

In the following the Abaqus model simulations will be used as a calibrating virtual testing tool to capture the impact behavior of ice at high velocities using a simple lumped-parameter viscoplastic model.

2.2 Contact Law

Equations of Motion:

The impact between a deformable sphere having an initial velocity v_o with a flat rigid surface can be modeled as shown in Figure 3.

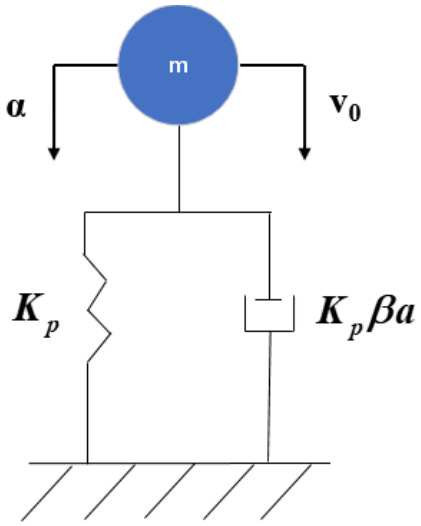

Figure 3: Sketch of the proposed viscoplastic model.

The motion of the sphere is described by,

$$m\ddot{a} = -F \tag{1}$$

where m is the mass of the hailstone, a is the displacement of the hailstone and F is the impact force to be obtained from a contact law given as,

$$F = K_p a(1+\beta\dot{a}) \tag{2}$$

The initial conditions are described as,

$$a(0) = 0, \dot{a}(0) = \dot{a}_0 = v_0 \tag{3}$$

Contact Stiffness (K_p):

In the above equation, K_p is the linear plastic contact stiffness determined by the properties of the contacting sphere and is calculated as,

$$K_p = 2\pi R p_0 \tag{4}$$

where the mean contact pressure is denoted as p_0 and the radius of the impactor as R. It has been shown that the mean contact pressure remains approximately constant when there is substantial damage (fully plastic flow) in the contact area [16], as shown in Figure 4.

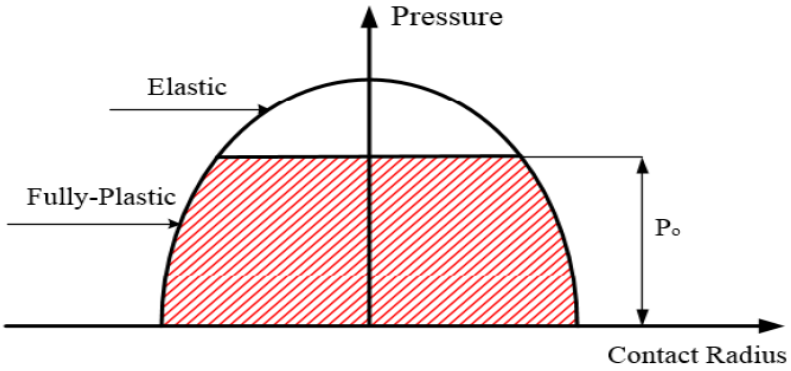

Figure 4: Contact pressure distribution.

The contact pressure is assumed to be equal with the tensile failure pressure of the ice, which is the failure threshold that the deviatoric stresses are set to zero and only hydrostatic stresses are allowed in the element. As shown in Figure 5, after impact, a constant pressure is applied in the elements that have failed (0.517 MPa), ensuring the hypothesis that the mean contact pressure remains approximately constant after failure. Using equation (4) the contact stiffness is calculated as 82.51 kN/m.

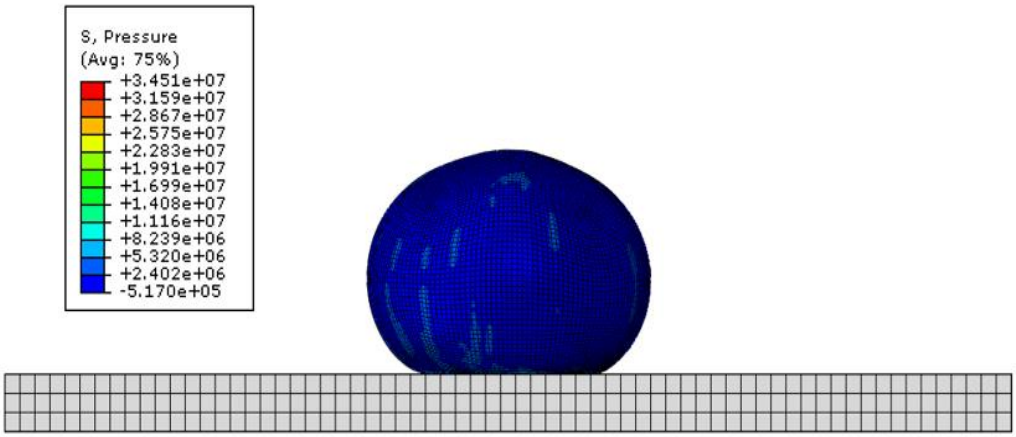

Figure 5: Pressure distribution of hailstone impact on rigid surface after failure.

Dissipation Parameter and Coefficient of Restitution:

Substituting the contact force into the equation of motion, it is easy to show that the impact problem is governed by the following differential equation given as,

$$m\ddot{a} + (K_p \beta a)\dot{a} + K_p a = 0 \tag{5}$$

which is similar to the well known Hunt-Crossley model [12]. Since the contact stiffness K_p is obtained from equation (4), the only parameter that needs to be determined in equation (5) is the dissipation parameter β. Traditionally, this has been done by matching the coefficient of restitution (COR) resulting from this model to the one obtained from experiments. In this study it will be accomplished by matching the COR obtained from Abaqus model simulations, which were shown to correlate well with the available experimental data (Figure 2).

The severity of impact can be assessed by the COR, as it expresses the energy loss in an impact event. Newton's definition for the COR is the easiest as it involves the ratio of the relative velocities of the impactor and the target after and before impact. It is simply given as:

$$COR = -\frac{\dot{a}_f}{\dot{a}_0} \tag{6}$$

Several expressions have been reported in the literature for the dissipation parameter and COR. In the present study, the simplified expression of Garib et al [17] is used, which assumes that at the end of the collision the contact force reduces to zero, but the final indentation velocity is not zero and results in the expression,

$$\beta = \frac{1}{COR\dot{a}_0} \tag{7}$$

It is well known from experiments that the COR is fairly constant for high velocity impact events in most materials (> 40 m/s). In the cases under study all the impact velocities are much higher. Using the Abaqus simulation results for an impact velocity v = 60.6 m/s the COR is estimated to be equal to 0.0078. Using equation (7) the dissipation parameter is obtained as β = 2.11 s/m. Thus, for the rest of the simulations at higher impact velocities, the dissipation parameter for each case is calculated from equation (7) using the same value of COR.

2.3 Time Domain Spectral Finite Element

Kinematic Assumptions:

The contact law described above was combined with a time domain spectral finite element (TDSFE), which was formulated using first order shear plate theory kinematic assumptions,

$$\begin{aligned} \mathbf{u}(\mathrm{x,y,z,t}) &= \mathrm{u}_0 + z\cdot\beta_x \\ \mathbf{v}(\mathrm{x,y,z,t}) &= \mathrm{v}_0 + z\cdot\beta_y \\ \mathbf{w}(\mathrm{x,y,z,t}) &= \mathrm{w}_0 \end{aligned} \tag{8}$$

where u_0 and v_0 denote the in-plane displacements, w_0 the normal displacement, β_x and β_y the in-plane rotations and z the thickness dimension of the plate.

Strain-displacement relation:

Composite structures under high-velocity impact loading exhibit geometrically nonlinear response. Therefore, the Green-Lagrange strains are assumed to have the following form:

$$\begin{aligned} \varepsilon_x &= \boldsymbol{u}_{,x} + \frac{1}{2}\boldsymbol{w}_{,x}^2 \\ \varepsilon_y &= \boldsymbol{v}_{,y} + \frac{1}{2}\boldsymbol{w}_{,y}^2 \\ \varepsilon_{xy} &= (\boldsymbol{u}_{,y} + \boldsymbol{v}_{,x}) + \boldsymbol{w}_{,x}\boldsymbol{w}_{,y} \\ \varepsilon_{yz} &= (\boldsymbol{u}_{,z} + \boldsymbol{w}_{,x}) \\ \varepsilon_{xz} &= (\boldsymbol{v}_{,z} + \boldsymbol{w}_{,y}) \\ \varepsilon_z &= 0 \end{aligned} \tag{9}$$

Finite Element Formulation:

The generalized equations presented in previous section are used as a foundation for developing a multi node plate finite element with C¬0 Lagrange shape functions. Exploitation of high order Lagrangian polynomial shape functions ensures the efficient spatial discretization in the plane of the plate. The nodes of the proposed element are located at Gauss-Lobatto-Legendre (GLL) integration points provided as solutions of the equation $\left(1-\xi_i^2\right)\cdot P_{p,\xi}\left(\xi_i\right)=0$ where $-1\le\xi,\eta\le 1$ is the local coordinate of the element.

Figure 6 shows an 81-node plate time domain spectral element (TDSFE), where the integration points are collocated with the element's nodes, as denoted earlier in the section. The generalized displacement degrees of freedom in the element, are approximated as,

$$\mathbf{U}_L(x,y,t)=\sum_{i=1}^{nodes}\mathbf{N}^i(x,y)\hat{\mathbf{U}}^i(t) \tag{10}$$

where over hat indicates nodal variables, superscript *i* denotes the respective node, and ***N*** is the in-plane shape function matrix.

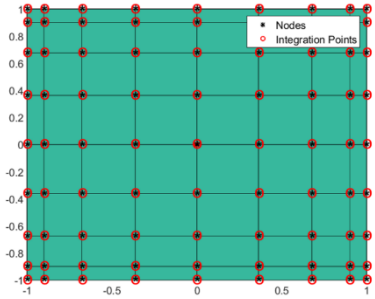

Figure 6: Outline of the developed 81-node plate TDSFE.

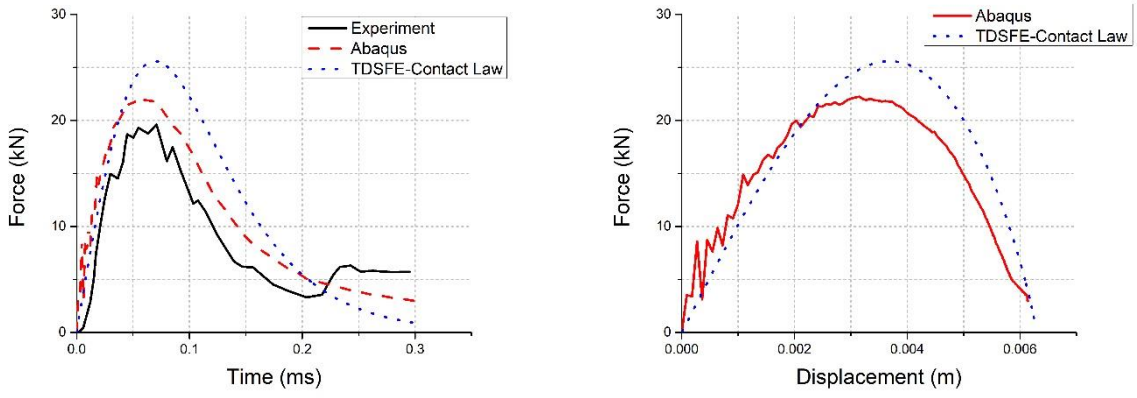
Validation of the Proposed Impact Model:

The capabilities of the proposed contact law combined with the TDSFE were tested for the impact case of a hailstone with diameter of 50.8 mm and velocity 60.6 m/s and the results provide an excellent approximation for both force-time history and force-displacement curve, as shown in Figure 7. As it will be demonstrated, below this case will be used as a calibration for the rest of the impact cases under study with excellent results.



(a) (b)

Figure 7: Validation of the proposed impact model for hailstone impact on rigid target with D = 50.8 mm and v = 60.6 m/s. (a) Force-time curve, (b) Force-displacement curve.

2.4 Contact Law Evaluation for Various Velocities

The proposed impact model is evaluated for three higher impactor velocities with constant COR = 0.0078 which was obtained based on the case shown in Figure 7. As mentioned above, the dissipation parameter for each impactor velocity is calculated using equation (7). As it can be seen in Figure 8, the proposed method captures the impact response of hailstone impact on rigid target quite accurately, demonstrating the validity of the viscoplastic contact law.

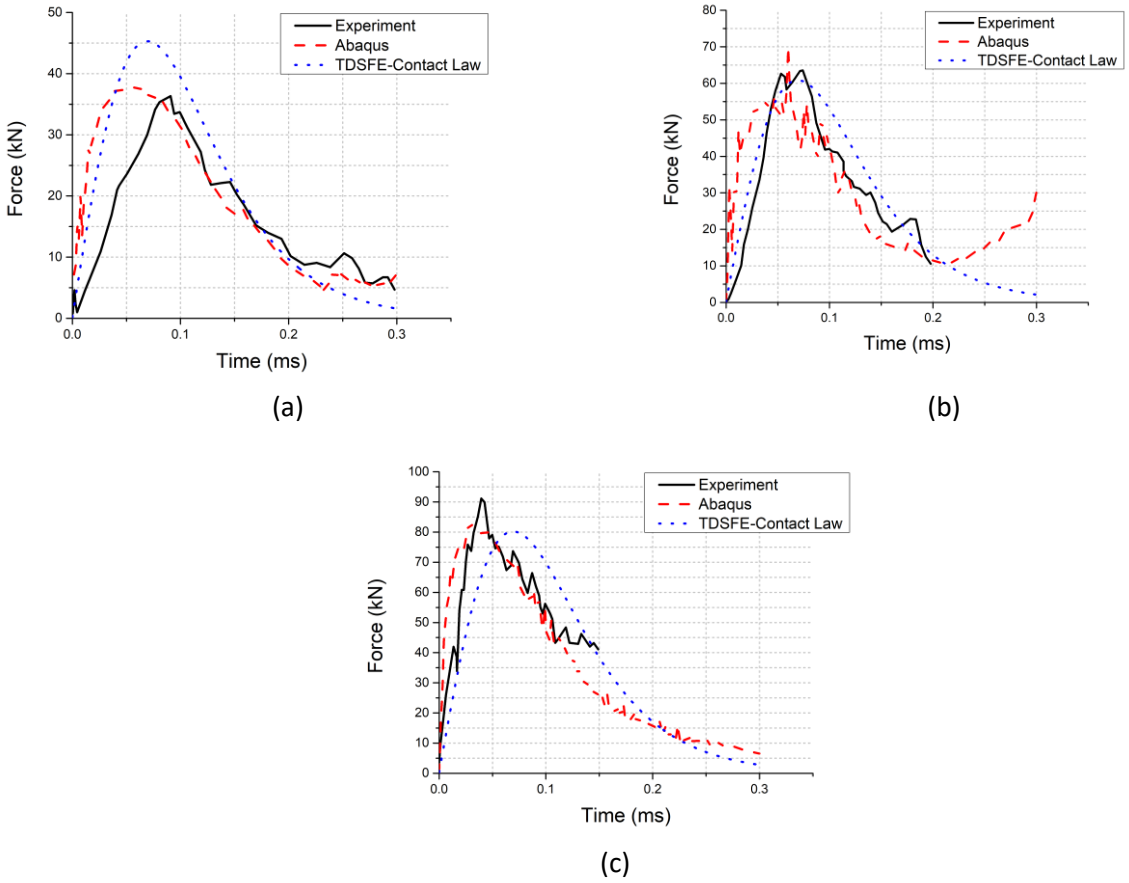


Figure 8: Contact law evaluation for hailstone impact on rigid target with D = 50.8 mm, (a) v = 107.3 m/s, (b) v = 144.1 m/s, (c) v = 190 m/s.

3 EXPERIMENTAL FACILITY

The laboratory is equipped with a functional Impact Test Bench (ITB), which mainly consists of three main parts: **i)** A pre-charged nitrogen gas gun. A sturdy gas gun (Figure 9) with a 10lit pressure vessel, 3m barrel and 60mm diameter bore is capable of launching any spherical projectile up to 50mm diameter and up to 972km/h (velocity was tested & verified for a 25mm diameter ice ball). The repeatability of impactor velocity and trajectory was thoroughly tested and calibrated for each impactor case (for different masses and velocities), in order to achieve accurate results which are further investigated by efficient micromechanical numerical models.

Figure 9: Impact Gas Gun

ii) Measurement devices and supporting apparatus. A high precision digital pressure gauge (Omega DPG1000DAR) for accurate measurements and repeatable impact velocities is located on the vessel. The entire impact event is captured by a high speed camera (Photron SA4) with typical 50k-100k fps capacity (Figure 10Figure 10a) and two chronographs (Chrony M-1) measure both the launching and the penetration velocity at each impact case (b). The impacted structure is monitored using SoA equipment. Strain gauge rosettes (LDT1-028K Piezosensors; high voltage capacity and high strain rate) are used for monitoring target's post-impact response. Sensor signals are captured using NI PXI 6070E at 10k samples/sec. A custom-made LabVIEW VI has also been developed to eliminate human error and ensure that all the apparatus is properly triggered at each impact experiment.

(a) (b)

Figure 10: Measurement devices and supporting apparatus. (a) High-speed camera. (b) Chronographs for measuring launching and penetration velocity.

iii) Non destructive testing apparatus. The lab has access to the Ultrapac II by Mistras Group (Figure 11a), which provides reliable C scans and is used for assesing pre- and post-impact condition of the impacted structures. The post-impact condition (i.e the size of the delaminated area) is schematically validated by micromechanical models. For complex composite structures such as sandwich panels and leading edges, an ultrasonic set-up of pitch-catch is conducted using the Olympus BondMaster 1000e+ (Figure 11b). The bond condition beneath the two probe tips (elements) will affect the characteristics of the acoustic energy that is transmitted between the two tips, hence the device is used for the investigation of delaminations and debondings.

(a) (b)

Figure 11: Non destructive testing apparatus. (a) Ultrapac II by Mistras Group. (b) Olympus Bondmaster.

The ITB was already employed by two Cleansky projects which were efficiently completed. The gas gun has been already employed to perform an adequate number of experiments, using both hailstone and steel projectiles of various diameters, per project requirements. As for the impacted targets, flat plates, thick sandwich plates and leading edges were mounted and successfully tested.

4 HAILSTONE IMPACT ON WOVEN GLASS/EPOXY COMPOSITE PLATES

Initially, virtual impact experiments on a rigid target were performed for hailstone of diameter of 25 mm and various velocities in the range 60.6-190 m/s, as in Section 2, in order to calculate the contact stiffness (40.6 kN/m) and the COR (0.007). After, a series of woven glass/epoxy plates (8 – Harness Satin weave), with properties listed in Table 3, were fabricated by a HexPly 1454/43%/664 with dimensions 300x300x1 mm^3 and lamination $[0/90]_s$. Autoclave processing was used to ensure efficiency and repeatability of the test method.

Material Property	Value
E_{11} (GPa)	23.126
E_{22} (GPa)	20.780
E_{33} (GPa)	12.431
$G_{13} = G_{23}$ (GPa)	2.779
G_{12} (GPa)	3.218
$V_{12} = V_{23}$	0.271
V_{12}	0.116
Density (kg/m^3)	1792
CPT (mm)	0.25
V_f (%)	41.5

Table 3: Mechanical Properties of Glass/Epoxy material.

The test plate was impacted by a hailstone of diameter of 25 mm and velocity of 165 m/s in our impact facility. In parallel, this impact case was modeled in Abaqus/Explicit. The composite plate was modeled with 3-D solid elements with reduced integration (C3D8R) and geometric nonlinearity was considered to capture large displacements and rotations. To ensure an adequate element size and number in the vicinity of contact region, an edge-biased technique was applied with the element size varying from 2 mm to 5 mm away from impact region. The results look very promising, ensuring the validity of the proposed impact model for hailstones of various diameters and velocities (Figure 12). The effect of geometric nonlinearity is shown to be crucial

for the accurate modelling of high-velocity impact on composite structures, as illustrated by the exact predictions of impact force and target displacement.

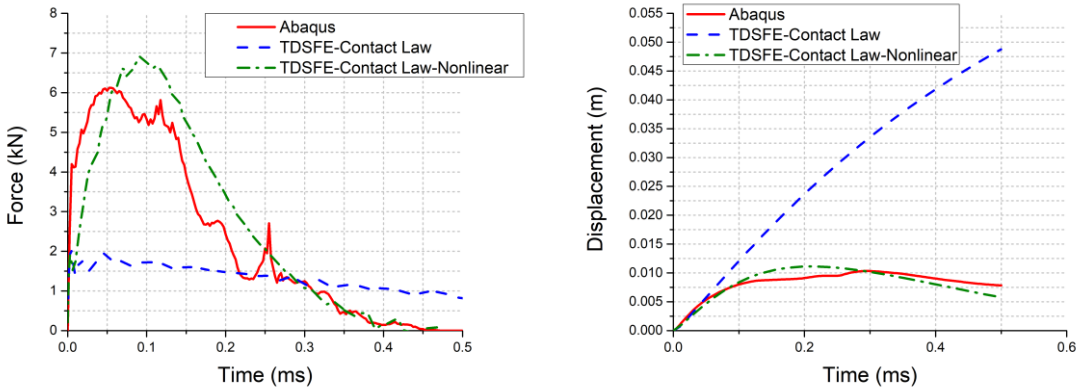

Figure 12: Hailstone impact on woven glass/epoxy laminated plate. (a) Force-history, (b) Target displace

Therefore, screenshots obtained from the high-speed camera illustrate wave excitations which were induced by hailstone impact. Qualitative comparisons of the developed impact model took place and their wavelength was clearly captured (Figure 13). Last but not least, the Abaqus 3-D model requires approximately 2.4 million DOFs, while the TDSFE requires approximately 26 thousands DOFs, accomplishing an over 98% reduction in the size of the required dynamic system.

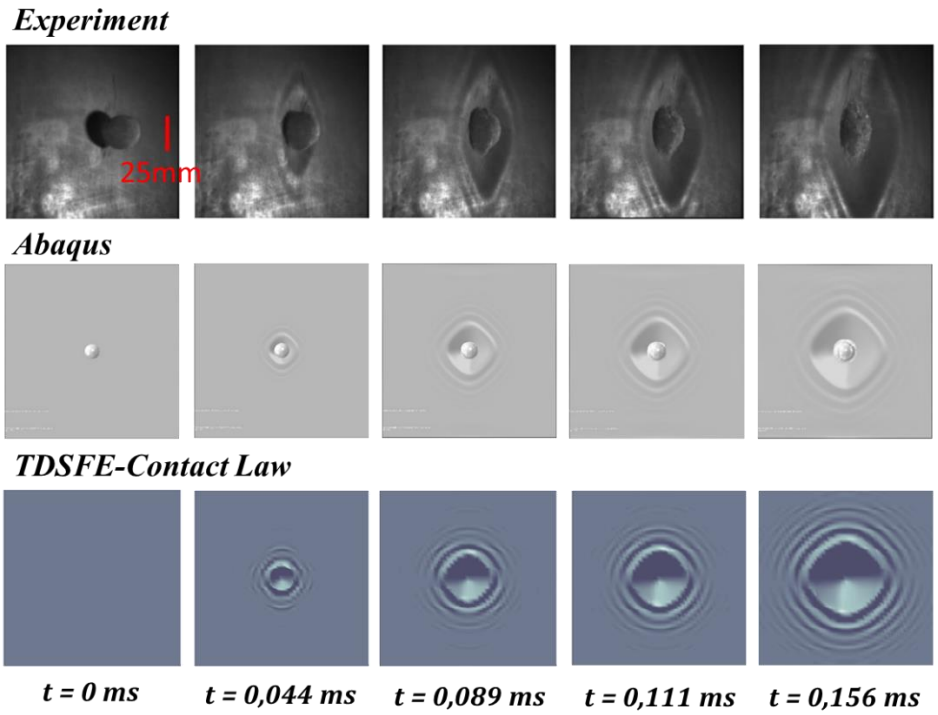

Figure 13: Numerical correlation of screenshots of impact on the glass/epoxy plate [0/90]s 300x300x1mm with 25mm hailstone at 165m/s.

5 CONCLUSIONS

A computationally efficient impact model has been presented, for the simulation of the hailstone impact response of composite laminates, combining a new visccoplastic contact law and a time domain plate spectral finite element with explicit time integration and geometric nonlinearity. The numerical evaluations illustrated very good agreement with experimental and 3-D solid element FEA results for hailstone impact on both rigid and deformable composite targets. In all cases, the impact force and displacement time response were predicted with good accuracy, while the computational efficiency and speed was drastically improved. Finally, it should be noted that the consideration of geometric nonlinearities contributed to the good predictions of impact response.

Abstract

Flow-like landslides are largely studied because they cause damage to the structures and loss of life. In particular, debris avalanches propagate quickly along slopes for hundred meters. This work deals with the dynamic impact of debris avalanches against civil structures. The analyses are carried out through a numerical code implementing the Smoothed Particle Hydrodynamic (SPH) method that has reasonable computational time for the accurate evaluation of kinematical features of the debris avalanches such as heights, velocities and pore water pressures during the propagation stage. The dynamic impact is evaluated for different scenarios of landslides differently triggered inside the source areas. Distinct literature formulations are used to evaluate the impact pressure and its time variation. The numerical results outline the ranges of potential impact pressures on civil structures the threated to be impacted by a debris avalanche. A comparison is also made with critical values of impact pressures recorded in a similar context, and it is outlined the potential damage from such impact scenarios for the existing structures.

Keywords: SPH, structures, landslide, dynamic impact, flow.

1 INTRODUCTION

Flow-like landslides includes several natural phenomena which propagate along the slopes (debris avalanches) or drainage line (debris flows). They are extremely rapid and travel for hundreds of meters with increase of volume during the propagation stage [1]. The attention is here focused on the debris avalanches defined by [2] as "very rapid to extremely rapid shallow flow of partially or fully saturated debris on a steep slope, without confinement in an established channel". Several methods have been used to analyze the propagation of flow-like landslides, e.g. Finite Element Method [3], Finite Difference Method [4], Material Point Method [5]. The "GeoFlow SPH" model (SPH) is used in this paper as it is considered capable to provide a good compromise of accuracy and time efficiency [6-7]. The area of Cervinara (Southern Italy) is selected as case study inside the wider context of the pyroclastic soils originated from the explosive eruptions of the Vesuvius volcano. The slopes facing the municipality of Cervinara are very steep, 35 degrees on average, and are covered by pyroclastic deposits 2-3 m thick [8]. In December 1999 a number of shallow landslides were triggered due to heavy rainfall and propagated as flows. Among these, a debris avalanche turned into a channelized flow and caused 5 victims [9]. Other soil volumes could be potentially triggered and the landslides could reach the piedmont area where several civil structures exist.

The paper proposes some preliminary numerical analyses to outline the ranges of velocity (v) and height (h) of the debris avalanches potentially occurring at specific points of the study area (Fig. 1). Then, the mean impact pressure (p) values are computed by using distinct formulations available in the literature.

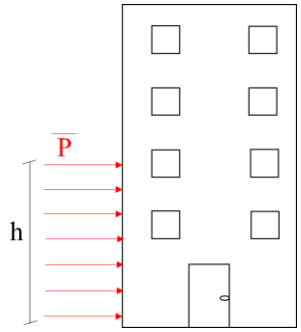

Figure 1: Schematic of the mean impact pressure (p) of a flow characterized by a velocity (v) and a height (h).

2 METHODS

The "GeoFlow_SPH" model proposed by [6] is here used to simulate the propagation pattern of a number of selected debris avalanches. This model is a depth-integrated hydromechanical coupled model that schematizes the propagating mass into a mixture of solid skeleton and pore water. It is based on a set of partial differential equations such as: i) the balance of mass of the mixture combined with the balance off the linear momentum of the pore water pressure; ii) the balance of the linear momentum of the mixture; iii) the rheological equation of the mixture; iv) the kinematical relations between velocity and deformation. The Smoothed Particle Hydrodynamics (SPH) numerical technique is particularly useful to ensure appropriate accuracy and reasonable computational times. More details are provided in [6-10] and [7]. The input data of the model are: the Digital Terrain Model (DTM) where the potential debris avalanches may propagate; the rheological features of the flows, here taken from [8]. Particularly, h_{trig} is the soil thickness in the triggering area; $tan\ \varphi_b$ is the base friction angle of the

flow propagating over the ground surface; h_w^{rel} is the height of the water table relative to the soil thickness in the triggering area; p_w^{rel} is the base pore water pressure divided by the soil liquefaction value; c_v is the soil consolidation coefficient; and E_r is the bed entrainment coefficient regulating the increase of landslide volume. Two set of rheological properties are referred, as taken from successful back-analyses of real debris avalanches occurred at locations not far from the study area, namely Monte Albino ("A" in Tab.1), and Monte Foresta ("F" Tab. 1).

Several potential triggering volumes are considered to propagate over the DTM (Fig. 2b). The peak impact force is calculated in correspondence of buildings (points B1, B2, B3, Fig. 2a) and streets (points S1, S2, Fig. 2a) starting from the height-velocity (*h*-*v*) pairs of the flow and using literature formulations.

Figure 2: a) Cervinara study area (Italy) and b) Digital Terrain Model (DTM) used.

The pressure induced by lateral forces could be very dangerous for structures as showed by [11]. Here, the pressure is considered applied on the structures as constant along the height as a simplification of real distribution during a natural phenomenon (Fig. 1). [12] proposed two formulations that depend on the impact mechanism: i) formation of a completely reflected wave; ii) formation of a vertical bulge; the last formulation depends on both height and velocity and is here considered (Eq. 3 in Tab. 2). [13] carried out real scale tests and laboratory tests to evaluate the impact pressure against rigid barriers and they evaluated the impact introducing an empirical coefficient *k* comprises between 1.5 and 5 (Eqs. 1 and 2, respectively in Tab. 2). Finally, [14] evaluate the impact force as the sum of a static component (height dependent) and a dynamic component (velocity dependent), (Eq. 4). The peak values of pressure versus height are compared with the maximum pressures applied to the structures as function of reinforced; the maximum pressure applied to the structures are taken by [11]. In particular, three reinforce level are considered taking into account a reinforced-concrete column: i)

strongly-reinforced; ii) medium-reinforced; iii) low-reinforced. It is possible to calculate the critical pressure that gives the ultimate bending moment inside the structures as function of flow height.

3 RESULTS AND DISCUSSION

The flow deposition heights are showed in Fig. 3 for both rheology A (Case A20) and rheology F (Case F20). The debris avalanches reach the structures in both cases and they are characterized by a maximum height equal to 1.5 m at the distal part of the flow deposit. The debris avalanche results in greater deposition height for the rheology "A" than for rheology "F" and the affected area is larger for the rheology "A" than rheology" F".

In Fig. 4 the heights and velocities computed in the control points are showed versus time. In correspondence of the structures (points B1 and B2) the flow deposits in both cases; while, the flow does not deposit in correspondence of the streets and the structure at point B3 where the flow height decreases until zero during the propagation stage.

The highest flow deposition height is equal to 6 m and is recorded for rheology A and in correspondence of point B2. The velocities increase quickly until a peak and then decreases down to zero in about 5 seconds. The maximum velocity is recorded in correspondence of the control point B3 for both rheologies (A and F) with the peak value is respectively equal to 16 m/s and 12 m/s. In correspondence of the street, the maximum height is simulated for rheology A and is equal to 3 m while the velocity is the lowest among all the control points and is equal to 1 m/s. The impact pressures are computed versus time considering different control points and rheologies in correspondence of the buildings (Fig. 5).

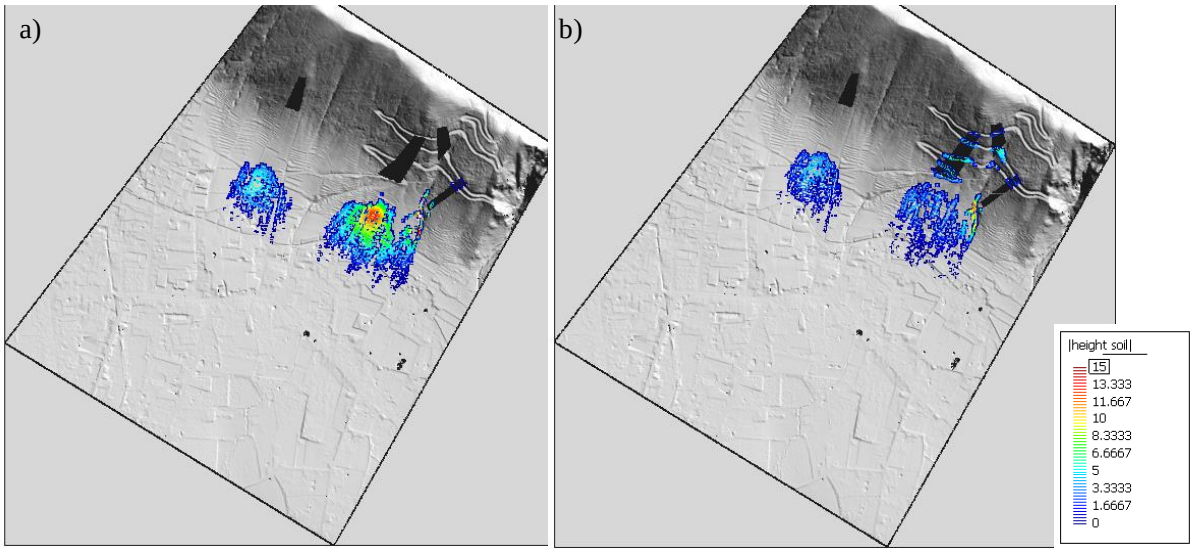

Figure 3: Deposition height of debris avalanche for: a) rheology A; b) rheology F.

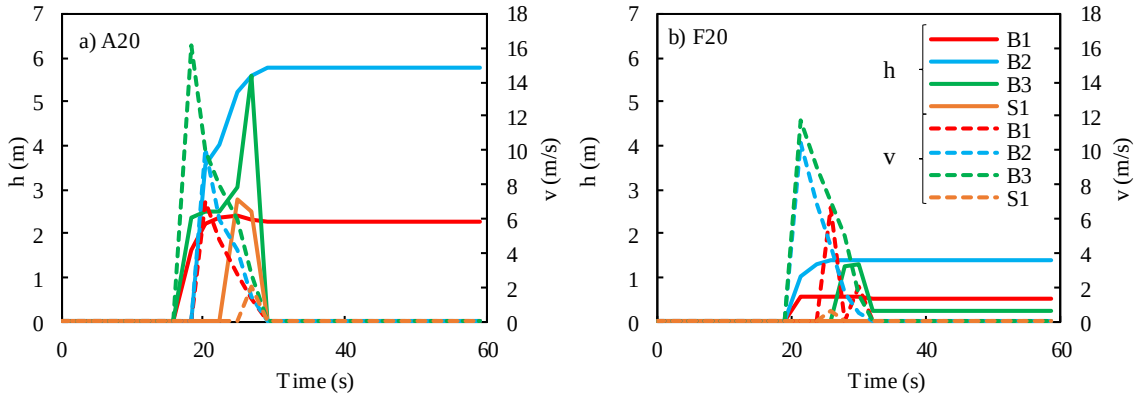

Figure 4: Heights (h) and velocity (v) versus time for a) rheology A and b) rheology F.

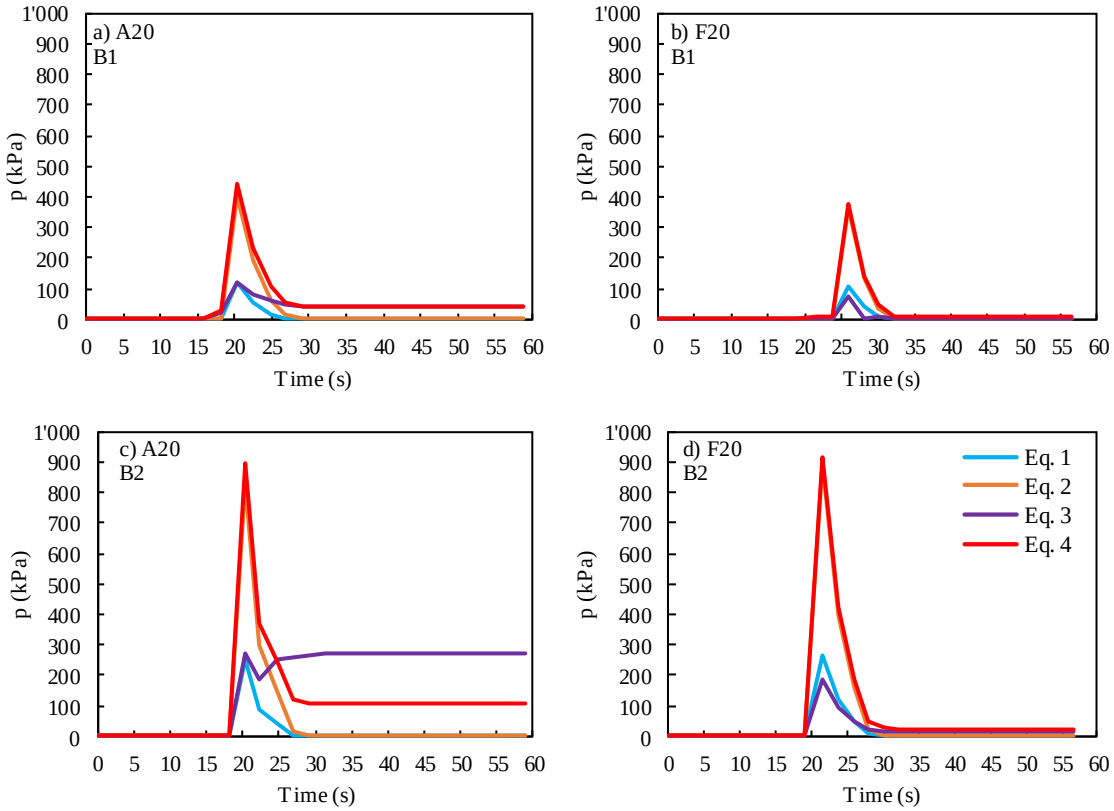

Figure 5: Maximum pressure (p) of the flow versus time in correspondence of the buildings (B1 and B2) for flow rheology A (Case A20, Fig. 5a, c) and rheology F (Case F20, Fig. 5b, d).

The impact pressure increases until a peak value (with the peak time at about 20 s) and then decreases. In general, the dynamic impulse of the pressure has duration less than 10 seconds in all the cases. The pressure decreases down to a constant value calculated through Eqs. 3-4, which are both dependent on height and velocity of the debris avalanche. The impact pressures are comparable for the Case A20 and Case F20. In particular, the maximum peak value is given by Eq. 4 and equal to 900 kPa and 2,000 kPa, respectively in correspondence of the points B2 and B3 (Fig. 6a) for case A20 and equal to 1,000 kPa in correspondence of the same point for case F20. The pressure calculated through the Eqs. 1 and 2 is comparable to the pressure calculated from Eq. 4 considering the maximum value of empirical coefficient k (equal to 5); at the same time, pressure computed through Eq. 1-2 are in agreement with the

pressure calculated through Eq. 3 considering the minimum value of *k* (equal to 1.5). The control point B3 has the highest value of pressure independent of the equation used for computing the pressure impact.

The case A20 presents the highest values of impact pressure in correspondence of the control point B3 (equal to 2,000 kPa) while the maximum impact pressures are comparable between the two rheologies considering the control points B1 and B2.

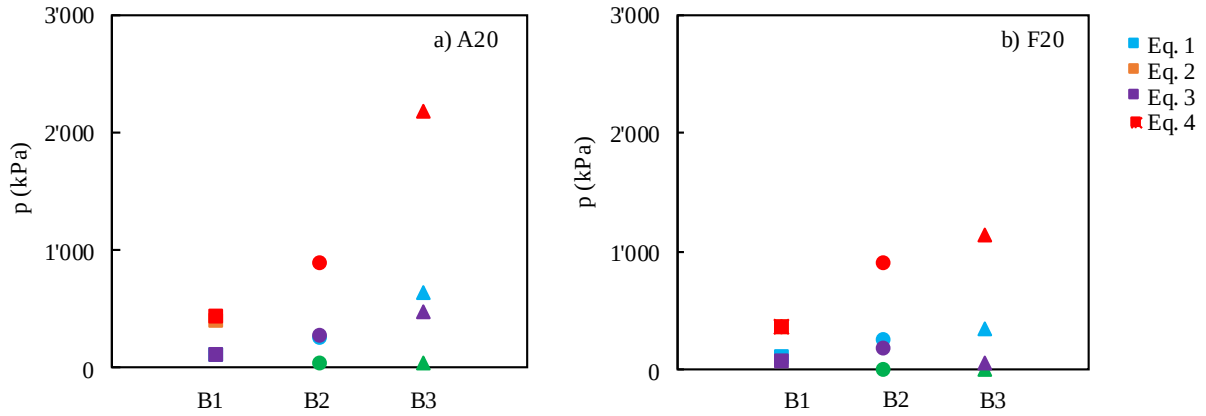

Figure 6: Peak pressure estimated in the different control points (B1, B2, and B3) for: a) flow rheology A; b) flow rheology F.

In Fig. 7, the pressure calculated through literature formulae is showed as function of the impact height and compared with the critical pressure of three levels of reinforced column reported in [11]. It is not possible to identify a critical value of impact pressure, but it is possible to individuate the trend of pressure as function of the impact height. In the case A20 (Fig. 7a), the pressures caused by the debris avalanches are lower than the critical pressure of the strongly-reinforced column for impact height less than 1 m; the medium-reinforced column and low-reinforced column can resist to the impact for values of impact height less than 0.8 m. The impact pressure increases when the impact height increase, then the structures should be not enough resistant for impact height more than 1 m. The strongly-reinforced column resists in correspondence of all control points considering the case F20 (Fig. 7b).

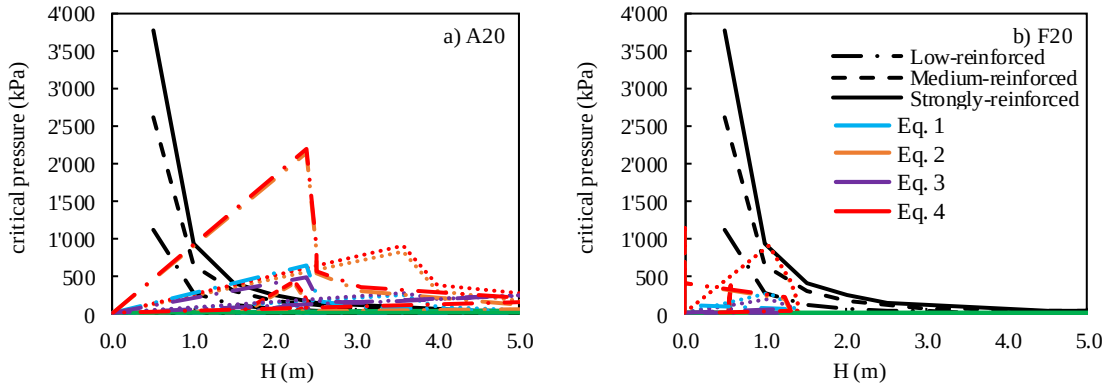

Figure 7: Black lines indicate the critical pressure computed for differently reinforced structures as a function the impact height (*H*) of a debris avalanche. Coloured lines indicated the flow pressure computed through different formulations (Eqs. 1-4) with reference to different control points such as B1 (dashed line), B2 (dots line), B3 (dashed dot line).

4 CONCLUSION

The paper deals with the dynamic phenomena of debris avalanche against structures during the propagation. Two different rheologies are taken into account and the area affected by different debris avalanches is studied; it is shown that the debris avalanches propagate until the urban zone. Then, the pairs of height-velocity are computed in several control points in correspondence of either building (B points) or streets (S points). During the propagation, the flow may produce two different scenarios: i) the height increases until a maximum value and then decreases until a constant value (there is a deposition of material); ii) the height increases until a maximum value and then decreases until a null value; while, the flow-velocities increases until a peak value and then decreases until null value. The impact pressure exerted against the structures is calculated considering distinct literature formulae and starting by the pairs height-velocity previously computed. The pressure versus time increases until the peak value and then decreases following two different trends: i) the flow impacted against the structures and a part of it deposited; in this case the deposition of material exerted a force also after the end of the propagation; ii) the flow propagate without deposition of material in the surrounding of the structure so that the force is null after the propagation of the flow. Finally, the range of maximum pressure are showed for each control point to give some indications to designer on the peak impact pressure due to an event such as a debris flow and take into account the several precautions for the aim taking into account that the peak pressure will be applied for several seconds.

A single critical value of flow pressure against the structure cannot be individuated because the critical pressure is dependent on the impact height. The pressures are plotted versus impact height and compared with the pressure that gives the ultimate bending moment taken by literature in relation to the impact height. The structures taken into account are able to resist to the debris avalanches for impact height less than 1 m in rheology A; while in rheology F, the strongly reinforced column is able to resist in al control points.

5 ACKNOWLEDGEMENTS

Prof. Manuel Pastor (Universidad Politecnica de Madrid, Spain) and co-workers are much acknowledged for having provided the “GeoFlow_SPH” code used for the numerical simulations. The authors wish to thank the Autorità di Bacino Liri-Garigliano e Volturno, which provided the data necessary to develop this work. This research was developed within the framework of different projects: i) Industrial Partnership PhD Course (Dottorato Industriale Regione Campania, Italia); ii) project FARB 2017 “Modellazione numerica e analisi inversa per frane tipo flusso” funded by the Italian Education and Research Ministry.

CONTACT OF VISCOELASTIC SIPED TYRE TREAD BLOCKS ON GRAVEL ROAD

Arne Leenders[1], **Stephanie Kahms**[1], **Matthias Wangenheim**[1]

[1]Institute of Dynamics and Vibration Research
Appelstraße 11, 30167 Hannover
e-mail: {leenders,kahms,wangenheim}@ids.uni-hannover.de

Keywords: multi-body system, tyre tread block, self-contact, viscoelasticity, gravel road, linear complementarity problem, friction, model order reduction.

Abstract. *One focus of modelling the movement of vehicle tyres on the road is the contact of the tread with the road surface. The tread can consist of many blocks, that vary in form and length and can exhibit a siped structure to improve the traction of the tyre on the road, especially for winter tyres. The rotation of the tyre leads to periodical impacts of each tread block into the road surface, which is often uneven. The road can have loose gravel on it or can be covered with grit (icy roads). To simulate the dynamics of a tyre on a gravel road, we suppose to focus on a single tyre tread block. This block gets into frictional contact with the surface, the granular material and also with itself, when the block is siped and the individual lips touch each other. In our model these contact configurations are formulated as linear complementarity problems. The tyre tread is made of an elastomer material, which possesses viscoelastic behaviour.*
With our approach we can simulate the dynamics of a tyre tread block concerning displacement of the gravel, external and self-contact of the tread block's lips. The simulation can help to investigate contact phenomena of a rolling tread for different surfaces and materials.

1 Introduction

Viscoelastic components like tyre tread blocks show elastic as well as viscous properties. They have dissipative character and their deformations are time-dependent [6]. The material's properties vary in temperature and frequency. Many types of rheological models exist to describe viscoelastic behaviour. One of the most established ones are the standard linear solid model and its extension, the generalized Maxwell-Wiechert-model [2, 13, 14]. These models contain components of masses, springs and dashpots, whose parameters can be fitted by experimental measurements.

2 Approach

By extracting stiffness and mass matrices of a tyre tread block out of commercial FEM software and combining them with rheological models for viscoelasticity we get a viscoelastic system of the tread block. The gravel is modelled as an accumulation of single pebbles, that have individual degrees of freedom. The combination of the viscoelastic tread block and the gravel represents a multi-body system, see **figure 1**.

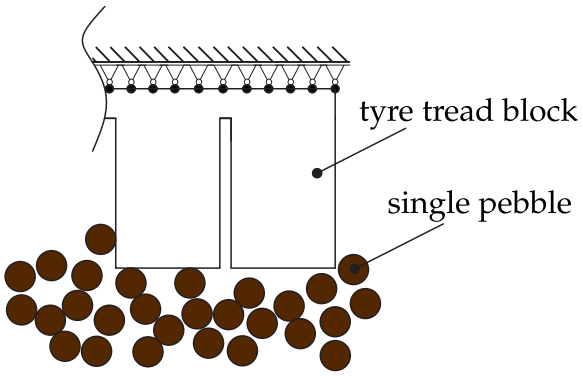

Figure 1: Multi-body system consisting of viscoelastic tread block and granular material

To lower the computational effort of solving the transient deformations of the viscoelastic system different model order reduction techniques can be applied. For our approach a reduction based method, called Craig-Bampton model order reduction, is implemented. This method retains important degrees of freedom (master dof), that are connected to boundaries of the system, where external forces or contact forces affect the structure [10]. The remaining slave dof are reduced and replaced by modal dof.
The occasional contact of the tyre tread into the road has to be considered. This kind of contact can be described by unilateral constraints. All constraints have to be fulfilled for every contact configuration. A mathematical way to solve the equations of motion with unilateral constraints simultaneously is the formulation as a linear complementarity problem (lcp) [8].

3 Mathematical description of viscoelastic multi-body system

The dynamical behaviour of a tyre tread block on gravel road is modelled as a multi-body system consisting of a viscoelastic tyre tread and rigid gravel. The granular material is modelled as rigid bodies as well as the road surface. The surface is modelled as rough and frictional. Including the unilateral contact forces a multi-body system in general can be expressed by:

$$\boldsymbol{M}\ddot{\boldsymbol{q}} + \boldsymbol{D}\dot{\boldsymbol{q}} + \boldsymbol{K}\boldsymbol{q} = \boldsymbol{F}_{\mathrm{ex}} + \boldsymbol{W}_{\mathrm{N}}\boldsymbol{F}_{\mathrm{N}} + \boldsymbol{W}_{\mathrm{T}}\boldsymbol{F}_{\mathrm{T}}\,. \tag{1}$$

The generalized holonomic degrees of freedom of the tread block and the gravel are contained in the vector $\boldsymbol{q}$, while $\boldsymbol{M}, \boldsymbol{D}, \boldsymbol{K}$ label the system's structural matrices of mass, damping and stiffness. The unilateral contact forces in normal and tangential direction $\boldsymbol{F}_{\mathrm{N}}, \boldsymbol{F}_{\mathrm{T}}$ are projected to the differential equations by the transformation matrices $\boldsymbol{W}_{\mathrm{N}}, \boldsymbol{W}_{\mathrm{T}}$. $\boldsymbol{F}_{\mathrm{ex}}$ represents the external forces acting onto the system.
For the viscoelastic standard linear solid model, see **figure 2**, the differential equations of second order yield without contact forces:

$$m\ddot{q} + kq + d_1\dot{y}_1 = F_{\mathrm{ex}}\,, \tag{2}$$

$$d_1\dot{y}_1 = k_1\left(q - y_1\right)\,. \tag{3}$$

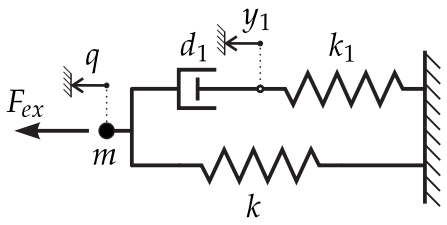

Figure 2: Standard linear solid model

The system of equations of motion can be solved numerically by schemes of time integration or event-based schemes. Time integration can provide faster and more robust solutions than event-based schemes and will be used in our approach [15, 1].
The combination of equations 2,3 would lead to a system of differential equations of third order. Differential equations with orders greater than two need multi-step time integration schemes. These methods use more than the last time step. Especially for contact situations with impacts that occur suddenly, one-step solvers are recommended because prior time steps, that are not affected by impacts, do not affect the results of the recent time step [4]. For this reason the time derivative of equation 3 is replaced by a backward difference quotient:

$$m\ddot{q}_{n+1} + kq_{n+1} + d_1\frac{y_{1,n+1} - y_{1,n}}{\Delta t} = F_{\mathrm{ex},n+1}\,, \tag{4}$$

$$d_1\frac{y_{1,n+1} - y_{1,n}}{\Delta t} = k_1\left(q_{n+1} - y_{1,n+1}\right)\,, \tag{5}$$

$$m\ddot{q}_{n+1} + kq_{n+1} + \underbrace{k_1\frac{d_1}{d_1 + k_1\Delta t}}_{k_{1,\mathrm{ers}}}\,q_{n+1}\,\underbrace{-k_1\frac{d_1}{d_1 + k_1\Delta t}y_{1,n}}_{F_{\mathrm{hist}}} = F_{\mathrm{ex},n+1}\,. \tag{6}$$

The term F_{hist} contains the historic restoring forces, that result from the viscoelastic material formulation.

4 Time-stepping scheme

The multi-body system (gravel and tread block) is solved by the *Newmark* time integration scheme [12]. This method is in particular used for dynamical problems. It contains two parameters β, γ, which control the numerical damping, stability and accuracy of the scheme. The

time-stepping equations are defined as:

$$\dot{\boldsymbol{q}}_{n+1}\left(\ddot{\boldsymbol{q}}_{n+1}\right) = \dot{\boldsymbol{q}}_n + \left[(1-\gamma)\,\ddot{\boldsymbol{q}}_n + \gamma\ddot{\boldsymbol{q}}_{n+1}\right]\Delta t\,, \tag{7}$$

$$\boldsymbol{q}_{n+1}\left(\ddot{\boldsymbol{q}}_{n+1}\right) = \boldsymbol{q}_n + \dot{\boldsymbol{q}}_n\Delta t + \left[\left(\frac{1}{2}-\beta\right)\ddot{\boldsymbol{q}}_n + \beta\ddot{\boldsymbol{q}}_{n+1}\right]\Delta t^2\,. \tag{8}$$

The *Newmark* parameters β, γ can be chosen in the range of $0 \leq \beta \leq \frac{1}{2}$, $0 \leq \gamma \leq 1$ [19]. The stability of the integration scheme is guaranteed for $\gamma \geq \frac{1}{2}\,, \beta \geq \frac{1}{4}\left(\gamma + \frac{1}{2}\right)^2$ [18]. The parameters control the stability and accuracy of the time integration and are chosen in the following as $\gamma = \frac{1}{2}, \beta = \frac{1}{4}$, which is called the Newmark scheme of constant average acceleration [19].

5 Unilateral external and self-contact

The contacts among the different parts of the multi-body system occur occasionally. In case of a contact unilateral constraints in the form of

$$\mathbf{0} \leq \boldsymbol{x} \perp \boldsymbol{z} \geq \mathbf{0} \tag{9}$$

have to be fulfilled simultaneously. A way to handle these constraints with the equations of motion of the dynamical system is the formulation as a linear complementarity problem, the combination of the equation system

$$\boldsymbol{A}\boldsymbol{x} + \boldsymbol{b} = \boldsymbol{z} \tag{10}$$

and the constraint conditions 9. With this kind of contact reaction it is possible to consider nonlinear mechanical effects like friction and impacts for multi-body contact situations with external and self-contact.
The constraints of the unilateral contact has to be divided into normal and tangential contact, see **figure 3**.

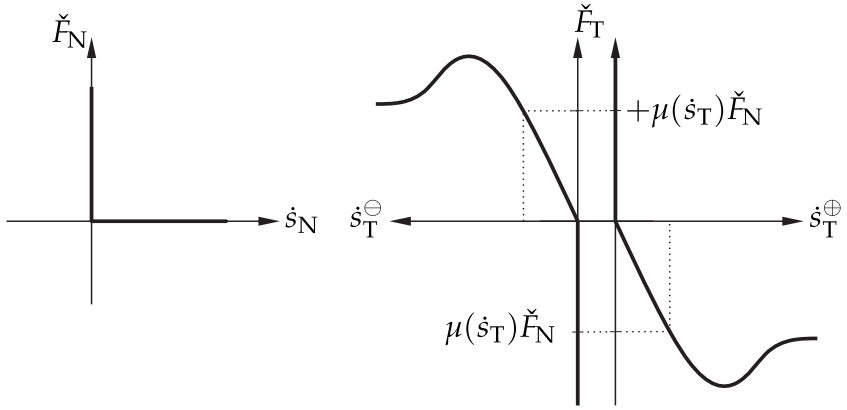

Figure 3: Complementarity conditions of normal and tangential unilateral contact

The normal contact constraint can be formulated by the complementarity condition

$$\mathbf{0} \leq \check{\boldsymbol{F}}_\mathrm{N} \perp \dot{\boldsymbol{s}}_\mathrm{N} \geq \mathbf{0}\,, \tag{11}$$

which means, that the relative velocity between both bodies $\dot{\boldsymbol{s}}_\mathrm{N}$ will be zero, if the contact normal force $\boldsymbol{F}_\mathrm{N}$ is greater than zero and vice versa [8]. Only one of both items can be greater

than zero. By separating the tangential relative velocity $\dot{\boldsymbol{s}}_\mathrm{T}$ into two nonnegative parts for each half space by

$$\dot{\boldsymbol{s}}_\mathrm{T} = \dot{\boldsymbol{s}}_\mathrm{T}^{\oplus} - \dot{\boldsymbol{s}}_\mathrm{T}^{\ominus}\,, \tag{12}$$

one can find complementarity conditions for the tangential unilateral contact in the same way with Coulomb's friction law and the matrix of friction coefficients $\underline{\underline{\boldsymbol{\mu}}}\,(\dot{\boldsymbol{s}}_\mathrm{T})$ [7]:

$$\begin{aligned} \mathbf{0} &\leq +\check{\boldsymbol{F}}_\mathrm{T} + \underline{\underline{\boldsymbol{\mu}}}\,(\dot{\boldsymbol{s}}_\mathrm{T})\,\check{\boldsymbol{F}}_\mathrm{N} \perp \dot{\boldsymbol{s}}_\mathrm{T}^{\oplus} \geq \mathbf{0}\,, \\ \mathbf{0} &\leq -\check{\boldsymbol{F}}_\mathrm{T} + \underline{\underline{\boldsymbol{\mu}}}\,(\dot{\boldsymbol{s}}_\mathrm{T})\,\check{\boldsymbol{F}}_\mathrm{N} \perp \dot{\boldsymbol{s}}_\mathrm{T}^{\ominus} \geq \mathbf{0}\,. \end{aligned} \tag{13}$$

The complementarity conditions and the equations of motion are defined by equations 1, 6, 11 and 13. To set up the entire lcp for contact configurations like impacts, we need an impact law and kinematic relations between the velocities $\dot{\boldsymbol{q}}$ and the gap functions $\dot{\boldsymbol{s}}$. We use Newton's impact law

$$\dot{\boldsymbol{s}}_\mathrm{N,e} = -\underline{\underline{\boldsymbol{\epsilon}}}_\mathrm{N}\dot{\boldsymbol{s}}_\mathrm{N,s}\,, \quad \dot{\boldsymbol{s}}_\mathrm{T,e} = -\underline{\underline{\boldsymbol{\epsilon}}}_\mathrm{T}\dot{\boldsymbol{s}}_\mathrm{T,s} \tag{14}$$

with the subscript 'e' denoting the end of an impact and 's' denoting the start. Because of the time integration the length of an impact is limited to the time step size. For the discretized form of equations 14 the velocities for Newton's impact law are the ones at the time step $n+1$ (end of impact) and time step n (start of impact).
The coefficients of restitution for the normal direction $\underline{\underline{\boldsymbol{\epsilon}}}_\mathrm{N}$ and tangential direction $\underline{\underline{\boldsymbol{\epsilon}}}_\mathrm{T}$ are chosen as zero. This leads to an energy loss for every impact of mass into another but this energy loss is small in contrast to the kinetic and deformation energy of the multi-body system [8, 16]. The advantage of coefficients of restitution being zero is the numerical solution of the contact configuration which is physically compatible. Coefficients greater than zero could lead to unrealistic 'flattering' of the tyre tread block's surface, which means that the masses in contact would oscillate inside the contact region because the contact forces and restoring structural forces of the tread block are accelerating the mass alternately.
The kinematic relations of the normal and tangential gap functions $\dot{\boldsymbol{s}}_\mathrm{N}, \dot{\boldsymbol{s}}_\mathrm{T}$ yield:

$$\dot{\boldsymbol{s}}_\mathrm{N} = \boldsymbol{W}_\mathrm{N}^\mathrm{T}\dot{\boldsymbol{q}} + \hat{\boldsymbol{w}}_\mathrm{N}\,, \quad \dot{\boldsymbol{s}}_\mathrm{T} = \boldsymbol{W}_\mathrm{T}^\mathrm{T}\dot{\boldsymbol{q}} + \hat{\boldsymbol{w}}_\mathrm{T}\,. \tag{15}$$

The items $\hat{\boldsymbol{w}}_\mathrm{N}, \hat{\boldsymbol{w}}_\mathrm{T}$ are the kinematic excitations of the masses within the multi-body system, e.g. due to cycloid movement of the tread block [8]. Using the equations of motion for the multi-body system on velocity level leads to

$$\int_{t_\mathrm{s}}^{t_\mathrm{e}} \left(\boldsymbol{M}\ddot{\boldsymbol{q}} - \boldsymbol{D}\dot{\boldsymbol{q}} - \boldsymbol{K}\boldsymbol{q} - \boldsymbol{W}_\mathrm{N}\boldsymbol{F}_\mathrm{N} - \boldsymbol{W}_\mathrm{T}\boldsymbol{F}_\mathrm{T}\right)\mathrm{d}t = \mathbf{0}\,, \tag{16}$$

$$\boldsymbol{M}\left(\dot{\boldsymbol{q}}_{\mathrm{n}+1} - \dot{\boldsymbol{q}}_\mathrm{n}\right) - \boldsymbol{D}\dot{\boldsymbol{q}}\Delta t - \boldsymbol{K}\boldsymbol{q}\Delta t - \boldsymbol{W}_\mathrm{N}\check{\boldsymbol{F}}_\mathrm{N} - \boldsymbol{W}_\mathrm{T}\check{\boldsymbol{F}}_\mathrm{T} = \mathbf{0}\,, \tag{17}$$

by integrating equation 1.
With the use of the definitions of the nonnegative impulses

$$\check{\boldsymbol{F}}_\mathrm{T}^{\oplus} = +\check{\boldsymbol{F}}_\mathrm{T} + \underline{\underline{\boldsymbol{\mu}}}\,(\dot{\boldsymbol{s}}_\mathrm{T})\,\check{\boldsymbol{F}}_\mathrm{N}\,, \tag{18}$$

$$\check{\boldsymbol{F}}_\mathrm{T}^{\ominus} = -\check{\boldsymbol{F}}_\mathrm{T} + \underline{\underline{\boldsymbol{\mu}}}\,(\dot{\boldsymbol{s}}_\mathrm{T})\,\check{\boldsymbol{F}}_\mathrm{N}\,, \tag{19}$$

and the summation of both equations

$$\check{\boldsymbol{F}}_\mathrm{T}^{\ominus} = 2\underline{\underline{\boldsymbol{\mu}}}\,(\dot{\boldsymbol{s}}_\mathrm{T})\,\check{\boldsymbol{F}}_\mathrm{N} - \check{\boldsymbol{F}}_\mathrm{T}^{\oplus}\,, \tag{20}$$

the entire complementarity conditions yield:

$$\mathbf{0} \leq \dot{\boldsymbol{s}}_{\mathrm{n+1}} = \begin{bmatrix} \dot{\boldsymbol{s}}_{\mathrm{N}} \\ \dot{\boldsymbol{s}}_{\mathrm{T}}^{\oplus} \\ \check{\boldsymbol{F}}_{\mathrm{T}}^{\ominus} \end{bmatrix} \perp \begin{bmatrix} \check{\boldsymbol{F}}_{\mathrm{N}} \\ \check{\boldsymbol{F}}_{\mathrm{T}}^{\oplus} \\ \dot{\boldsymbol{s}}_{\mathrm{T}}^{\ominus} \end{bmatrix} = \check{\boldsymbol{F}} \geq \mathbf{0}\,. \tag{21}$$

Combining equation 6, written in matrix form to include all masses of the multi-body system and containing the contact forces, with the Newmark equations 8 leads to:

$$\boldsymbol{M}\ddot{\boldsymbol{q}}_{\mathrm{n+1}} + \boldsymbol{K}\boldsymbol{q}_{\mathrm{n+1}} + \boldsymbol{K}_{\mathrm{1,ers}}\boldsymbol{q}_{\mathrm{n+1}} = \boldsymbol{F}_{\mathrm{ex,n+1}} + \boldsymbol{F}_{\mathrm{hist,n}} + \boldsymbol{W}_{\mathrm{N,n+1}}\boldsymbol{F}_{\mathrm{N,n+1}} + \boldsymbol{W}_{\mathrm{T,n+1}}\boldsymbol{F}_{\mathrm{T,n+1}}\,, \tag{22}$$

$$\begin{aligned} \underbrace{\left[\boldsymbol{M} + \left(\boldsymbol{K} + \boldsymbol{K}_{\mathrm{1,ers}}\right)\beta_{\mathrm{lcp}}\Delta t^2\right]}_{\boldsymbol{M}_{\mathrm{ers}}}\ddot{\boldsymbol{q}}_{\mathrm{n+1}} &= \boldsymbol{F}_{\mathrm{ex,n+1}} + \boldsymbol{F}_{\mathrm{hist,n}} + \boldsymbol{W}_{\mathrm{N,n+1}}\boldsymbol{F}_{\mathrm{N,n+1}} + \boldsymbol{W}_{\mathrm{T,n+1}}\boldsymbol{F}_{\mathrm{T,n+1}} \\ &\quad - \underbrace{\left(\boldsymbol{K} + \boldsymbol{K}_{\mathrm{1,ers}}\right)}_{\boldsymbol{K}_{\mathrm{ers}}} \underbrace{\left(\boldsymbol{q}_n + \dot{\boldsymbol{q}}_n\Delta t + \left(\frac{1}{2} - \beta_{\mathrm{lcp}}\right)\ddot{\boldsymbol{q}}_n\Delta t^2\right)}_{\boldsymbol{q}_{\mathrm{n,ers}}}\,, \end{aligned} \tag{23}$$

$$\begin{aligned} \dot{\boldsymbol{q}}_{n+1} = \underbrace{\dot{\boldsymbol{q}}_n + \left(1 - \gamma_{\mathrm{lcp}}\right)\Delta t\ddot{\boldsymbol{q}}_n}_{\dot{\boldsymbol{q}}_{\mathrm{n,ers}}} + \gamma_{\mathrm{lcp}}\Delta t\ddot{\boldsymbol{q}}_{n+1}\boldsymbol{M}_{\mathrm{ers}}^{-1}\Big[\boldsymbol{F}_{\mathrm{ex,n+1}} \ldots \\ + \boldsymbol{F}_{\mathrm{hist,n}} + \boldsymbol{W}_{\mathrm{N,n+1}}\boldsymbol{F}_{\mathrm{N,n+1}} + \boldsymbol{W}_{\mathrm{T,n+1}}\boldsymbol{F}_{\mathrm{T,n+1}} - \boldsymbol{K}_{\mathrm{ers}}\boldsymbol{q}_{\mathrm{n,ers}}\Big]\,. \end{aligned} \tag{24}$$

This additional Newmark parameters $\beta_{\mathrm{lcp}}, \gamma_{\mathrm{lcp}}$ only exist for the lcp. These parameters control the stability of the calculation. We choose $\beta_{\mathrm{lcp}} = 0.5$ and $\gamma_{\mathrm{lcp}} = 1$ to stabilize the calculation by introducing numerical damping. With the kinematic relations 15, the abbreviations 18-20 and the identities $\check{\boldsymbol{F}}_{\mathrm{N}} = \boldsymbol{F}_{\mathrm{N}}\Delta t\,, \check{\boldsymbol{F}}_{\mathrm{T}} = \boldsymbol{F}_{\mathrm{T}}\Delta t$ the final equation system yields:

$$\begin{aligned} \begin{bmatrix} \dot{\boldsymbol{s}}_{\mathrm{N}} \\ \dot{\boldsymbol{s}}_{\mathrm{T}}^{\oplus} \\ \check{\boldsymbol{F}}_{\mathrm{T}}^{\ominus} \end{bmatrix} &= \begin{bmatrix} \gamma_{\mathrm{lcp}}\boldsymbol{W}_{\mathrm{N}}^{\mathrm{T}}\boldsymbol{M}_{\mathrm{ers}}^{-1}\left(\boldsymbol{W}_{\mathrm{N}} - \boldsymbol{W}_{\mathrm{T}}\underline{\underline{\boldsymbol{\mu}}}\left(\dot{\boldsymbol{s}}_{\mathrm{T}}\right)\right) & \gamma_{\mathrm{lcp}}\boldsymbol{W}_{\mathrm{N}}^{\mathrm{T}}\boldsymbol{M}_{\mathrm{ers}}^{-1}\boldsymbol{W}_{\mathrm{T}} & \mathbf{0} \\ \gamma_{\mathrm{lcp}}\boldsymbol{W}_{\mathrm{T}}^{\mathrm{T}}\boldsymbol{M}_{\mathrm{ers}}^{-1}\left(\boldsymbol{W}_{\mathrm{N}} - \boldsymbol{W}_{\mathrm{T}}\underline{\underline{\boldsymbol{\mu}}}\left(\dot{\boldsymbol{s}}_{\mathrm{T}}\right)\right) & \gamma_{\mathrm{lcp}}\boldsymbol{W}_{\mathrm{T}}^{\mathrm{T}}\boldsymbol{M}_{\mathrm{ers}}^{-1}\boldsymbol{W}_{\mathrm{T}} & \boldsymbol{I} \\ 2\underline{\underline{\boldsymbol{\mu}}}\left(\dot{\boldsymbol{s}}_{\mathrm{T}}\right) & -\boldsymbol{I} & \mathbf{0} \end{bmatrix} \begin{bmatrix} \check{\boldsymbol{F}}_{\mathrm{N}} \\ \check{\boldsymbol{F}}_{\mathrm{T}}^{\oplus} \\ \dot{\boldsymbol{s}}_{\mathrm{T}}^{\ominus} \end{bmatrix} \ldots \\ &\quad + \begin{bmatrix} \boldsymbol{W}_{\mathrm{N}}^{\mathrm{T}}\left[\dot{\boldsymbol{q}}_{\mathrm{n,ers}} + \gamma_{\mathrm{lcp}}\Delta t\boldsymbol{M}_{\mathrm{ers}}^{-1}\left(\boldsymbol{F}_{\mathrm{ex,n+1}} + \boldsymbol{F}_{\mathrm{hist,n}} - \boldsymbol{K}_{\mathrm{ers}}\boldsymbol{q}_{\mathrm{n,ers}}\right)\right] + \hat{\boldsymbol{w}}_{\mathrm{N}} \\ \boldsymbol{W}_{\mathrm{T}}^{\mathrm{T}}\left[\dot{\boldsymbol{q}}_{\mathrm{n,ers}} + \gamma_{\mathrm{lcp}}\Delta t\boldsymbol{M}_{\mathrm{ers}}^{-1}\left(\boldsymbol{F}_{\mathrm{ex,n+1}} + \boldsymbol{F}_{\mathrm{hist,n}} - \boldsymbol{K}_{\mathrm{ers}}\boldsymbol{q}_{\mathrm{n,ers}}\right)\right] + \hat{\boldsymbol{w}}_{\mathrm{T}} \\ \mathbf{0} \end{bmatrix}\,. \end{aligned} \tag{25}$$

The most time-consuming task during the contact simulation is the contact detection because of the different detection routines for external and self-contact. Especially the identification of undercuts and beadings within the self-contact detection routine requires particular attention. All contacts, which are found within one time step, are sorted in the following particular order: Self-contacting masses (superscript 'self') of the viscoelastic block are taken into account first, then all contacts of the viscoelastic body (superscript 'visco') with gravel or the road and last all contacts among the solid bodies (superscript 'sb') are considered:

$$\boldsymbol{W}_{\mathrm{N/T}}^{\mathrm{T}} = \begin{bmatrix} \boldsymbol{W}_{\mathrm{N/T}}^{\mathrm{self}} & \boldsymbol{W}_{\mathrm{N/T}}^{\mathrm{visco}} & \boldsymbol{W}_{\mathrm{N/T}}^{\mathrm{sb}} \end{bmatrix}^{\mathrm{T}} \tag{26}$$

The viscoelastic tyre tread block is forced kinematically onto a cycloid, that is typical for a rolling movement of a tyre. The kinematic excitations of all masses of the viscoelastic body are cycloids with individual radii for all mass points. The solid bodies are not excited. For each contact pair the different material properties have to be considered. That means the coefficients of restitution and the friction coefficients can be set differently for each body pair. The final lcp 21,25 then is solved by the pivoting Lemke algorithm [11].

6 Model order reduction

The computational effort of the contact detection and solving the lcp can be high, because the contact configurations can change every time step and the amount of variables of the lcp varies. To lower the computation time, the *Craig-Bampton* model order reduction is implemented [3]. This method reduces the number of physical dof by selected nodes, that are important to describe the system's behaviour [9]. With an efficient choice of the dof the accuracy of the solution remains high [5, 17]. Every single pebble is modelled as a rigid body that only contains two translational and one rotational dof. Those dof can not be reduced. The tyre tread block is represented by a system of coupled nodes, that can be divided into surface nodes and inner nodes inside the tread block. The surface nodes, see **figure 4**, are partly affected by boundaries or contact to surrounding bodies.

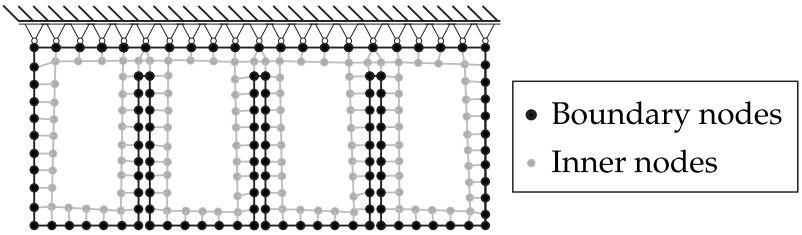

Figure 4: Definition of master and slave nodes for applying Craig-Bampton model order reduction

The surface nodes are defined here as the master nodes, whose dof are retained. The Craig-Bampton-reduction is a combined static-modal reduction. The inner nodes, defined as the slave nodes, are replaced by a selected number of modal dof of the inner system. Sorting the generalized holonomic coordinates, the vector $\boldsymbol{q}$ can be written as $\boldsymbol{q} = [\boldsymbol{q}_\mathrm{M}\ \boldsymbol{q}_\mathrm{S}]^\mathrm{T}$, where the subscripts 'M' and 'S' denote the master and slave coordinates. The equations of motion for the multibody system for the undamped case without contact then read as

$$\begin{bmatrix} \boldsymbol{M}_\mathrm{MM} & \boldsymbol{M}_\mathrm{MS} \\ \boldsymbol{M}_\mathrm{SM} & \boldsymbol{M}_\mathrm{SS} \end{bmatrix} \begin{bmatrix} \ddot{\boldsymbol{q}}_\mathrm{M} \\ \ddot{\boldsymbol{q}}_\mathrm{S} \end{bmatrix} + \begin{bmatrix} \boldsymbol{K}_\mathrm{MM} & \boldsymbol{K}_\mathrm{MS} \\ \boldsymbol{K}_\mathrm{SM} & \boldsymbol{K}_\mathrm{SS} \end{bmatrix} \begin{bmatrix} \boldsymbol{q}_\mathrm{M} \\ \boldsymbol{q}_\mathrm{S} \end{bmatrix} = \begin{bmatrix} \boldsymbol{F}_\mathrm{M} \\ \boldsymbol{F}_\mathrm{S} \end{bmatrix} . \tag{27}$$

The slave nodes are selected in a way, that they are not affected by external or contact forces. Therefore the inner forces yield $\boldsymbol{F}_\mathrm{S} = \boldsymbol{0}$, which leads to the dependency of the slave dof on the master dof in the static case:

$$\boldsymbol{q}_\mathrm{s} = -\boldsymbol{K}_\mathrm{ss}^{-1} \boldsymbol{K}_\mathrm{sm} \boldsymbol{q}_\mathrm{m} \, . \tag{28}$$

The additional expression of the slave dof by the modal coordinates $\boldsymbol{\eta}$ requires solving the eigenvalue problem of the inner system

$$\left(\boldsymbol{K}_\mathrm{SS} - \omega_j^2 \boldsymbol{M}_\mathrm{SS} \right) \boldsymbol{\phi}_{\mathrm{S},l} = 0 \quad \forall\ l = 1, 2, \ldots, n_\mathrm{max} \, , \tag{29}$$

which leads to the $n_{\max}$ linear independent eigenvectors, of which only a lower amount of $n_{\lim}$ selected eigenvectors is used. The eigenvectors are summarized by the modal matrix

$$\underbrace{\left[\boldsymbol{\phi}_{\mathrm{S},1}\,,\ldots,\boldsymbol{\phi}_{\mathrm{S},n_{\lim}}\right]}_{\boldsymbol{\Phi}_{\mathrm{S,mod}}}. \tag{30}$$

The transformation of the coordinates of the unreduced system $\boldsymbol{q} = \boldsymbol{T}_{\mathrm{CB}}\boldsymbol{q}_{\mathrm{red}}$ into the reduced vector $\boldsymbol{q}_{\mathrm{red}} = [\boldsymbol{q}_{\mathrm{M}}\ \boldsymbol{\eta}]^{\mathrm{T}}$ is done by the transformation matrix

$$\boldsymbol{T}_{\mathrm{CB}} = \begin{bmatrix} \boldsymbol{I} & \boldsymbol{0} \\ -\boldsymbol{K}_{\mathrm{SS}}^{-1}\boldsymbol{K}_{\mathrm{SM}} & \boldsymbol{\Phi}_{\mathrm{S,mod}} \end{bmatrix}. \tag{31}$$

The model order reduction then reads for the multi-body system with contact:

$$\boldsymbol{T}_{\mathrm{CB}}^{\mathrm{T}}\boldsymbol{M}\boldsymbol{T}_{\mathrm{CB}}\ddot{\boldsymbol{q}}_{\mathrm{red}} + \boldsymbol{T}_{\mathrm{CB}}^{\mathrm{T}}\boldsymbol{D}\boldsymbol{T}_{\mathrm{CB}}\dot{\boldsymbol{q}}_{\mathrm{red}} + \boldsymbol{T}_{\mathrm{CB}}^{\mathrm{T}}\boldsymbol{K}\boldsymbol{T}_{\mathrm{CB}}\boldsymbol{q}_{\mathrm{red}} = \boldsymbol{T}_{\mathrm{CB}}^{\mathrm{T}}\boldsymbol{F}_{\mathrm{ex}} + \boldsymbol{W}_{\mathrm{N}}\boldsymbol{T}_{\mathrm{CB}}^{\mathrm{T}}\boldsymbol{F}_{\mathrm{N}} + \boldsymbol{W}_{\mathrm{T}}\boldsymbol{T}_{\mathrm{CB}}^{\mathrm{T}}\boldsymbol{F}_{\mathrm{T}}. \tag{32}$$

7 Simulation of a tyre tread block on gravel road

The simulation of a tyre tread block on gravel road is performed for a cycloid movement of the tread with a rotation speed of $\omega = 3\,\mathrm{s}^{-1}$ and a belt diameter of the tyre of $d_{\mathrm{i}} = 650\,\mathrm{mm}$. The gravel is represented by a accumulation of 80 balls with varying diameter and weight. The time step size is chosen as $\Delta t = 1 \cdot 10^{-5}\,\mathrm{s}$. The siped tread structure has the following dimensions: length $20\,\mathrm{mm}$ and width $8\,\mathrm{mm}$. The temporal evaluation of the cycloid movement of the block is shown in **figure 6**. The surface masses of the viscoelastic block without contact are represented by blue markers, the ones in contact by red markers. The figures show that most of the gravel is displaced by the tread block. Some small stones are pressed on the road with the result that the lips of the tread block bend. After $t = 0.2\,\mathrm{s}$ the bending of the lips is high enough that self-contact of the block occurs. One single pebble is clamped between two block lips, when the tread moves upwards on the cycloid. The normalised contact forces, that are acting on each lip, are shown in **figure 5**. Within the first duration of $0.15\,\mathrm{s}$ the block has not yet

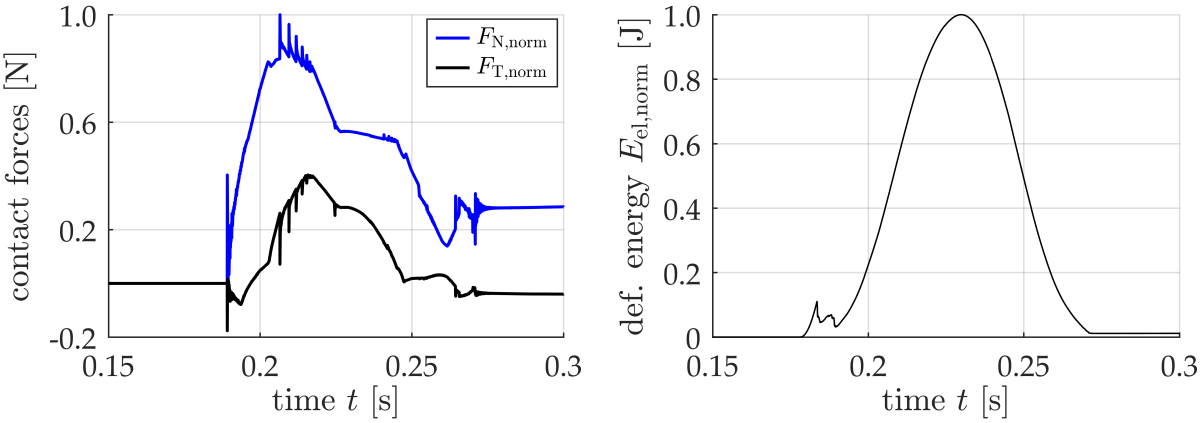

Figure 5: Contact forces acting on each lip, that clamps the pebble (left) and deformation energy of the viscoelastic tyre tread block (right)

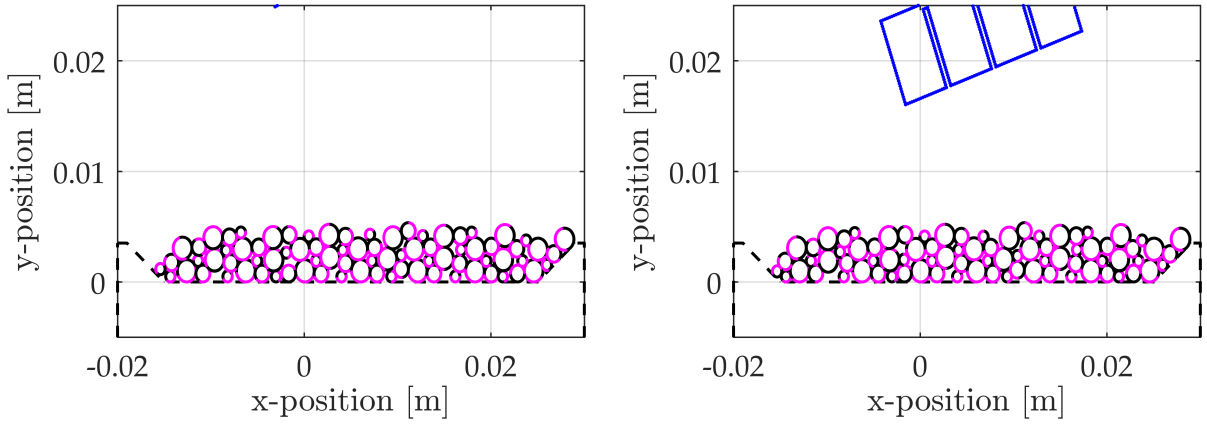
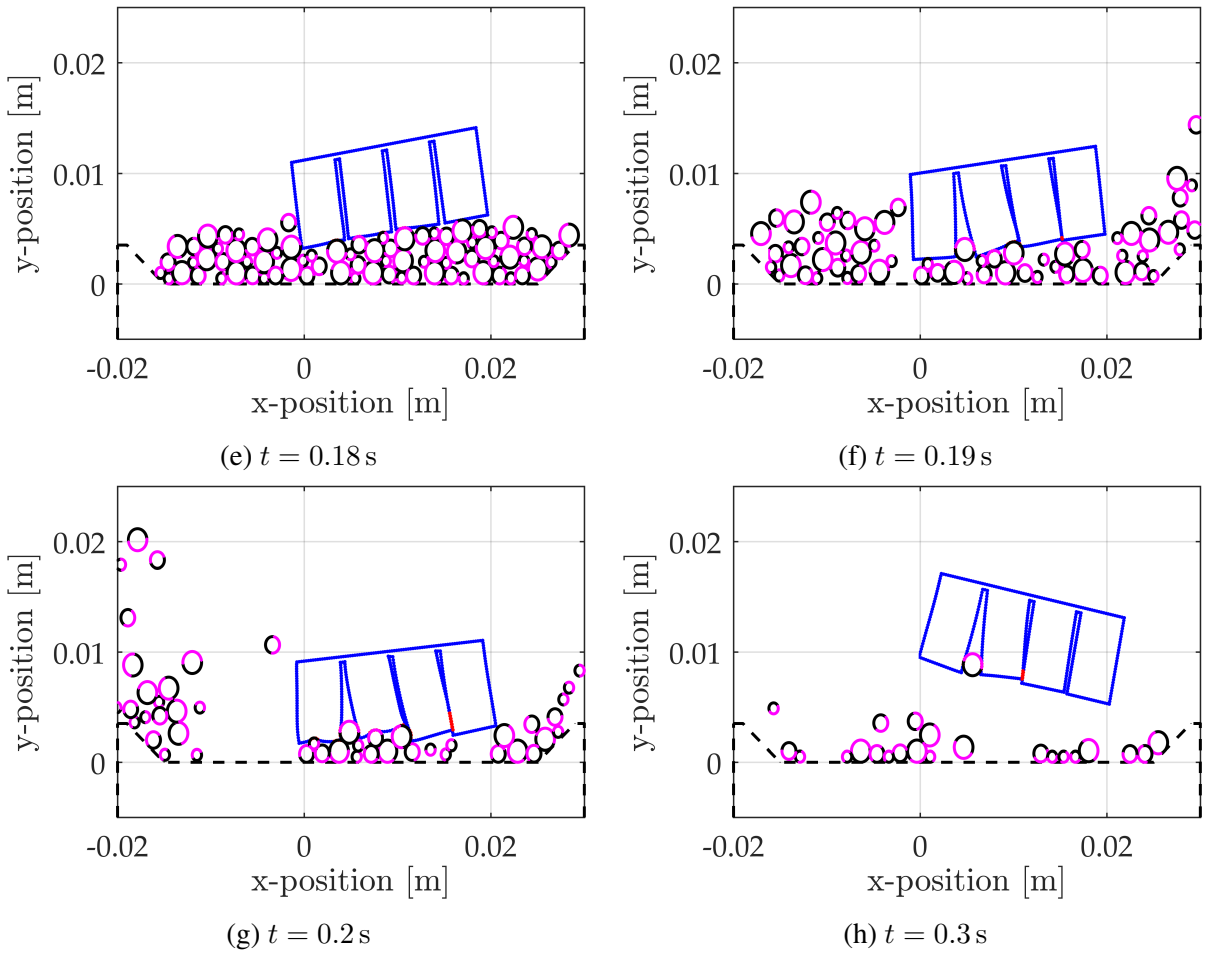
come into contact with the gravel on the road. The contact forces rise, just as the block hits the gravel and the block's lips are bended by the clamped pebble, see **figure 6 (e)-(f)**. The pebbles

on the ground push the clamped one between the lips so the contact forces increase further and then decrease towards constant values, when the tread block leaves the contact area on the road. The pebble sticks between the lips and the contact forces oscillate because of further impulses due to other pebbles. The normalised elastic deformation energy, see **figure 5**, is greater than the oscillatory energy of the tread block. For this reason, the kinetic energy is left out here. The elastic deformation energy shows an initial rise and decrease, which is caused by the bending and rebound of the incoming block's lip at the initial contact with the gravel. The subsequent increase up to the maximum value occurs as the lips begin to bend due to the sticking pebble. The self-contact of the lips contributes to the elastic deformation energy. After leaving the contact area the energy decreases about a small value because of the viscoelastic material properties.



(a) $t = 0.094\,\mathrm{s}$ (b) $t = 0.12\,\mathrm{s}$

(c) $t = 0.16\,\mathrm{s}$ (d) $t = 0.17\,\mathrm{s}$



(e) $t = 0.18\,\mathrm{s}$ (f) $t = 0.19\,\mathrm{s}$

(g) $t = 0.2\,\mathrm{s}$ (h) $t = 0.3\,\mathrm{s}$

8 Conclusions

In this paper the frictional and impulsive multi-body contact of a viscoelastic tyre tread block on granular road is simulated. The unilateral contact configurations of the multi-body system, consisting of block and granular material, are considered by complementarity conditions. To lower the computational effort, the Craig-Bampton model order reduction is applied.
With our simulation it is possible to consider the transient deformations of a tyre tread block and the displacements of granular material for a cycloid movement of the block into the road. Both the displacement of the gravel by the moving tread block and the sticking of single pebbles between the block's lips can be simulated. Even self-contact of the lips can be shown.

Keywords: Natural hazards, Snow Avalanche, Impact Loadings, Pile-up, Work-Energy Theorem, Dynamic Magnification Factors, Pylons, Walls.

Abstract. *Snow avalanches are a significant natural hazard in many mountainous regions throughout the world. Although long recognized that avalanche impact can easily destroy buildings and other infrastructure, design codes rarely, if at all, consider dynamic magnification factors. The underlying problem is that flowing snow at impact behaves both as a solid and as a fluid. The combination of solid and fluid behaviour makes it difficult to characterize the avalanche impact loading. The solid behaviour of flowing snow leads to pile-up regions of highly compacted snow in front of the structure. This dead-zone often adopts the form of a prismatic wedge with two distinct shear planes. The wedge serves to deflect avalanche snow around the impacted object. Because avalanche snow likewise exhibits fluid behaviour, the deflected snow can easily bypass the structure without stopping. In this paper we model the compaction, pile-up and deflection of avalanche snow around walls, pylons and trees. The work energy theorem is used to model the forces assocated with the compaction process and therefore pile-up phase. We show why the pile-up produces intensive, short duration loadings in the form of a triangular impulse. We quantify the duration time as a function of the pile-up geometry and compactive properties of the flowing snow. This allows us to both quantify the impact duration as well as select the appropriate form of the impulsive loading. If the eigenfrequency of the structure is known, dynamic magnification factors can be calculated for avalanche impact on a wide range of structure geometries, especially ski-lift masts, walls and power transmission towers.*

1 INTRODUCTION

In mountain environments snow avalanches pose a considerable threat to the built infrastructure [1, 2, 3, 4]. Structural engineers require calculation methods to relate avalanche speed to design loads in order to construct structures that can survive avalanche impact (Fig. 1). At present snow engineering practice applies the generic formula

$$p = \frac{1}{2} C_D \rho_\Phi V_\Phi^2 \tag{1}$$

to caluate the impact *pressure* p as a function of avalanche density ρ_Φ and velocity V_Φ^2 [5]. The pressure factor C_D accounts for avalanches impacting thin (C_D=1) and wide (C_D=2) structures. A more general equation to calculate the impact *force* $F(t)$ on a structure hit by a snow avalanche is,

$$F(t) = F_\Delta(t) + F_\Upsilon(t) + \oint_E f(s,t)\, ds. \tag{2}$$

Figure 1: On March 8, 2017 a snow avalanche destroyed several chalets at the Swiss village of Salvan, Canton Wallis. Impact pressures were higher than 30 kPa. The air-blast from the avalanche blew down several trees behind the buildings. The building on the right was completely destroyed. The picture appeared in the *Walliser Bote* on March 8, 2017.

This formula characterizes the three physical processes that must be considered at impact: (1) the shock loading $F_\Delta(t)$ caused by the solid, entirely plastic "pile-up" of snow mass in front of the structure, (2) the deflection force $F_\Upsilon(t)$ arising from the fluid movement of snow mass around the structure and (3) edge forces $f(s,t)$ which are produced when the deflected snow jams the on-coming avalanche mass at the exterior edges E of the structure. The line integral

is given by the fact that jamming forces $f(s,t)$ are defined per unit edge length. The upper limit of the integration is given by the flow height of the avalanche which defines the sum of the exposed edges of the structure. An important distinction between the two approaches is that first approach (Eq. 1) calculates a mean *pressure*, whereas the second approach (Eq. 2) predicts time-dependent *forces* that are assumed to be distributed unequally over the structure at impact.

By far the greatest challenge of developing methods to predict avalanche impact forces is due to the complex solid-fluid behaviour of avalanche snow. The piled-up snow typically forms a solid "deadzone" in the shape of a prismatic wedge (Fig. 2). (Hence there designation with the capital greek symbol Δ.) The wedge consists of highly compacted snow that serves to efficiently deflect the on-coming avalanche snow around the impacted object. That is, at impact both solid and fluid behaviour is evident. The solid material response is complicated further by the irreversible compactibility (or *Stauchen*) of avalanche snow. Bulk avalanche flow densities ρ_Φ range between (say) ρ_Φ = 150 kg/m^3 for a disperse flowing/powder avalanche to (say) ρ_Φ = 450 kg/m^3 for a dense wet snow avalanche [1]. Density measurements of piled-up snow in front of obstacles indicates that final compaction densities are over $\rho_\Delta \geq$ 500 kg/m^3 [6]. The dynamic, impulsive loading at impact results from the compaction of the avalanche snow from density ρ_Φ to density ρ_Δ. The time required to compact the snow to build the wedge therefore defines the duration of the impact loading and therefore the rate of energy dissipation and the impulsive (shock) response of the structure.

In this paper we develop a method to calculate how snow piles-up at impact allowing us to estimate the magnitude, form and duration of the impulsive loading $F_\Delta(t)$. This is a necessary prerequisite to determine the shock response (failure) of structures impacted by snow avalanches. We begin by considering forces for pile-up without deflection. This serves to introduce the application of the work-energy theorem to determine forces from the compaction of avalanche snow at impact. We then turn our attention to the more realistic problem of pile-up with deflection. This analysis allows us to determine dynamic magnification factors for simple structures such as cantilever-type constructions such as pylons and masts which are typical for ski-lifts and power transmission lines. We provide several example calculations. The first example considers an avalanche impacting trees, where the eigenfrequencies are low. The second example treats an avalanche impacting a circular ski-lift pylon, a common problem in avalanche mitigation.

2 PILE-UP WITHOUT DEFLECTION: FORCES F_Ξ

For the purpose of explanation we find the force F_Ξ where all avalanche mass piles-up completely at impact in front of the structure (Fig. 3). There is no deflection ($F_\Upsilon = 0$) or jamming ($f(s,t) = 0$). In this case the impact force $F(t) = F_\Xi$.

We consider a dense avalanche Φ with velocity V_Φ, height h_Φ and bulk density ρ_Φ impacting a rigid structure. The structure of width w is positioned at the position x=0; the positive x-direction defining the upstream direction of the pile-up. For simplicity we assume the avalanche strikes the structure with a mean depth-averaged velocity and density; that is, both variables are constant over the flow height defined in the z-direction, but can vary in the streamwise direction and therefore time. We do not consider the impact of the powder dust cloud Π. For now we assume that the height of the structure h is higher than the flow h_Φ i.e. there is no overtopping of the structure. The width of the flow is assumed to be larger than the width of the obstacle.

We describe the pile-up process by considering avalanche mass immediately before and after the pile-up (Fig. 3). All the incoming mass is piled-up. The avalanche is divided into "compacting" avalanche snow, the *knautschzone* (region Ξ, density not yet ρ_Ω, velocity not yet zero,

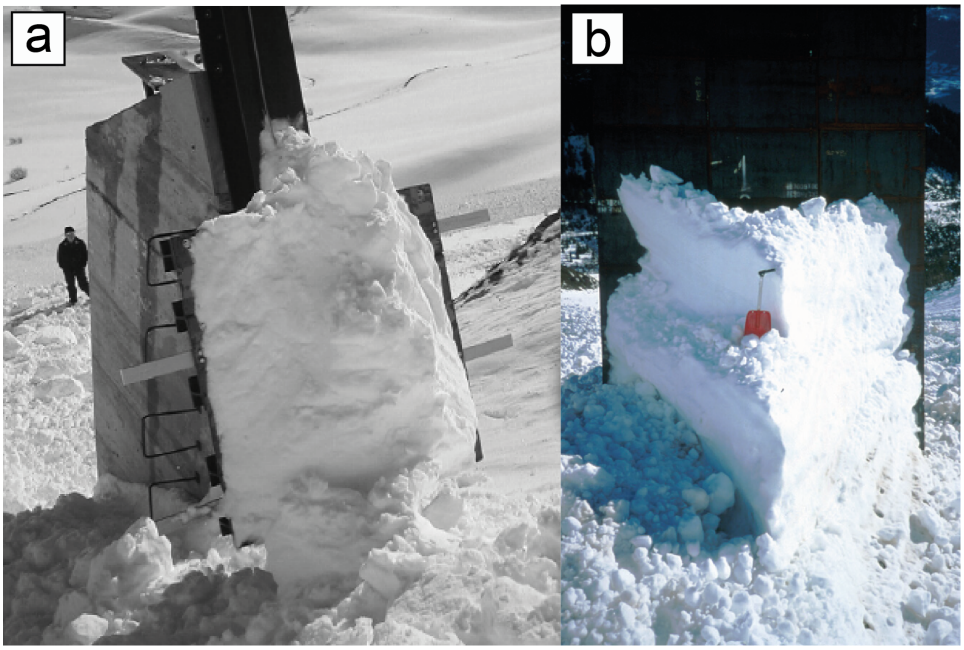

Figure 2: Examples of impact wedges. a) Pile-up at the measurement pylon at the French Col du Lautaret test site reported by [6]. Note the dihedral shape of a triangular prism. The width of the impact plane is 1 m. The reported compaction density was 540 kg/m^3; wedge angles ω_1=40° and ω_2=50°, impact pressures of 30 kPa, see [6] for details. b) Pile-up at the measurement wall at the Swiss Vallée de la Sionne test site [7]. The wall is 7m high and 3.5 m in width. The impact wall was designed to resist 500 kPa pressures. The depositions are from an wet snow avalanche recorded on December 12, 1998 with maximum recorded forces of 61 kN. Measured densities are 500 kg/m^3 at the wedge apex and 450 kg/m^3 at the wall. Photograph: M. Kern, SLF

time t) and "compacted" avalanche snow (region Ω, density ρ_Ω, no velocity, time $t + \Delta t$). Measurements of compacted snow density are rare. Thibert [6] measured a pile-up density ρ_Ω of 540 kg/m^3 in front of the instrumented pylon at the French Col du Lautaret test site.

The avalanche mass arriving at the obstacle M_Ξ and stopping within the time interval Δt is

$$M_\Xi = \rho_\Phi h_\Phi w \left[V_\Phi \Delta t \right]. \tag{3}$$

The corresponding change of kinetic energy ΔK_Ξ of the avalanche is therefore

$$\Delta K_\Xi = \frac{1}{2} M_\Xi(t) V_\Phi^2 = \frac{1}{2} \rho_\Phi h_\Phi w \left[V_\Phi^3 \Delta t \right]. \tag{4}$$

The length of the compacted, pile-up zone is denoted S_Ω, the height h_Ω. The pile-up height might be larger than or equal to the incoming avalanche height $h_\Omega \geq h_\Phi$. Because we do not have overtopping, we assume it remains smaller than the height of the obstacle $h_\Omega < h$. The length of the pile-up zone is growing at the rate $\dot{S}_\Omega$; it is given by conservation of mass,

$$\dot{S}_\Omega = \frac{\rho_\Phi(t) h_\Phi(t)}{\rho_\Omega h_\Omega} V_\Phi(t). \tag{5}$$

During the pile-up, the region Ξ of length $V_\Phi(t)\Delta t$ in the x-direction compacts, increasing the length of the compaction zone Ω (Fig. 3). The difference in the locations of the center-of-mass of the compacting zone Ξ and the piled-up mass Ω defines the braking distance $d_{\Xi \to \Omega}$ over which the incoming mass must stop,

$$d_{\Xi \to \Omega} = \frac{1}{2} \left[V_\Phi \Delta t - \dot{S}_\Omega \Delta t \right]. \tag{6}$$

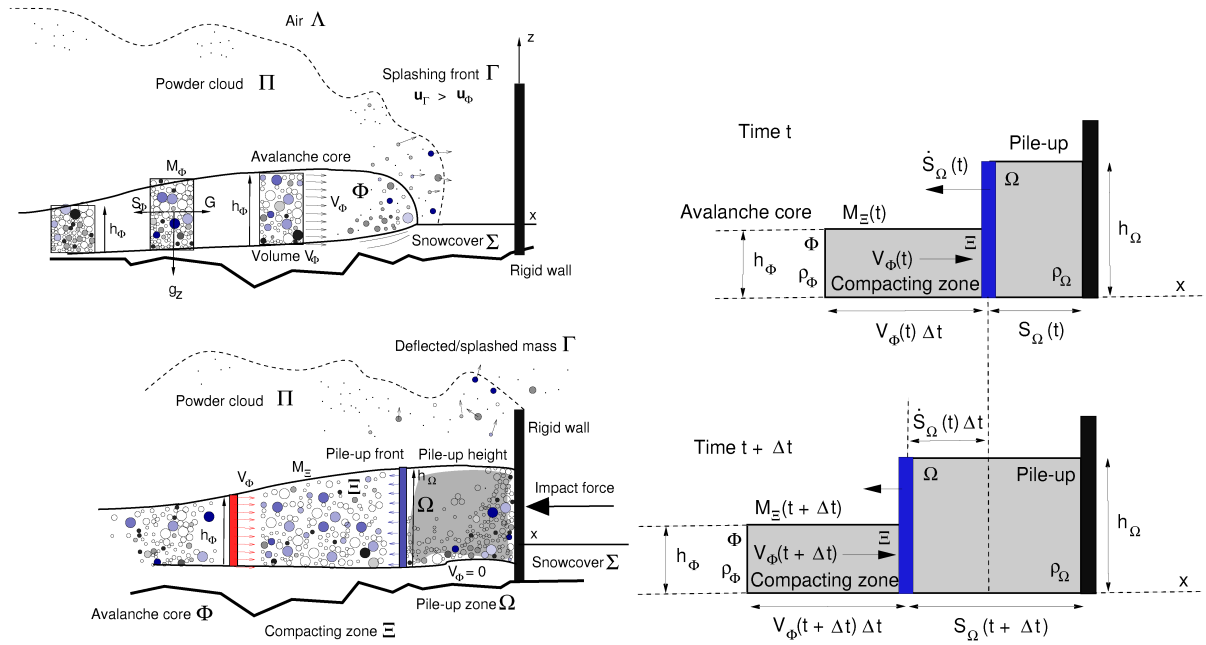

Figure 3: Avalanche impact with no deflection. The upstream zone is divided into three regions: the dense flowing avalanche Φ, the compacting region Ξ and the pile-up or accumulation zone Ω. The avalanche arrives at time t travelling with the velocity V_Φ, bulk density ρ_Φ and flow height h_Φ. Within the time interval Δt the *knautschzone* Ξ develops in front of the structure with length $V_\Phi \Delta t$. A pile-up zone Ω with length S_Ω forms. The pile-up zone is increasing at the speed $\dot{S}_\Omega$.

The mean force on the obstacle F_Ξ is found by equating the work-done by the braking and the change of kinetic avalanche energy in the compaction zone ΔK_Ξ,

$$F_\Xi d_{\Xi\to\Omega} = [p_\Xi h_\Omega w]\, d_{\Xi\to\Omega} = \Delta K_\Xi \tag{7}$$

or,

$$F_\Xi = \rho_\Phi h_\Phi w \frac{V_\Phi}{\left[V_\Phi - \dot{S}_\Omega\right]} V_\Phi^2 \tag{8}$$

The impact pressure p_Ξ is found assuming the force is applied uniformly over the impact area $h_\Omega w$. Therefore,

$$p_\Xi = \rho_\Phi \frac{h_\Phi}{h_\Omega} \frac{V_\Phi}{\left[V_\Phi - \dot{S}_\Omega\right]} V_\Phi^2 \tag{9}$$

and with the subsitution of the equation for mass conservation

$$p_\Xi = \rho_\Phi \frac{h_\Phi}{h_\Omega} \left[1 - \frac{\rho_\Phi h_\Phi}{\rho_\Omega h_\Omega}\right]^{-1} V_\Phi^2. \tag{10}$$

It is therefore possible to define an pressure factor C_D for the pile-up without deflection regime,

$$C_D^\Xi = 2\frac{h_\Phi}{h_\Omega} \left[1 - \frac{\rho_\Phi h_\Phi}{\rho_\Omega h_\Omega}\right]^{-1}. \tag{11}$$

Note that the pressure factor becomes infinite when $\rho_\Phi h_\Phi = \rho_\Omega h_\Omega$. These values of equivalent C_D are in agreement with measured values for all $\rho_\Omega > \rho_\Phi$, see Fig. 4b, and compare to

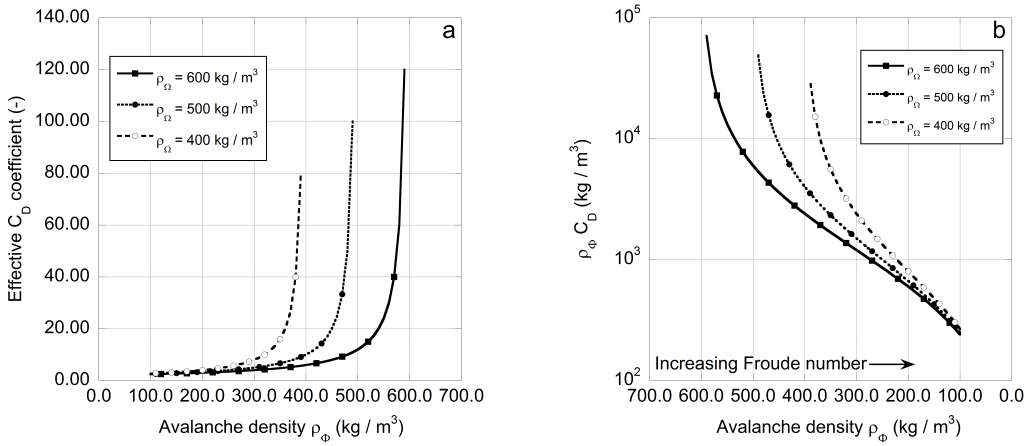

Figure 4: a) Effective C_D^{Ξ} coefficient (Eq. 11) for different incoming avalanche densities ρ_Φ and three compaction densities ρ_Ω. The flow height and pile-up heights are equal $h_\Phi = h_\Omega$. Large effective C_D coefficients result when $\rho_\Phi \approx \rho_\Omega$. In this case compacting (braking) distances are short and impact pressures are large. b) The calculated $\rho_\Phi C_D$ are in agreement with values derived from full scale measurements, e.g. [8]. For the sake of comparison to measured values we plot the calculated $\rho_\Phi C_D$ values with decreasing density to mimic increasing Froude numbers (higher Froude numbers correspond to lower flow densities). This produces the effect that effective pressure factors C_D are higher for lower flow velocities.

[8]. This result suggests that impact pressures of slow moving avalanches can be large if the density of the incoming avalanche is near the compaction density. Substitution of Eq. 1 into the work-energy theorem (Eq. 8) leads to

$$C_D^{\Xi} = \frac{V_\Phi \Delta t}{d_{\Xi \to \Omega}}. \tag{12}$$

The pressure factor is therefore the length of the *knautschzone* Ξ relative to the braking distance $d_{\Xi \to \Omega}$.

3 PILE-UP WITH DEFLECTION: FORCES F_Δ

We again consider a dense avalanche Φ impacting a rigid structure with velocity V_Φ, height h_Φ and bulk density ρ_Φ. This time, however, a prismatic wedge forms at the face of the structure and avalanche snow is deflected (Fig. 5). We assume symmetry (a head-on interaction with the structure). The structure of half width w_0 is positioned at x=0; the positive x direction defining the incoming avalanche direction; the y direction is defined along the width of the obstacle. The total width of the obstacle is therefore 2 w_0. We make the same avalanche flow assumptions as for the previous case.

In the time interval Δt the incoming mass of the avalanche core M_Φ is partitioned into two parts. The mass that is deflected M_Υ and the mass that is piled-up in a triangular wedge M_Δ

$$M_\Phi = \underbrace{\rho_\Phi h_\Phi w V_\Phi \Delta t}_{\textit{Incoming mass}} = \underbrace{M_\Upsilon}_{\textit{Deflected mass}} + \underbrace{M_\Delta}_{\textit{Wedge mass}}. \tag{13}$$

The mass piled-up on the wedge per unit width (y-direction) m_Δ is

$$m_\Delta(y) = \left(1 - \frac{y}{w}\right) \rho_\Delta h_\Delta \dot{S}_\Delta \Delta t. \tag{14}$$

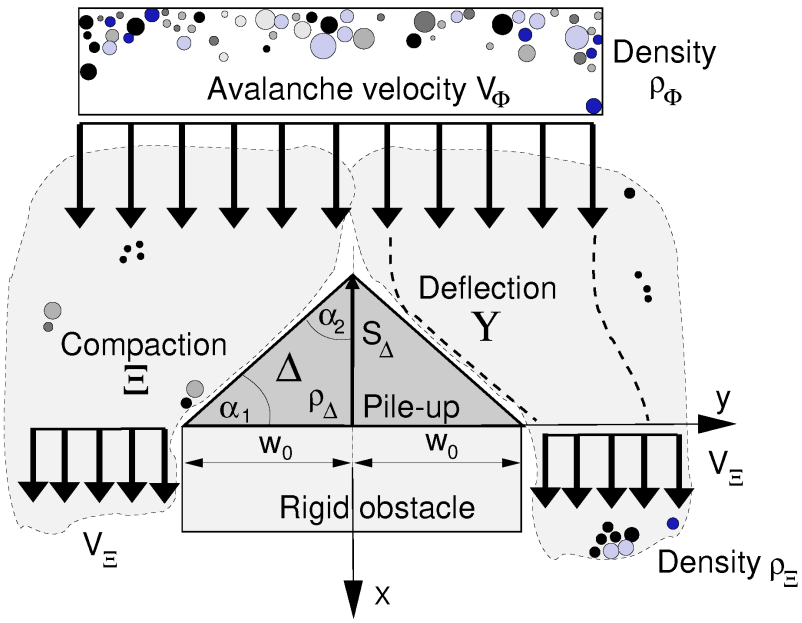

Figure 5: Definition of wedge-shaped pile-up with deflection plus compaction in front of the obstacle. The avalanche approaches the obstacle in the positive x-direction with velocity V_Φ. The bulk density of the flow is ρ_Φ. A pile-up wedge Δ is formed. The density of the piled-up snow is ρ_Δ. The length of the wedge in the flow (negative) x-direction is S_Δ. The speed the length of the triangular wedge grows is $\dot{S}_\Delta$. The wedge geometry is defined by the angle α_1 with α_2 = 90° - α_1.

where S_Δ is the length of the wedge in the x-direction at the location x=0, see Fig. 5. The speed the wedge is growing is therefore $\dot{S}_\Delta$. The total mass of the snow pile up is found by integration

$$M_\Delta = \int_0^w m_\Delta(y)dy = \frac{1}{2}\rho_\Delta h_\Delta w \dot{S}_\Delta \Delta t. \tag{15}$$

The loss of kinetic energy $k_\Delta(y)$ per unit length in the y-direction is

$$k_\Delta(y) = \frac{1}{2}m_\Delta(y)V_\Phi^2 = \frac{1}{2}\left(1 - \frac{y}{w}\right)\rho_\Delta h_\Delta \dot{S}_\Delta V_\Phi^2. \tag{16}$$

The kinetic energy is lost over the ”braking” distance

$$d_{\Phi\to\Delta}(y) = \frac{1}{2}\left[V_\Phi \Delta t - \left(1 - \frac{y}{w}\right)\dot{S}_\Delta \Delta t\right]. \tag{17}$$

From the work-energy theorem, the force per unit length f_Δ is applied

$$f_\Delta d_{\Phi\to\Delta} = k_\Delta. \tag{18}$$

Therefore,

$$f_\Delta = \frac{k_\Delta}{d_{\Phi\to\Delta}} = \frac{\left[\left(1 - \frac{y}{w}\right)\dot{S}_\Delta\right]}{\left[V_\Phi - \left(1 - \frac{y}{w}\right)\dot{S}_\Delta\right]}\rho_\Delta h_\Delta V_\Phi^2 \tag{19}$$

This value can be integrated over width of the triangle w (y-direction) to find the mean pile-up force F_Δ on the obstacle

$$F_\Delta = \int_0^w f_\Delta(y)dy = \left[\frac{V_\Phi}{\dot{S}_\Delta}\ln\left(\frac{V_\Phi}{V_\Phi - \dot{S}_\Delta}\right) - 1\right]\rho_\Delta h_\Delta w V_\Phi^2. \tag{20}$$

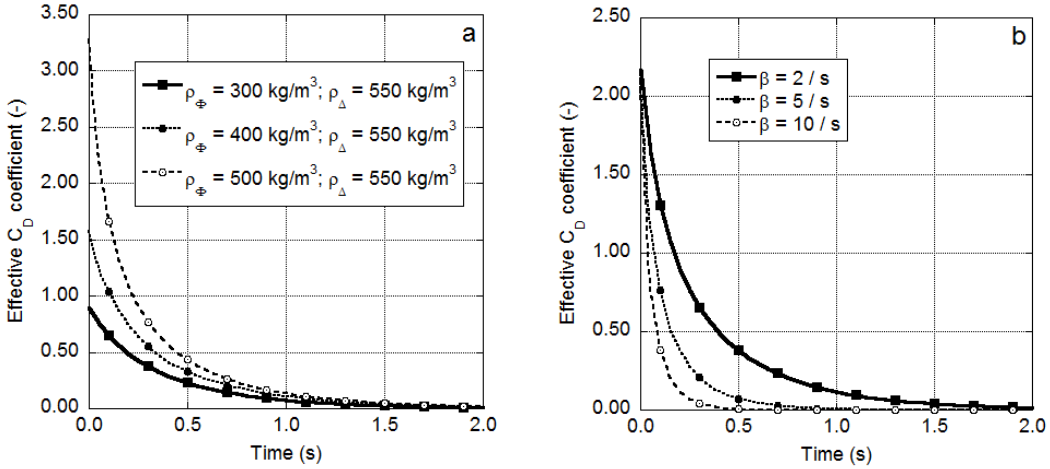

Figure 6: a) Effective C_D^{Δ} coefficient (Eq. 22) for different incoming avalanche densities ρ_Φ and three wedge pile-up densities ρ_Δ. The flow height and pile-up heights are equal $h_\Phi = h_\Omega$. Large effective C_D^{Δ} coefficients result when $\rho_\Phi \approx \rho_\Delta$. b) Effective C_D^{Δ} coefficient (Eq. 22) for different β values. Note that the pile-up times vary between 0.25s and 1.0s.

The pile-up pressure acting on the rigid obstacle is

$$p_\Delta = \frac{F_\Delta}{w h_\Delta} = \left[\frac{V_\Phi}{\dot{S}_\Delta} \ln\left(\frac{V_\Phi}{V_\Phi - \dot{S}_\Delta}\right) - 1\right] \rho_\Delta V_\Phi^2. \tag{21}$$

The pressure retains a V_Φ^2 dependency with the pre-multiplier serving as the pressure factor C_Δ,

$$C_D^{\Delta} = 2\left[\frac{V_\Phi}{\dot{S}_\Delta} \ln\left(\frac{V_\Phi}{V_\Phi - \dot{S}_\Delta}\right) - 1\right] \tag{22}$$

At present the model contains no constitutive parameters. The quantity $\dot{S}_\Delta$ controls the duration of the wedge formation and therefore the duration of the pile-up loading. We consider the growth of the wedge to be given by the relationship

$$\dot{S}_\Delta = \frac{\rho_\Phi}{\rho_\Delta} V_\Phi \exp\left(-\beta t\right). \tag{23}$$

The coefficient β (dimension 1/s) therefore describes the partitioning of the incoming mass into the deflected and piled-up mass. At a certain time, when the wedge is sharp enough, the growth of the wedge stops. Clearly other constitutive formulations can be postulated. The pressure factor C_D^{Δ} is a function of time, see Fig. 6.

4 RESULTS: DYNAMIC MAGNIFICATION FACTORS

The results of the preceeding section (Fig. 6) demonstrate that the impact pressure for pile-up p_Δ is well represented by a triangular impulse of the form

$$p_\Delta \approx p_\Delta(0)\left[1 - t/t_1\right] \tag{24}$$

where t_1 defines the duration time of the impulse. The dynamic magnification factor D for triangular impulse loadings are treated in standard structural dynamics texts, see [9]. Table

1 presents D values for various impulse length t_1/T ratios (T is the period of vibration of the impacted structure). Periods of vibration for steel pylons and trees can be found using Rayleigh's method treating the structure as a partially loaded cantilever beam [10]. At the ground the structures are fixed allowing no translational deformation or bending rotations. The flow height of the avalanche defines the region on the cantilever which is loaded at impact.

t_1/T	0.20	0.40	0.50	0.75	1.00	1.50	2.00
D	0.60	1.05	1.19	1.38	1.53	1.68	1.76

Table 1: Dynamic magnification factors for triangular impulse loadings, from [9].

The first practical result of our analysis is that pylon-type structures with eigenfrequencies of greater than 5Hz (approximately) should consider dynamic magnification factors in design and back analysis. Interestingly, mature spruce trees, typical for most mountain environments have eigenfrequencies of ω = 1Hz (and lower) [10, 11] and therefore long periods of vibration $T \approx 6$ s. From the results above we find pile-up loading intervals $0.25 \leq t_1 \leq 1.0$ s. The calculated impulse length ratios are between $0.04 \leq t_1/T \leq 0.17$. The dynamic magnification factors for trees are less than 1 meaning that $0.1 \leq D \leq 0.6$ (Table 1). This result indicates that trees are able to withstand short duration avalanche pile-up loadings, but are remain susceptible to longer duration air-blasts. This result would explain the extensive forest damage caused by powder avalanches and the fact that many trees can withstand the impact of fast moving avalanche cores, see Fig. 1.

For the next example problem we consider a circular ski-lift pylon made of steel with a height of H= 15m and diameter of d = 1m. The thickness of the steel section is 3cm. The pylon is struck by an avalanche with flow height h_Φ = 3m. For this loading, the calculated eigenfrequency of the pylon is approximately ω = 80 Hz, the period of vibration $T \approx 0.08$s. Calculated impulse length ratios are $t_1/T > 3$, indicating large dynamic magnification factors D = 1.76 (Table 1). Unlike trees, rigid steel structures appear to be more vulnerable to impulsive pile-up loadings.

Finally we consider the impact forces on wall depicted in Fig. 2b [7]. This wall has a total width of 3.5m. Measured maximum reaction forces on the right, center and left supports are 29kN, 61kN and 49kN respectively for a wet snow avalanche impacting the wall with a 4m flow height and velocity of 4.6m/s. The length of the pile-up wedge was found to be 2m. This pile-up height can be reproduced using a β=1.5/s. The calculated reaction forces from Eq. 20, assuming a direct hit, are 38kN, 63kN and 38kN.

5 CONCLUSIONS

In this paper we have applied the work-energy theorem to calculate the magnitude, form and duration of the impulse loading that results when mass is piled-up in the form of prismatic wedge. We consider two cases – pile-up without deflection (force F_Ξ) and pile-up with deflection (force F_Δ). The model assumes a single constitutive parameter (β) that defines the loading interval which can be compared to the vibration period of the impacted structure. Dynamic magnification factors can therefore be calculated and used in structural design. An interesting and unexpected result of our analysis is that trees appear to have low magnification factors $D \leq 0.5$, in comparison to rigid steel structures $D \geq 1.5$. This result would help explain the usefulness of forests in avalanche defense and the danger caused by avalanches to the built environment.

Abstract. *A wide variety of system inversion algorithms has been proposed in the literature, tackling the problem of force identification, parameter estimation, and state/response estimation. Recently, much focus has gone to recursive joint input-state estimation and joint input-state-parameter estimation, where the forces applied to the structure, the corresponding system states, and its parameters are simultaneously estimated in a recursive fashion. In order to reduce the computational load, these techniques are frequently used in combination with modally reduced order models. This paper shows that a model order reduction can lead to large estimation errors in the system inversion caused by disregarding the contribution of the so-called out-of-band modes. A recently developed computationally efficient quasi-static correction technique, which can be used in state-space modeling, is implemented and evaluated for both joint input-state estimation and joint input-state-parameter estimation. The evaluation is based on numerical simulations. It is shown that the quasi-static correction significantly reduces the estimation errors introduced by the model order reduction.*

1 INTRODUCTION

In civil and mechanical engineering, system inversion techniques are applied to observe the states, inputs, and parameters of a structure, based on data obtained from sensors (accelerometers, strain gauges, ...) and a model of the structure. Various techniques for force and state/response estimation have been proposed in the literature, tackling the problem in the frequency domain or the time domain [6, 14]. Recently, much focus has gone to recursive joint input-state estimation. Commonly adopted techniques are the Augmented Kalman filter (AKF) [8, 13], the so-called Gillijns and De Moor filter (GDF), proposed in [5] and further extended in [7], [12], and [9] and the Dual Kalman filter (DKF) [2]. Several extensions of these algorithms for joint input-state-parameter estimation have recently been developed, allowing for the tracking of uncertain parameters in addition the estimation of the inputs and system states. The AKF was extended by Naets et al. in [13], the GDF was extended by Wan et al. in [16], the smoothing variant of the GDF presented in [9] was extended by Maes et al. in [10], and the DKF algorithm was extended by Azam et al. in [1].

System inversion techniques are commonly used in combination with modally reduced order models to reduce the computational load. Indeed, the use of a full order finite element model for most applications results in large computation times. However, modal truncation can introduce large estimation errors in the system inversion. These errors are caused by disregarding the quasi-static contribution of the out-of-band modes within the frequency band of interest, which is mostly important near antiresonance and at very low frequencies, where the response of the structure is essentially quasi-static. A novel technique to account for the quasi-static contribution of the out-of-band modes was recently presented in [11]. As opposed to already existing quasi-static correction techniques [3, 4, 15], this technique can be used in state-space modeling, commonly adopted in system inversion.

This contribution presents a demonstration of the quasi-static correction technique presented in [11] for joint input-state estimation and joint input-state-parameter estimation. The demonstration is based on numerical simulations, hereby considering the case of a simply supported steel beam.

The outline of the paper is as follows. Section 2 briefly recapitulates the quasi-static correction technique presented in [11]. Next, Section 3 presents a demonstration of the correction technique for joint input-state estimation and joint input-state-parameter estimation. Finally, Section 4 concludes the work.

2 QUASI-STATIC CORRECTION IN STATE-SPACE MODELING

For a linear dynamic system described in modal coordinates, any displacement/strain $d(t) \in \mathbb{R}$ can be written as a sum of modal contributions:

$$d(t) = \sum_{m=1}^{\infty} \phi_{\mathrm{d}m} z_m(t) \tag{1}$$

with $\phi_{\mathrm{d}m} \in \mathbb{R}$ the mode shape component for a given mode m at the assumed output location and $z_m(t) \in \mathbb{R}$ the corresponding modal displacement. Under the assumption of proportional damping, the modal displacement $z_m(t)$ for a given mode m satisfies the following differential equation:

$$\ddot{z}_m(t) + 2\xi_m\omega_m\dot{z}_m(t) + \omega_m^2 z_m(t) = \boldsymbol{\phi}_m^{\mathrm{T}}\mathbf{S}_{\mathrm{p}}\mathbf{p}(t) \tag{2}$$

where $\omega_m \in \mathbb{R}$ and $\xi_m \in \mathbb{R}$, and $\boldsymbol{\phi}_m \in \mathbb{R}^{n_{\mathrm{dof}}}$ denote respectively the natural frequency, the modal damping ratio, and the mode shape vector corresponding to mode m, $\mathbf{S}_{\mathrm{p}} \in \mathbb{R}^{n_{\mathrm{dof}} \times n_{\mathrm{p}}}$ is

a selection matrix specifying the force locations, and $\mathbf{p}(t) \in \mathbb{R}^{n_\mathrm{p}}$ is the force vector with n_p components.

The quasi-static correction technique proposed in [11] assumes the following approximation:

$$d(t) \approx \sum_{m=1}^{n_\mathrm{m}} \phi_{\mathrm{d}m} z_m(t) + \sum_{n=1}^{n_\mathrm{p}} \phi'_{\mathrm{d}n} z'_n(t) \tag{3}$$

For the first n_m modes, the full dynamic contribution is accounted for. For the higher modes, the quasi-static correction required for each force component is obtained by a so-called dummy mode. The number of dummy modes equals the number of force components n_p. For every force component $p_n(t)$, the modal displacement $z'_n(t)$ corresponding to the dummy mode is obtained by solving the following differential equation:

$$\ddot{z}'_n(t) + 2\xi'_n\omega'_n\dot{z}'_n(t) + \omega'^2_n z'_n(t) = \phi'_{\mathrm{p}n} p_n(t) \tag{4}$$

where ω'_n and ξ'_n are respectively the natural frequency and modal damping ratio assigned to dummy mode n, which are both user defined parameters. The mode shape components $\phi'_{\mathrm{p}n}$ and $\phi'_{\mathrm{d}n}$ are determined such that the static response of the structure (at 0 Hz) is correctly represented by the modally reduced order model. The following expressions are obtained:

$$\phi'_{\mathrm{p}n} = \omega'_n \sqrt{\mathbf{S}_{\mathrm{p}_n}^\mathrm{T}\mathbf{K}^{-1}\mathbf{S}_{\mathrm{p}_n} - \sum_{m=1}^{n_\mathrm{m}} \frac{\mathbf{S}_{\mathrm{p}_n}^\mathrm{T}\boldsymbol{\phi}_m\boldsymbol{\phi}_m^\mathrm{T}\mathbf{S}_{\mathrm{p}_n}}{\omega_m^2}} \tag{5}$$

$$\phi'_{\mathrm{d}n} = \frac{\omega'^2_n}{\phi'_{\mathrm{p}n}} \left(\mathbf{S}_\mathrm{d}\mathbf{K}^{-1}\mathbf{S}_{\mathrm{p}_n} - \sum_{m=1}^{n_\mathrm{m}} \frac{\phi_{\mathrm{d}m}}{\omega_m^2}\boldsymbol{\phi}_m^\mathrm{T}\mathbf{S}_{\mathrm{p}_n} \right) \tag{6}$$

where $\mathbf{S}_{\mathrm{p}_n}$ contains the n-th column of the selection matrix $\mathbf{S}_\mathrm{p}$. Note that the expressions for the mode shape components in Eqs. (5) and (6) only require the first n_m mode shapes and natural frequencies.

In case of a single force ($n_\mathrm{p} = 1$), applying the Fourier transform to Eq. (3) and introducing the Fourier transform of Eqs. (2) and (4) allows calculating the transfer function $H''_{\mathrm{dp}}(\omega)$ of the approximating system obtained by introduction of the dummy mode. After extension to velocity and acceleration measurements, the following expression is obtained:

$$H''_{\mathrm{dp}}(\omega) = (i\omega)^q \left(\sum_{m=1}^{n_\mathrm{m}} \frac{\phi_{\mathrm{d}m}\phi_{\mathrm{p}m}}{-\omega^2 + 2i\xi_m\omega_m\omega + \omega_m^2} + \frac{\phi'_{\mathrm{d}1}\phi'_{\mathrm{p}1}}{-\omega^2 + 2i\xi'_1\omega'_1\omega + \omega'^2_1} \right) \tag{7}$$

where ω is the angular frequency in rad/s and q is an integer which equals 0 for displacements, 1 for velocities, and 2 for accelerations. The natural frequency ω'_n and modal damping ratio ξ'_n of every dummy mode have to be chosen such that the contribution of this mode to the transfer function $H''_{\mathrm{dp}}(\omega)$ is nearly constant in the frequency range of interest, hereby accounting for the quasi-static contribution of the out-of-band modes. The natural frequency ω'_n of the dummy modes should be chosen larger than the upper limit ω_u of the frequency band of interest, but smaller than the Nyquist frequency ω_N adopted for the time discretization. The damping ratio ξ'_n should be chosen sufficiently small to avoid a dynamic contribution of the dummy mode within the frequency band of interest. The reader is referred to [11] for an in-depth discussion on the choice of the natural frequency and modal damping ratio assigned to the dummy modes.

3 DEMONSTRATION

In this section, the quasi-static correction technique described in Section 2 is demonstrated for joint input-state estimation (Section 3.1) and joint input-state-parameter estimation (Section 3.2).

The structure considered in the demonstration is the simply supported steel beam shown in figure 1. The beam has a length of $1\ \mathrm{m}$ and a rectangular cross section of width $50.8\ \mathrm{mm}$ and height $25.4\ \mathrm{mm}$. The Young's modulus, Poisson's ratio, and material density are initially taken as $210\ \mathrm{GPa}$, 0.3, and $7750\ \mathrm{kg/m^3}$, respectively. Ideal hinges are assumed at both ends of the beam, only constraining the translation of the end nodes and not their rotation.

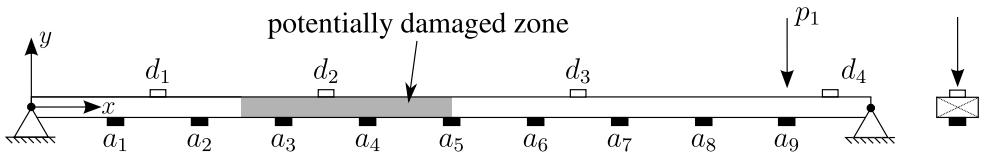

Figure 1: Side view (left) and front view (right) of a simply supported steel beam, indicating the force p_1 and the locations where the vertical response of the structure is calculated (a_i: acceleration i, d_i: displacement i).

A two-dimensional finite element (FE) model of the beam with 100 Euler-Bernoulli beam elements is constructed. Only bending in the vertical plane is considered. Shear deformation is not accounted for. The first four natural frequencies obtained from the beam model are 59.9 Hz, 239.6 Hz, 538.3 Hz, and 955.2 Hz. The corresponding bending mode shapes are shown in Fig. 2. A modal damping ratio of 0.25% is assumed for all modes.

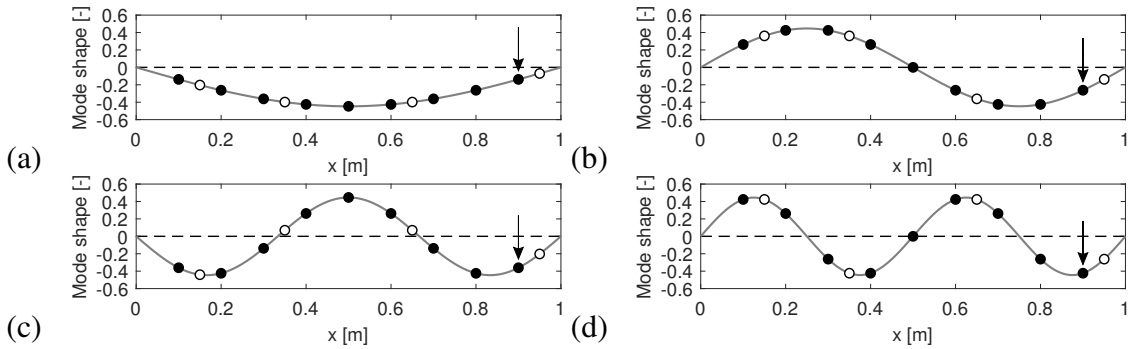

Figure 2: Mode shape along the neutral axis of the simply supported beam, for (a) mode 1, (b) mode 2, (c) mode 3, and (d) mode 4. The undeformed neutral axis is shown by a black dashed line. The markers indicate the output coordinates (black: acceleration, white: displacement). The arrow indicates the force location.

The excitation of the beam consists of a vertical impact force p_1, applied at a distance of $0.1\ \mathrm{m}$ from the right support. The impact force is a triangular pulse that increases linearly from zero at time $t = 0.1\ \mathrm{s}$ to $100\ \mathrm{N}$ at $t = 0.102\ \mathrm{s}$, before decreasing linearly to zero at $t = 0.104\ \mathrm{s}$, shown in Fig. 3. A subset of nine vertical accelerometers $a_1 - a_9$ and four vertical displacement sensors $d_1 - d_4$ is considered in the following analysis. The focus is put on the frequency band from 0 to 1000 Hz, which contains most of the dynamic response of the beam due to the impact loading.

Figure 4 compares the transfer function that relates displacement d_4 to the force p_1, (1) for the full order model (200 modes), (2) a modally reduced order model which includes the contribution of the first four modes, and (3) a modally reduced order model which includes the

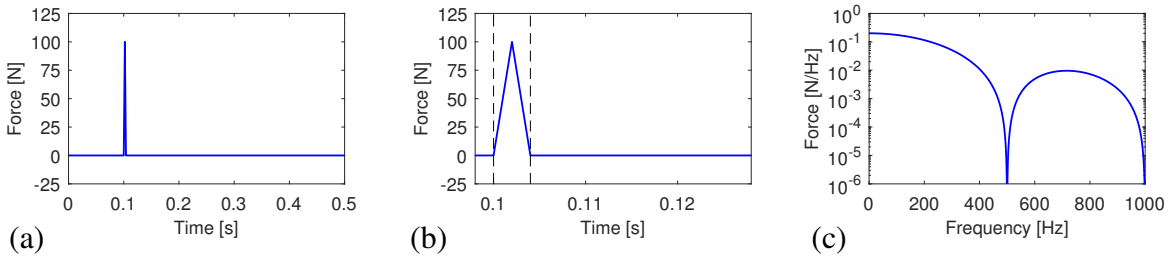

Figure 3: (a) Time history, (b) detail time history, and (c) frequency spectrum up to 1000 Hz of the applied impact force. The begin and end of the impact are indicated in (b) by a vertical dashed line.

full dynamic contribution of the first four modes and a single dummy mode to account for the quasi-static contribution of the out-of-band modes to the frequency band of interest. The natural frequency ω_1' and modal damping ratio ξ_1' of the dummy mode are assigned a value of 1800 Hz and 2%, respectively. For the selected parameter values, the contribution of the dummy mode to the transfer function $H''_{\mathrm{dp}}(\omega)$ is nearly constant within the frequency band of interest (0 to 1000 Hz). The three transfer functions nearly coincide at resonance, where a single mode dominates the response of the system. A large difference between the transfer function of the full order model and the modally reduced order model without dummy mode correction is observed near antiresonance, where higher modes that are omitted in the modal truncation significantly contribute to the system response. Within the frequency band of interest, the transfer function of the modally reduced order model with dummy mode correction nearly coincides with the transfer function of the full order model. For higher frequencies, the approximation deviates from the full-order model. Therefore, a model with dummy mode correction can only be used for calculations within a predefined frequency range.

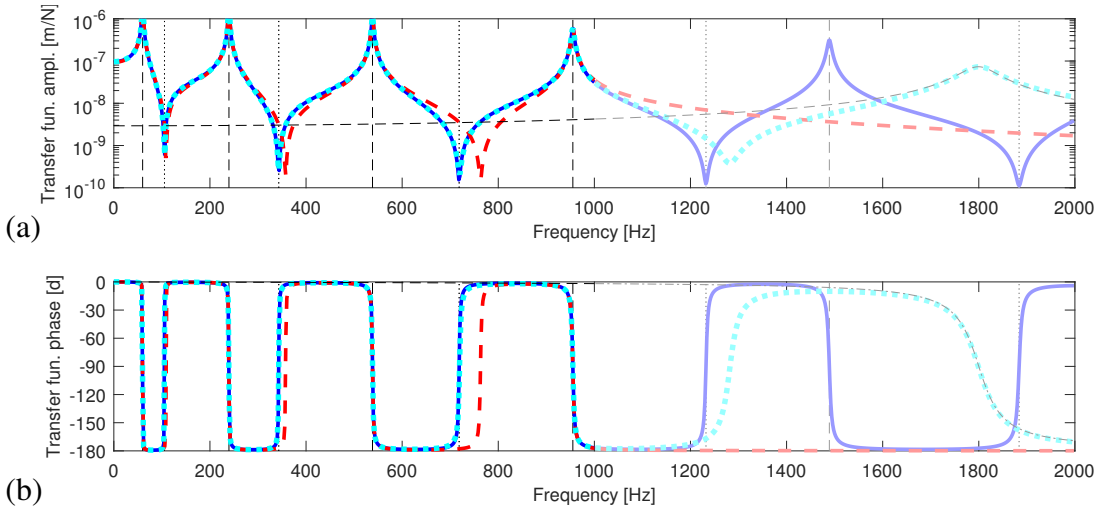

Figure 4: (a) Amplitude and (b) phase of transfer function of the full order model (200 modes, blue solid line), a modally reduced order model with 4 modes, without quasi-static correction (red dashed line), and a modally reduced order model with 4 modes, with dummy mode correction (cyan dotted line) that relates displacement d_4 to force p_1. The contribution of the dummy mode is indicated by a black dash-dotted line. The undamped natural frequencies are indicated by vertical dashed lines, the antiresonance frequencies of the full-order model by vertical dotted lines.

3.1 Joint input-state estimation

In this section, the recursive joint input-state estimation algorithm presented in [12] is applied to estimate the impact force p_1 applied to the simply supported steel beam. In the present example, a state-space model representing the dynamic behavior of the beam in the frequency range from 0 to 1000 Hz is constructed from the first four bending modes of the beam ($n_\mathrm{m} = 4$). The static contribution of the higher modes is accounted for by a single dummy mode ($n_\mathrm{p} = 1$), with a natural frequency and modal damping ratio of 1800 Hz and 2%, respectively (see also figure 4). The expressions for the system matrices are given in [11]. A sampling rate of 10 kHz is applied, using a first-order hold (FOH) assumption on the input in the time discretization of the model.

The input is reconstructed from displacement d_4 and acceleration a_9 (see Fig. 1). The response is obtained from a forward frequency domain calculation, hereby considering a full-order model that includes all modes of the structure. The signals obtained from the forward calculation are polluted with additive sensor noise, which is drawn independently from a normal distribution with a zero mean value and a standard deviation of 10^{-8} m for the displacements and 10^{-4} m/s^2 for the accelerations. In the application of the joint input-state estimation algorithm, the initial state vector estimate $\hat{\mathbf{x}}_{[0|-1]}$ and its corresponding error covariance matrix $\mathbf{P}_{\mathrm{x}[0|-1]}$ are both assigned zero values. The process noise covariance matrix $\mathbf{Q}$ and the process-measurement noise cross-correlation matrix $\mathbf{S}$ are both assumed zero, since no unmodeled forces or modeling errors are present. The matrix $\mathbf{R}$ accounts for measurement noise and is assumed diagonal, with the noise variance (diagonal values) corresponding to the actual measurement noise, i.e. 10^{-16} m^2 for the displacements and 10^{-8} m^2/s^4 for the accelerations.

Fig. 5 shows the force $\hat{p}_1$ estimated by the joint input-state estimation algorithm, using both the modally reduced order model without dummy mode correction and the model with dummy mode correction. In both cases, the estimated force is lowpass filtered with a cutoff frequency of 1000 Hz in order to retain only information within the frequency band of interest and to remove the dynamic contribution of the dummy mode at higher frequencies. A comparison of the estimated forces with the actual applied force shows how the introduction of the dummy mode allows to significantly reduce the force estimation errors. For both models, the triangular pulse is accurately reconstructed. For the model without quasi-static correction, however, the force time history right after the pulse is characterized by large oscillations, which are due to modeling errors that are mainly situated near the antiresonance frequencies (Fig. 5c). For the model with quasi-static correction, these oscillations are much less pronounced.

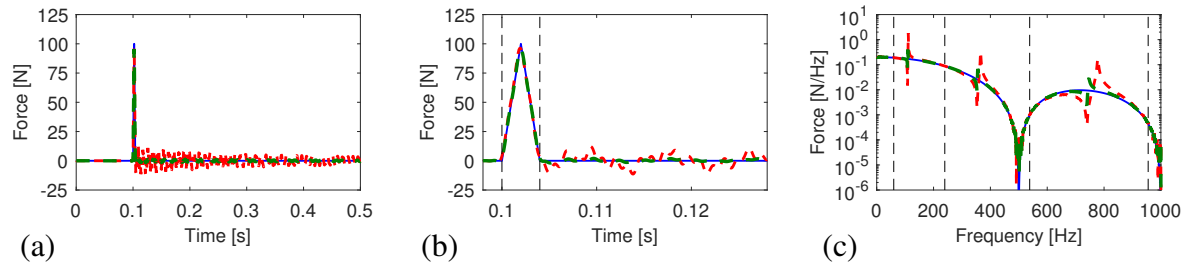

Figure 5: (a) Time history, (b) detail time history, and (c) frequency spectrum up to 1000 Hz of the estimated force $\hat{p}_1$ obtained from the joint input-state estimation algorithm using the model without dummy mode correction (red dashed line), using the model with dummy mode correction (green dashed line), and comparison to the applied force (blue solid line). The begin and end of the impact are indicated in (b) by a vertical dashed line. The undamped natural frequencies are indicated in (c) by vertical dashed lines.

3.2 Joint input-state-parameter estimation

In this section, the recursive joint input-state-parameter estimation algorithm presented in [10] is adopted for parameter estimation in presence of unknown inputs. Consider the case where the part of the simply supported steel beam situated at $L/4 < x < L/2$ is characterized by a reduced stiffness, for example due to corrosion. The reduction in stiffness is modeled as a local reduction of the Young's modulus from 210 GPa to 190 GPa, which corresponds to a reduction of 9.5%.

The dynamic system model is parameterized by a single parameter θ, which relates the Young's modulus E of the damaged section to the initial Young's modulus of the healthy structure ($E = \theta \times 210$ GPa). In the joint input-state-parameter estimation, the initial parameter value is assumed 1 (no damage). The target value of this parameter is 190 GPa$/210$ GPa $= 0.905$.

For demonstration purposes, a series of four impacts is considered. The time between two consecutive impacts is 0.5 s. The response applied in the joint input-state-parameter estimation consists of displacements d_1 and d_4 and accelerations a_2 and a_9 (see Fig. 1). Two additional sensors are added compared to the case of joint input-state estimation, as to obtain a system which is observable in terms of the unknown input and the unknown parameter. The reader is referred to [10] for a discussion on the sensor network design. As for the case of joint input-state estimation, two different models are considered in the system inversion. The first model is a modally reduced order model that includes the dynamic contribution of the first four bending modes without quasi-static mode correction. The second model is a modally reduced order model that includes the dynamic contribution of the same four bending modes with additionally the contribution of a single dummy mode. The same dummy mode parameters as those assumed in section 3.1 have been selected.

Although the smoothing algorithm presented [10] allows to adopt a delay in the estimation, this was deemed unnecessary in the present case, since a collocated acceleration measurement is used. Therefore, no delay is applied. In the application of the smoothing algorithm, the initial state $\hat{\mathbf{x}}_{[0|-1]}$ is assigned zero values for the modal displacements and velocities and a unit value is assigned for the parameter θ, corresponding to the original structure before damage. Due to the perturbation of the model in terms of the parameter θ, the corresponding model uncertainty should be reflected in the process noise covariance matrix $\mathbf{Q}$, through the choice of the parameter covariance matrix $\mathbf{Q}_\theta$. This matrix, which is in this case given by a scalar $\sigma^2_{Q_\theta}$, regularizes the parameter estimation. Indeed, $\sigma^2_{Q_\theta}$ is the variance characterizing the parameter variation over time. The choice of a large variance $\sigma^2_{Q_\theta}$ enables a large variation of the parameter between two time steps, leading to a potentially fast convergence of the parameter towards its actual value. Such choice, however, makes the parameter estimation more sensitive to noise and modeling errors (see also [10]). In this case, a parameter variance $\sigma^2_{Q_\theta} = 10^{-16}$ is adopted. The entries of the noise covariance matrices $\mathbf{Q}$ and $\mathbf{S}$ which correspond to process noise on the dynamic system states are assigned zero values. The measurement noise covariance matrix $\mathbf{R}$ is assumed identical to this assumed in section 3.1.

Fig. 6 shows the time history of the force $\hat{p}_1$ and the parameter $\hat{\theta}$ estimated by the joint input-state-parameter estimation algorithm and a comparison of the actual force and parameter values. During the first 0.1 seconds, i.e. before the first impact is applied, the structure is at rest and the algorithm does not get any information regarding the unknown structural parameter. This results in almost constant parameter estimates during this period, as observed from Fig. 6b. Some negligible oscillations of the parameter values are present, which are due to measurement

noise. As soon as the first impact is applied, the parameter estimate is characterized by a significant variation, where the parameter estimate first changes abruptly and drops below the target value 0.905 for both models, hereafter converging towards this target value. For the model without quasi-static correction, a much larger drop in the parameter value is observed than for the model with quasi-static correction. Once the parameter estimates have converged towards the true parameter value, one would expect that the parameter estimates stay close to the true parameter values, with small oscillations that are attributed to measurement noise. This is, however, not entirely true, due to the presence of modeling errors, which are inevitable. When the next impact is applied, the parameter estimate drops again, hereafter showing a convergence towards to the target parameter value. For the model without quasi-static correction, a larger variation of the parameter estimate following the impact is observed than for the model with quasi-static correction.

For each of the four impacts, the triangular pulse is accurately reconstructed for both models. This is in line with the findings of section 3.1, where it was found that the quasi-static correction is only of minor importance for the reconstruction of the triangular pulse. As for the case of joint input-state estimation, however, the force time history right after the pulse is characterized by large oscillations without quasi-static correction. Furthermore, it is worth noting that the first triangular pulse is also accurately identified, whereas this estimation relies on the wrong stiffness ($\theta = 1$). This is due to the fact that the response during a short pulse is mainly determined by the structural mass, which is correctly represented by the model, and only to a minor extent by the structural stiffness [3].

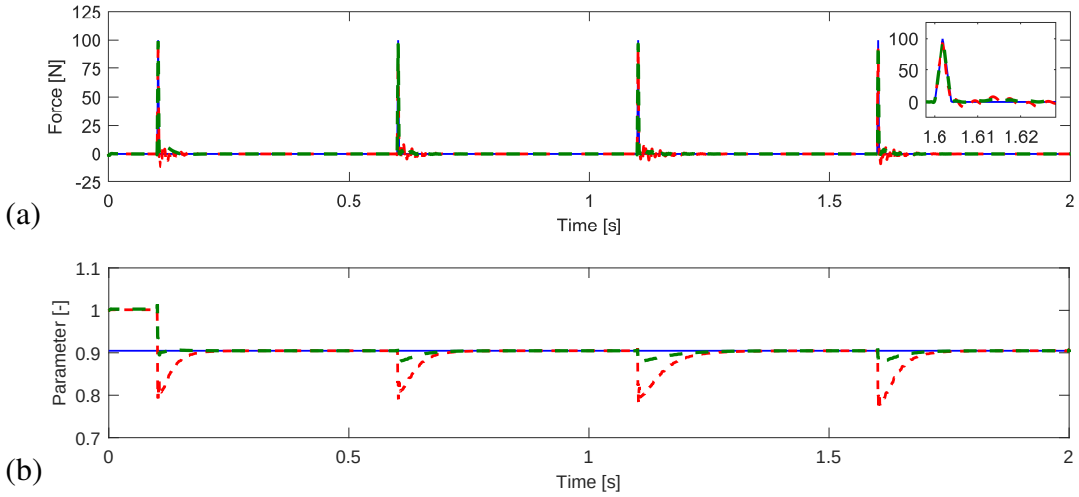

Figure 6: Time history of (a) the estimated force $\hat{p}_1$ and (b) the estimated parameter $\hat{\theta}$ obtained from the joint input-state-parameter estimation algorithm using the model without dummy mode correction (red dashed line), using the model with dummy mode correction (green dashed line), and comparison to the actual force and parameter values (blue solid line).

4 CONCLUSIONS

This paper evaluates the use of quasi-static correction of modally reduced order models for joint input-state estimation and joint input-state-parameter estimation in structural dynamics. Numerical simulations show that disregarding the contribution of so-called out-of-band modes can lead to significant errors in input and parameter estimation. Though not shown here, the same applies to state and response estimation. A recently developed quasi-static correction

technique is implemented and shown to be successful in reducing the modeling errors introduced by the model order reduction. This correction results in significantly smaller estimation errors in the system inversion.

Keywords: Viscoelastic beam, beam dynamics, damping identification, damping control, linear systems.

Abstract. *Viscoelastic materials are widely utilized in different engineering areas, however it is still not so easy to properly assess their mechanical properties, in terms of viscoelastic - frequency dependent modulus. Standard experimental procedures are utilized in this direction (e.g. DMA - Dynamic mechanical analysis), but such techniques still present some complexities, and this is why possible alternative approaches would be desirable. For example, the experimental investigation of a viscoelastic beam dynamics would be challenging, especially for the intrinsic simplicity of this kind of test. In this direction, a deep understanding of damping mechanisms in viscoelastic beams results to be a quite important task to better predict their dynamics. With the aim to elucidate damping properties in such structures, in this paper an analytical study of the transversal vibrations of a viscoelastic beam is presented. By means of a dimensional analysis, some key parameters are presented, which depend on the material properties and the beam geometry. In this way, by properly tuning such disclosed parameters, e.g. the dimensionless beam length once the material is chosen, it is possible to enhance or suppress some resonant peaks, one at a time or more simultaneously. This is a remarkable possibility to efficiently control damping in these structures, and the results presented in this paper may help in elucidating experimental procedures for the characterization of viscoelastic materials.*

1 INTRODUCTION

Nowadays, in the common engineering applications, the vibrating structures are mostly characterized by composite materials, with superior damping and high energy absorbing properties. The viscoelastic mechanical response of such materials must be correctly considered during the design process of structural components, thus making of huge importance the full comprehension of phenomena involving viscoelastic energy dissipation [1, 2, 3, 4, 5]. Viscoelasticity plays a key role in many applications, such as: (i) rolling contacts [6, 7, 8], (ii) sliding contacts [9, 10, 11, 12], (iii) crack propagation [13, 14, 15], (iv) seals [1], (v) adhesives and biomimetic adhesives [2, 3, 4], (vi) viscoelastic dewetting transition [16]. Many theoretical studies on the dynamics of non-viscous damped oscillators, for both SDOF [21, 22], and MDOF [23, 24] systems, have been presented in literature. Also viscoelastic continuous systems have been theoretically and experimentally investigated in their dynamics, such as beams and plates [25, 26, 27]. However, most of these studies do not present a qualitative analysis of the dynamic characteristics of such systems, in terms of eigenvalues and their connection with the most representative physical parameters. Only in Ref. [28], a comprehensive analysis of a single degree-of-freedom non-viscously damped oscillator has been presented. Extending this kind of investigation to continuous systems would be of crucial concern when viscoelastic properties of materials must be properly established. In particular, it is quite common in the experimental assessments of the viscoelastic properties of these materials, to consider beam-like structures as standard geometries [18, 19, 20]. With the aim to shed light on the vibrational behaviour of such systems, in this paper a detailed study of the dynamics of a viscoelastic beam is presented. We recall that the viscoelastic materials are characterized by the most general stress-strain relation [29]

$$\sigma\left(x,t\right)=\int_{-\infty}^{t}d\tau G\left(t-\tau\right)\dot{\varepsilon}\left(x,\tau\right) \tag{1}$$

where $\dot{\varepsilon}(t)$ is time derivative of the strain, $\sigma(t)$ is the stress, $G\left(t-\tau\right)$ is the time-dependent relaxation function, which is related, in the Laplace domain, to the viscoelastic modulus $E\left(s\right)$ through the relation $E\left(s\right)=sG\left(s\right)$. Usually, a discrete version of $E\left(s\right)$ is utilized to characterize linear viscoelastic solids, which can be represented in the Laplace domain as

$$E\left(s\right)=E_{0}+\sum_{k}E_{k}\frac{s\tau_{k}}{1+s\tau_{k}} \tag{2}$$

where E_0 is the elastic modulus of the material at zero-frequency, τ_k and E_k are the relaxation time and the elastic modulus respectively of the generic spring-element in the generalized linear viscoelastic model [29]. The general trend of the viscoelastic modulus $E(\omega)$ is shown in Figure 1. It can be observed that at low frequencies the material is in the 'rubbery' region, indeed $\mathrm{Re}[E(\omega)]$ is relatively small and approximately constant (Figure 1-a), and the viscoelastic dissipations related to the imaginary part $\mathrm{Im}[E(\omega)]$ of the viscoelastic modulus becomes negligible (Figure 1-b). At very high frequencies the material is elastically very stiff (brittle-like). In this 'glassy' region $\mathrm{Re}[E(\omega)]$ is again nearly constant but much larger (generally by 3 to 4 orders of magnitude) than in the rubbery region. The intermediate frequency range (the so called 'transition' region) determines the energy dissipation, and can completely deviate the modal behaviour of a viscoelastic solid from the equivalent elastic one. Moreover, the transition region, and hence the functions $\mathrm{Re}[E(\omega)]$ and $\mathrm{Im}[E(\omega)]$, can be shifted towards higher or smaller frequencies by simply varying temperature, because of the viscoelastic modulus $E(\omega)$ dependence on temperature [29].

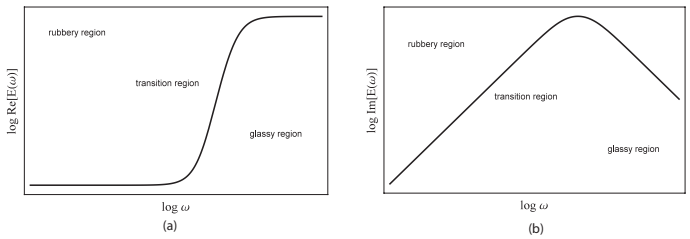

Figure 1: The real part (a) and the imaginary part (b) of the elastic modulus $E(\omega)$ of a generic viscoelastic material.

Of course, only the knowledge of the analytical vibrational response of a viscoelastic structure can provide the right parametric quantities, useful to accurately enlighten the relationship between the material properties and the modal contents. In this direction, the flexural vibrations of a viscoelastic beam is analytically studied in this paper, and by introducing some non-dimensional parameters, a qualitative analysis of the eigenvalues is presented. At first, an ideal viscoelastic material is considered, i.e. characterized by one single relaxation time. This kind of study, indeed, is useful for a first understanding of the physical parameters enclosed in the problem. Finally, some considerations are pointed out regarding the vibrational response of the beam in case of real viscoelastic materials.

2 BEAM DYNAMICS

In this section the analytical dynamic response of a viscoelastic beam with rectangular cross section is derived. Let be L, W, and H respectively the length, the width and the thickness of the beam, and let us assume that $L \gg W$, $L \gg H$. Assuming also that the displacement along the z-axis $|u(x,t)| \ll L$, the Bernoulli theory of transversal vibrations can be applied and therefore it is possible to neglect the influence of shear stress in the beam. It is worth noticing that this hypotesis does not limit the validity of the analysis, since the attention is paid to the first resonant peaks, which are not affected by shear deformations. Hence, the general equation of motion is [30]

$$J_{xz} \int_{-\infty}^{t} d\tau E(t-\tau) \frac{\partial^4 u(x,\tau)}{\partial x^4} + \mu \frac{\partial^2 u(x,t)}{\partial t^2} = f(x,t) \tag{3}$$

where $\mu = \rho A$, ρ is the bulk density of the material the cantilever is made of, A is the area of the cross section of the beam, i.e. $A = WH$, $J_{xz} = (1/12)WH^3$, and $f(x,t)$ is the generic forcing term. It must be highlighted that some additional terms could be considered in Eq.(3), representing different kind of damping contributes [31] (e.g. viscous damping and hysteresis damping). In the present study such terms are neglected, but it is important to underline that the results obtained in this paper are not affected by this assumption from a qualitative point of view. The forced solution of the above problem Eq.(3) can be found in the form of a series of the eigenfunction $\phi_n(x)$ of the following problem

$$J_{xz} \int_{-\infty}^{t} d\tau E(t-\tau) u_{xxxx}(x,\tau) + \mu u_{tt}(x,t) = 0 \tag{4}$$

($u_x(x,t) = \partial u(x,t)/\partial x$, $u_t(x,t) = \partial u(x,t)/\partial t$), with the opportune boundary conditions. In this study, the free-free boundary conditions are considered

$$\begin{aligned} u_{xx}(0,t) &= 0 \\ u_{xxx}(0,t) &= 0 \\ u_{xx}(L,t) &= 0 \\ u_{xxx}(L,t) &= 0 \end{aligned} \tag{5}$$

. By Laplace transforming the time-dependence in Eq.(4), and considering equal to zero the initial conditions, it is easy to show that the eigenfunctions $\phi(x,s)$ must satisfy the following equation

$$\phi_{xxxx}(x) - \beta_{eq}^4(s)\,\phi(x) = 0 \tag{6}$$

where it is defined

$$\beta_{eq}^4(s) = -\frac{\mu\, s^2}{J_{xz} E(s)} \tag{7}$$

. The boundary conditions then become

$$\begin{aligned} \phi_{xx}(0) &= 0 \\ \phi_{xxx}(0) &= 0 \\ \phi_{xx}(L) &= 0 \\ \phi_{xxx}(L) &= 0 \end{aligned} \tag{8}$$

The solution of the above Eq.(6) can be written in the form

$$\phi(x,s) = W_1 \cos[\beta_{eq}(s)\,x] + W_2 \sin[\beta_{eq}(s)\,x] + W_3 \cosh[\beta_{eq}(s)\,x] + W_4 \sinh[\beta_{eq}(s)\,x] \tag{9}$$

and by requiring that the determinant of the system matrix obtained from Eqs.(8) is zero, one obtains

$$[1 - \cos(\beta_{eq} L)\cosh(\beta_{eq} L)] = 0 \tag{10}$$

The solutions $\beta_n L = c_n$ of the above Eq.(10) are well known [30], and they are the same of the perfectly elastic case. In particular, from the following relation

$$-\frac{\mu\, s^2}{J_{xz} E(s)} = (\beta_n)^4 = \left(\frac{c_n}{L}\right)^4 \tag{11}$$

it is possible to calculate the complex conjugate eigenvalues s_n corresponding to the n_{th} mode, and the real poles s_k related to the material viscoelasticity (a detailed analysis of the eigenvalues will be shown in the next section). The values β_n allow to determine the eigenfunctions $\phi_n(x)$

$$\phi_n(x) = \cosh(\beta_n x) + \cos(\beta_n x) - \frac{\cosh(\beta_n L) - \cos(\beta_n L)}{\sinh(\beta_n L) - \sin(\beta_n L)}\left[\sinh(\beta_n x) + \sin(\beta_n x)\right] \tag{12}$$

which are equal to the eigenfunctions of the elastic case.

2.1 Response decomposition

The solution of Eq.(3) can be calculated, by considering (see Ref.[26]) the decomposition of the system response into the modes $\phi_n(x)$ of the beam

$$u(x,t) = \sum_{n=1}^{+\infty} \phi_n(x)\, q_n(t) \tag{13}$$

and by utilizing the orthogonality condition

$$\frac{1}{L}\int_0^L dx \phi_n(x)\, \phi_m(x) = \delta_{nm} \tag{14}$$

where δ_{nm} is Kronecker delta function. Indeed, by projecting the equation of motion on the function $\phi_m(x)$ of the basis, Eq.(3) becomes

$$\mu \ddot{q}_n(t) + J_{xz}\beta_n^4 \int_{-\infty}^{t} d\tau E(t-\tau)\, q_n(\tau) = f_n(t) \tag{15}$$

where $f_n(t) = \frac{1}{L}\int_0^L dx f(x,t)\, \phi_n(x)$ is the projected force term. In the Laplace domain, therefore, one has that Eq.(13) can be written

$$U(x,s) = \sum_{n=1}^{+\infty} \phi_n(x) \frac{F_n(x,s)}{\mu s^2 + J_{xz}\beta_n^4 E(s)} \tag{16}$$

3 VISCOELASTIC MODEL - SYSTEM EIGENVALUES

Let us consider an ideal viscoelastic material with a single relaxation time τ_1, whose elastic properties can be represented by the modulus

$$E(s) = E_0 + E_1 \frac{\tau_1 s}{1+\tau_1 s} \tag{17}$$

By substituting the previous complex function in Eq.(11), the characteristic equation for each n_{th} mode can be obtained

$$\tau_1 s^3 + s^2 + (E_0 + E_1)\tau_1 r_n s + r_n E_0 = 0 \tag{18}$$

where $r_n = (\beta_n)^4 J_{xz}/\mu$. Notice that the solutions of the cubic equation Eq.(18) can be i) one real root and two complex conjugate roots, ii) all roots real. This means that one eigenvalue is always related to an overdamped motion. When the other two eigenvalues are complex conjugate, they represent the oscillatory contribute of the n_{th} mode in the beam dynamics. Otherwise, in case of three real roots, the n_{th} mode is not oscillatory.

3.1 Dimensional analysis

With regards to the transverse motions of a narrow, homogenous beam with a bending stiffness $E_0 J_{xz}$ and density ρ, the value of the natural frequencies can be calculated using a simple formula which is always valid, regardless of the boundary conditions [32]:

$$\omega_n = \left(\frac{c_n}{L}\right)^2 \sqrt{\frac{E_0 J_{xz}}{\rho A}} \tag{19}$$

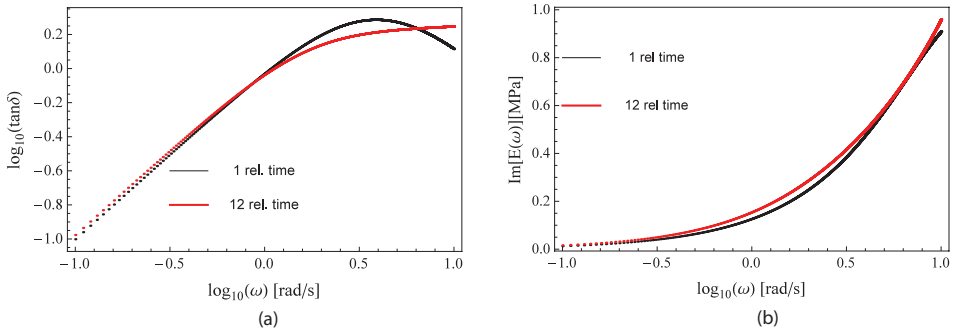

Figure 2: The function $\tan\delta = \mathrm{Im}[E(\omega)]/\mathrm{Re}[E(\omega)]$ (a) and the imaginary part of the viscoelastic modulus $E(\omega)$ (b), of a rubber like material [36]. Black curves are obtained, in a limited frequency range, by considering one single relaxation time. Red curves are the fitting results, with 12 relaxation times, in a wider frequency range, of experimental DMA described in Ref.[36].

where coefficient c_n depends on the specific boundary conditions. The first natural frequency, in particular, can be written as

$$\omega_1 = \alpha^2 \delta_1 \tag{20}$$

being $\delta_1 = (c_1^2/H)\sqrt{E_0/(12\rho)}$, and $\alpha = H/L$ the dimensionless beam length. The non-dimensional eigenvalue is now defined

$$\bar{s} = s/\delta_1 \tag{21}$$

and in particular one has, for the n_{th} mode, $\omega_n^2 = E_0\beta_n^4 J_{xz}/\mu = r_n E_0$ and $\delta_n = (c_n^2/H)\sqrt{E_0/(12\rho)}$.

By substituting Eq.(21) in Eq.(18), the following non-dimensional characteristic equation is obtained

$$\bar{s}^3 + \bar{s}^2\frac{1}{\theta_1} + (1+\gamma_1)\alpha^4\Delta_n^2\bar{s} + \frac{1}{\theta_1}\alpha^4\Delta_n^2 = 0 \tag{22}$$

where $\Delta_n = \delta_n/\delta_1$, and having defined the dimensional groups

$$\theta_1 = \delta_1\tau_1 \tag{23}$$

$$\gamma_1 = E_1/E_0 \tag{24}$$

. Eq.(22) can be then re-written as

$$\bar{s}^3 + \sum_{j=0}^{2} a_j^j \bar{s}^j = 0 \tag{25}$$

where $a_0 = (1/\theta_1)\alpha^4\Delta_n^2$, $a_1 = (1+\gamma_1)\alpha^4\Delta_n^2$, $a_2 = 1/\theta_1$.

By defining

$$Q = \frac{3a_1 - a_2^2}{9} \tag{26}$$

$$R = \frac{9a_2a_1 - 27a_0 - 2a_2^3}{54} \tag{27}$$

the discriminant of Eq.(25) is defined as $D = Q^3 + R^2$. In our case, the discriminant D, indicated as $D(n)$, is function of n, i.e. of the number of the n_{th} mode considered

$$D(n) = \frac{\alpha^4 \Delta_n^2 \left\{4 + \alpha^4 \Delta_n^2 \theta_1^2 \left[8 - \gamma_1 (20 + \gamma_1) + 4\alpha^2 (1 + \gamma_1)^3 \Delta_n^2 \theta_1^2\right]\right\}}{108 \theta_1^4} \tag{28}$$

This function $D(n)$ plays a key role in the understanding the nature of the roots of Eq.(25), as it will be widely discussed in Section of Results.

At last, the beam cross-section acceleration $A(x, s)$ in terms of the above defined non-dimensional groups is formulated, considering that $A(x, s) = s^2 U(x, s)$ (see Eq.(16))

$$A(x, \bar{s}) = F_0 \sum_{n=1}^{+\infty} \frac{\bar{s}^2 (1 + \theta_1 \bar{s}) \phi_n(x) \phi_n(x_f)}{\mu \theta_1 \left(\bar{s}^3 + \sum_{j=0}^{2} a_j \bar{s}^j\right)} \tag{29}$$

being $\phi_n(x)$ the eigenfunctions defined in Eq.(12), and being the forcing term impulsive.

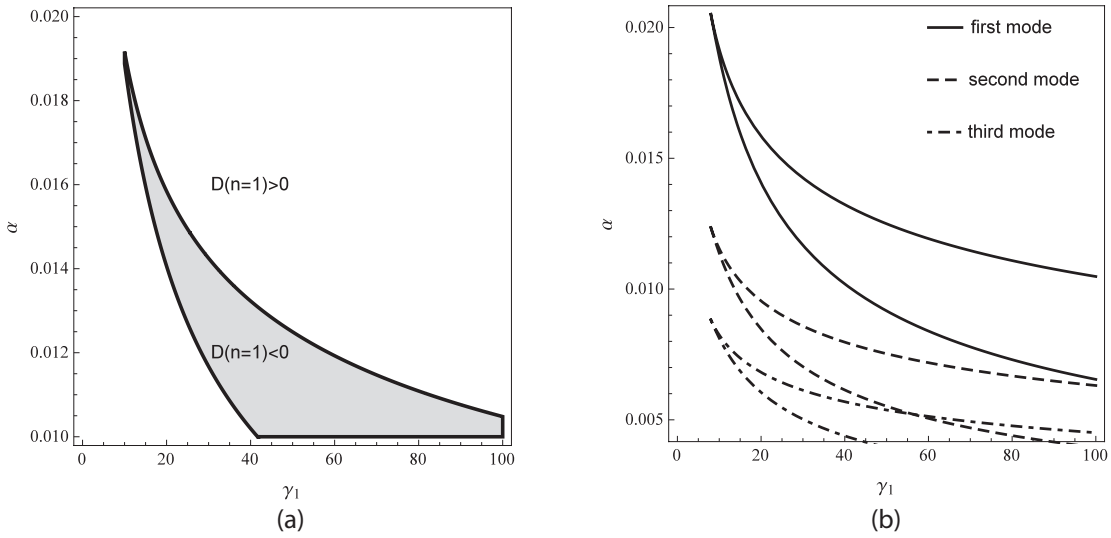

Figure 3: The region map for the first flexural mode of the beam $n = 1$, for $\theta_1 = \bar{\theta}_1$ (a). The shaded area indicates the parameter (α, γ_1) combinations which determine the suppression of the first peak. Similar region maps are shown, for the first three modes $n = 1, 2, 3$ (b). Interestingly, for several values of α and γ_1, some areas at $D(n) < 0$ are overlapped, determining the suppression of more peaks simultaneously.

4 RESULTS

In this section the main results of the presented analysis are discussed. The flexural vibrations of a viscoelastic beam with rectangular cross section and thickness $H = 1\,[\mathrm{cm}]$, which oscillates in the xz-plane are studied. The analysis starts from the characterization of a self-adhesive synthetic rubber found in literature [36]. The elastic modulus, experimentally obtained from DMA, has been fitted by Eq.2 with twelve relaxation times, in the frequency range $0 - 10^6\,[\mathrm{Hz}]$ [36]. A beam made of this material ($\rho = 1000\,[\mathrm{kg/m^3}]$), rectangular cross section with $H = 1\,[\mathrm{cm}]$ and $L = 50\,[\mathrm{cm}]$, has the first resonant peak in the frequency range $0 - 10\,[\mathrm{rad/s}]$. In order to evaluate the influence of the beam length on the first peak, the reduced frequency range $0 - 10\,[\mathrm{rad/s}]$ has been considered, in which the elastic modulus has been characterized

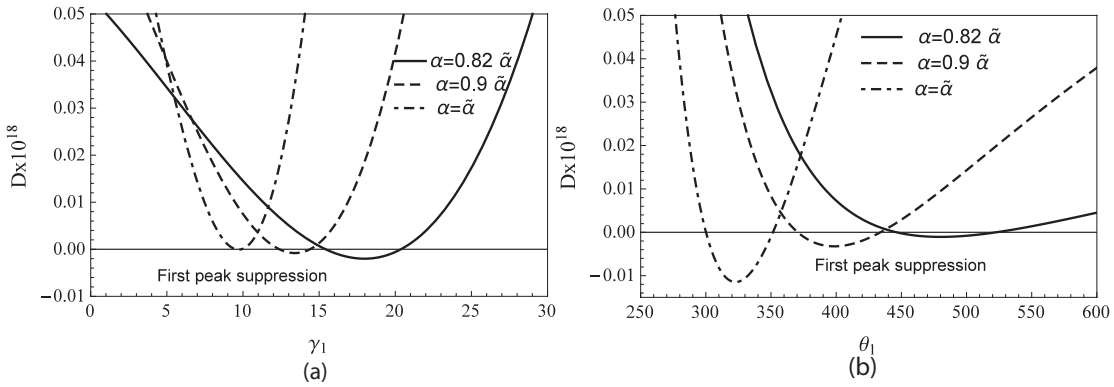

Figure 4: The discriminant $D\,(1)$ for the first mode $n = 1$, as a function of γ_1, for $\theta_1 = \bar{\theta}_1$ (a), and as a function of θ_1, for $\gamma_1 = \bar{\gamma}_1$ (b), for different values of α, i.e $\alpha = 0.82\tilde{\alpha}$ (solid line), $\alpha = 0.9\tilde{\alpha}$ (dashed line), $\alpha = \tilde{\alpha}$ (dot-dashed line).

by means of one single relaxation time. The parameters obtained by the fitting procedure, by means of (Eq.17), are $E_0 = 1.27 * 10^5$ [Pa], $E_1 = 2.018 * 10^6$ [Pa], $\tau_1 = 0.0628$ [s], from which one obtains $\bar{\gamma}_1 = E_1/E_0 = 15.9.$ and $\bar{\theta}_1 = \delta_1\tau_1 = 457.6$, being $\delta_1 = 7283$. It must be pointed out that the behaviour of the material is represented pretty well by this approximation in such limited frequency range, as one can observe in Figure 2, where it is shown the comparison between the original curve (red) and the reduced curve fitted by considering one relaxation time (black), in terms of the function $\tan\delta = \mathrm{Im}[E\,(\omega)]/\,\mathrm{Re}[E\,(\omega)]$ (Figure 2-a) and the imaginary part $\mathrm{Im}[E\,(\omega)]$ (Figure 2-b) of the viscoelastic modulus $E\,(\omega)$. Moving from this reference rubber like material, the two properties considered constant in the numerical calculations are $\rho = 1000$ [kg/m^3] and $E_0 = 1.27 * 10^5$ [Pa], so that the parameters δ_n are constant, and the other properties E_1 and τ_1 are taken varying in the analysis by means of γ_1 and θ_1. The only geometrical parameter which is considered varying in calculations, is the beam length L. In particular, the ratio $\alpha = H/L$ is changed maintaining H constant.

In must be observed that for each n_{th} mode, the three eigenvalues (solutions of Eq.(25)) can be calculated. The two complex conjugate eigenvalues represent the oscillatory counterpart of the beam n_{th} mode. The real eigenvalue gives rise to a pure dissipative contribute. However, when the discriminant $D\,(n)$, defined in Eq.(28), is negative $D\,(n) < 0$, all roots of Eq.(22) are real, and the n_{th} mode is not oscillatory. In Figure 3-a, a region map is shown, for the first flexural mode of the beam ($n = 1$), with $\theta_1 = \bar{\theta}_1$. The shaded area is obtained with the parameter values (α, γ_1) which give the condition $D\,(1) < 0$. Analogous maps, for the first three flexural modes of the beam, are represented by the correspondent curves in Figure 3-b, which are obtained by finding the two real solutions $\alpha = \alpha\,(\gamma_1)$ of the equation $D\,(n) = 0$, for $n = 1, 2, 3$. By properly combining the parameters (α, γ_1), different peaks can be suppressed simultaneously, since the areas which give the condition $D\,(n) < 0$ for different values of n are overlapped. In particular, this means that, once the material is prescribed, i.e. for given values of θ_1 and γ_1, the dynamics of the beam can be decisively modified by varying its length L. The sign of the discriminant $D\,(1)$, for the first mode, can be directly deduced by means of the curves plotted in Figure 4, where $D\,(1)$ is shown as a function of γ_1 (Figure 4-a), for $\theta_1 = \bar{\theta}_1$, and as a function of θ_1, for $\gamma_1 = \bar{\gamma}_1$ (Figure 4-b), for different values of α, i.e. $\alpha = 0.82\tilde{\alpha}$ (solid line), $\alpha = 0.9\tilde{\alpha}$ (dashed line), $\alpha = \tilde{\alpha}$ (dot-dashed line), where it has been considered the reference beam length equal to $\tilde{L} = 52[\mathrm{cm}]$. In Figure 5 the system response is represented, in terms of the acceleration modulus $|A\,(\bar{x}, \omega)|$ (see Eq.29), evaluated at the beam section $x = x_f = \bar{x} = 0.5L$,

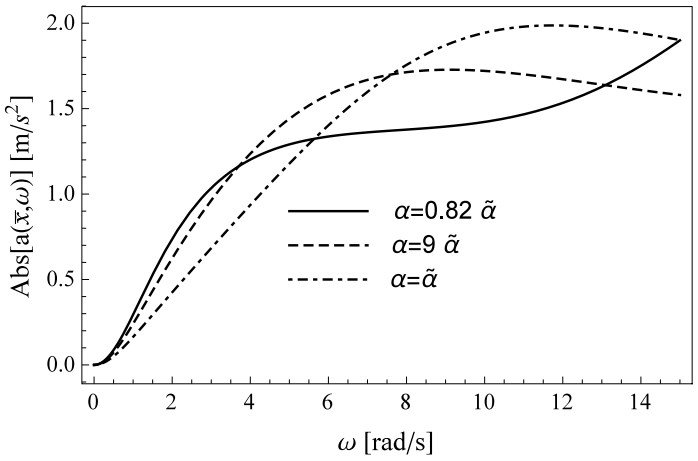

Figure 5: The acceleration modulus $|A(\bar{x},\omega)|$ of the viscoelastic beam with one relaxation time, in the section $x = x_f = \bar{x} = 0.5L$, for $\theta_1 = \bar{\theta}_1$, $\gamma_1 = \bar{\gamma}_1$, and for three different values of α, i.e. $\alpha = 0.82\tilde{\alpha}$ (solid line), $\alpha = 0.9\tilde{\alpha}$ (dashed line), $\alpha = \tilde{\alpha}$ (dot-dashed line). For $\alpha = 0.82\tilde{\alpha}$, being $D(1) < 0$, the first peak is suppressed.

for $\theta_1 = \bar{\theta}_1$ and $\gamma_1 = \bar{\gamma}_1$. Three different values of beam length L are considered, i.e. $\alpha = 0.82\tilde{\alpha}$ (solid line), $\alpha = 0.9\tilde{\alpha}$ (dashed line), $\alpha = \tilde{\alpha}$ (dot-dashed line), which give a damped first peak for $\alpha = 0.9\tilde{\alpha}$ and $\alpha = \tilde{\alpha}$, a suppressed first peak for $\alpha = 0.82\tilde{\alpha}$, being $D(1) < 0$ in the last case, as one can notice in Figure 4.

It is important to underline that, because of the intrinsic characteristics of viscoelastic materials [29], which see the viscoelastic modulus $E(\omega)$ depending on temperature, the above mentioned damping effect can be observed just modifying the surrounding temperature. Indeed, increasing or decreasing the working temperature, the functions $\mathrm{Re}[E(\omega)]$ and $\mathrm{Im}[E(\omega)]$ are shifted towards higher or smaller frequencies respectively, and consequently the material damping is differently spread in frequency, as well as the parameter θ_1 assumes different values.

However, once the material is prescribed, i.e. the viscoelastic modulus $E(\omega)$ is defined with the related parameters, θ_1 and γ_1, the dimensionless beam length α plays a crucial role in the possible overlapping of the first natural frequency ω_1 with the transition region. Moreover, in the hypothesis of linearity, such considerations can be extended to all the peaks, since the system can be decoupled and each vibration mode can be studied independently.

In conclusion, through the defined dimensionless parameters, it is possible to completely disclose the transversal vibrations of a viscoelastic beam. Suppressing certain peaks, by varying the beam length with α, or by changing the material properties (i.e. θ_1 and γ_1) for example by modifying the surrounding temperature, is an appealing chance for different applications. In particular, it is important to stress that, although the real viscoelastic materials present more than two relaxation times, the number of relaxation times to be considered in modelling the beam dynamics, does not represent a limit of our study. Indeed, it has been shown that it is always possible to divide the frequency spectrum under analysis in several intervals, thus allowing the decreasing of the predominant time relaxations number in such intervals. Moreover, by varying the beam length, it is possible to study a wide frequency range, by focusing the attention only to the first resonant peaks, so that the (Euler-Bernoulli) hypothesis still remains valid.

5 CONCLUSIONS

An analytical study of the transversal vibrations of a viscoelastic beam has been presented. The analytical solution has been obtained by means of modal superposition. In particular, the eigenvalues strongly depend on the material viscoelasticity, and they increase in number with the relaxation times of the viscoelastic modulus. A dimensional analysis has been performed, which has disclosed the fundamental parameters involved in the vibrational behaviour of the beam. Such parameters depend on both the material properties and the beam geometry. Some new characteristic maps related to the eigenvalues nature of the studied system have been provided, that can be drawn for each natural frequency of the beam. In comparison to the existing maps presented in literature for a sdof system, these maps may help in determining the parameter compounds needed to enhance or suppress certain frequency peaks, one at a time or more simultaneously, and the same approach can be exploited for any kind of mdof system. Results have shown that, by maintaining constant the thickness of the beam cross section, the dimensionless beam length can be utilized as key parameter to properly adjust the resonant peaks, once the material has been selected, thus becoming a powerful tool for many applications, from system damping control to materials characterization.

Keywords: Model updating, multi-span viaduct, periodic structures, free wave characteristics

Abstract. *The K032 viaduct of the A11 highway is a recently built multi-span viaduct in Bruges, Belgium. The viaduct is a typical quasi-periodic structure with, even at low frequencies, a high modal density. This leads to difficulties in distinguishing between these clustered modes in modal identification as well as the pairing of experimental and numerically predicted mode shapes in finite element model updating. Alternatively, for periodic structures, use can be made for structural identification of the so-called free wave characteristics. A model updating method based on free wave characteristics has recently been proposed for periodic structures. In this work, this method is applied to the K032 viaduct. Vibrational measurements were first conducted on the viaduct to identify the free wave characteristics. Next, the discrepancy between the calculated and identified free wave characteristics is minimized to update the finite element model of the viaduct. The model updating results are validated by comparing the measured frequency response functions and those calculated from the updated finite element model.*

1 INTRODUCTION

Vibration-based finite element model updating is widely used in civil engineering to calibrate numerical models with unknown or poorly known parameters [3, 4, 9]. It is usually performed by minimizing the discrepancy between the calculated and experimentally identified dynamic data, which are generally modal characteristics including natural frequencies and mode shapes. For repetitive structures, as often found in school and office buildings, multi-span bridges and parking buildings, mode clustering occurs with closely spaced natural frequencies and mode shapes with similar wavelength [10, 11]. This leads to difficulties in distinguishing between the modes in modal identification and consequently poses challenges in model updating where matching the measured and calculated modes is required. As alternatives, the use of free wave characteristics in the model updating of periodic structures has been explored in [11]. Free wave characteristics for periodic structures, including propagation constants and free waves, have been extensively studied by means of Floquet theory [1, 8]. In this work, the proposed model updating method is applied on the K032 viaduct (figure 1), a multi-span quasi-periodic viaduct in Bruges, where free waves were identified from vibration measurements and used to update the finite element model.

Figure 1: The K032 viaduct.

The K032 viaduct is introduced in section 2. The wave propagation theory is briefly introduced in Section 3. The measurement and the identification of the free waves of the viaduct are elaborated in Section 4. These measured free waves are used to update the finite element model of K032 in Section 5. Conclusions are given in Section 6.

2 The K032 viaduct

The K032 viaduct consists of two curved integral bridges K032L and K032R in parallel with each other. Each bridge has 23 spans, with most of the spans having a length of around 35 m. The total length of the viaduct is about 800 m. The two bridge are connected by a passway at the 19th and 20th span, allowing traffic to pass from one bridge to the other. Each bridge is composed of concrete girders with solid sections and concrete columns supported by pile foundations. The viaduct is divided into 5 zones, as shown in figure 2, with different material properties and cross section dimensions. Zones 2 and 3 are nearly periodic, giving the possibility for the analysis of free wave characteristics. The cross section dimensions of the deck and columns and the pile configuration of bridge K032R at sections A-A are shown in figures 3. The lateral view of K032R at zone 3 is shown in figure 4, where the lengths of columns and piles are given. Small variances are found on the lengths of columns and piles. At this zone, concrete grade C56/60 is used for the bridge deck and the columns, grade C35/45 is used for the piles and the pile caps.

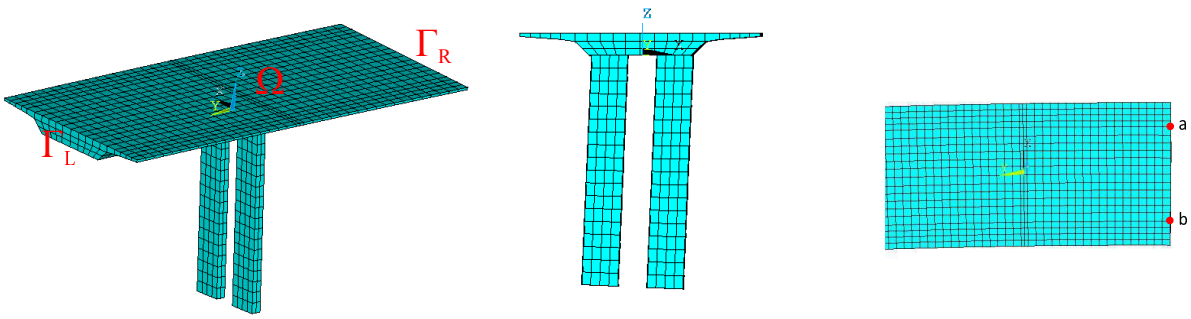
3 Free wave characteristics

The calculation of the free wave characteristics is briefly recapitulated in this subsection for the case of multi-coupled one-dimensional infinite periodic structures. The procedure is applied for a repetitive unit of bridge K032R at zone 3 shown in figure 4. The finite element model of the deck and column of one unit is shown in figure 5. This unit is taken from the center of one span to the center of the next span. It is modeled in ANSYS using solid45 elements. The stiffness and mass matrices are extracted from ANSYS and coupled in MATLAB to the model of the pile foundation in StaBIL [2]. The piles are modeled using beam elements in StaBIL and the surrounding soil is modeled by static distributed springs with lateral ($k^{\mathrm{s}}_{\mathrm{lateral}}$), axial ($k^{\mathrm{s}}_{\mathrm{axial}}$) and end-bearing axial ($k^{\mathrm{s}}_{\mathrm{end}}$) stiffness. The pile cap is assumed to be rigid and the column base is fixed at the center of the cap. From the finite element model of the pile foundation, the static impedance matrix is calculated and coupled to the degrees of freedom which correspond to the support of columns.



(a) 3D (b) Longitudinal view (c) Lateral view

Figure 5: The ANSYS model of one unit at zone 3.

The degrees of freedom (DOFs) of a repetitive unit are divided into two sets (figure 5a): the interface DOFs (at interfaces Γ_{L} and Γ_{R}) and the internal DOFs (in the internal domain Ω). Γ_{L} and Γ_{R} contain the DOFs that are coupled with the adjacent units on the left and right hand side, respectively. Ω contains the remaining internal DOFs that are not coupled with the adjacent units. The free wave characteristics are found by solving the free vibration problem of an infinitely long periodic structure without external forces, leading to the following condensed system of equation of motion considering the DOFs at Γ_{L} and Γ_{R} only.

$$\begin{bmatrix} \hat{\mathbf{F}}_{\mathrm{L}} \\ \hat{\mathbf{F}}_{\mathrm{R}} \end{bmatrix} = \begin{bmatrix} \mathbf{D}^{(\mathrm{c})}_{\mathrm{LL}} & \mathbf{D}^{(\mathrm{c})}_{\mathrm{LR}} \\ \mathbf{D}^{(\mathrm{c})}_{\mathrm{RL}} & \mathbf{D}^{(\mathrm{c})}_{\mathrm{RR}} \end{bmatrix} \begin{bmatrix} \hat{\mathbf{u}}_{\mathrm{L}} \\ \hat{\mathbf{u}}_{\mathrm{R}} \end{bmatrix} \tag{1}$$

where $\hat{\mathbf{F}}_{\mathrm{L}}$ and $\hat{\mathbf{F}}_{\mathrm{R}}$ are forces transfered at the interfaces, and $\mathbf{D}^{(\mathrm{c})}$ is the condensed dynamic stiffness matrix, $\hat{\mathbf{u}}_{\mathrm{L}}$ and $\hat{\mathbf{u}}_{\mathrm{R}}$ are the displacements at the interfaces.

According to the Floquet theory [1, 8], the displacements and forces at one unit are related to those of the next unit by a propagation constant μ as follows:

$$\hat{\mathbf{u}}_{\mathrm{L},r+1} = e^{\mu}\hat{\mathbf{u}}_{\mathrm{L},r} \tag{2a}$$

$$\hat{\mathbf{F}}_{\mathrm{L},r+1} = e^{\mu}\hat{\mathbf{F}}_{\mathrm{L},r} \tag{2b}$$

where the subscripts r and $r+1$ refer to unit r and the next unit $r+1$.

For compatibility and equilibrium to hold, the following equations are required:

$$\hat{\mathbf{u}}_{\mathrm{L},r+1} = \hat{\mathbf{u}}_{\mathrm{R},r} \tag{3a}$$

$$\hat{\mathbf{F}}_{\mathrm{L},r+1} = -\hat{\mathbf{F}}_{\mathrm{R},r} \tag{3b}$$

Introducing conditions (2a) and (2b) and the compatibility and equilibrium equations (3a) and (3b) in the equation of motion leads to the following quadratic eigenvalue problem:

$$[\mathbf{D}_{\mathrm{LR}}^{(\mathrm{c})} e^{2\mu} + (\mathbf{D}_{\mathrm{LL}}^{(\mathrm{c})} + \mathbf{D}_{\mathrm{RR}}^{(\mathrm{c})}) e^{\mu} + \mathbf{D}_{\mathrm{RL}}^{(\mathrm{c})}]\{\hat{\mathbf{u}}_{\mathrm{L}}\} = \mathbf{0} \tag{4}$$

The corresponding forces at the left interface Γ_{L} are calculated from $\hat{\mathbf{u}}_{\mathrm{L}}$:

$$\hat{\mathbf{F}}_{\mathrm{L}} = [\mathbf{D}_{\mathrm{LL}}^{(\mathrm{c})} + e^{\mu} \mathbf{D}_{\mathrm{LR}}^{(\mathrm{c})}]\{\hat{\mathbf{u}}_{\mathrm{L}}\} \tag{5}$$

By solving the eigenvalue problem (4), n_{c} pairs of free waves are obtained where n_{c} is the number of the coupling DOFs. Each pair contains one positive going and one identical but negative going free wave, characterized by a pair of negative and positive propagation constants. A propagation constant is a complex number with the real and imaginary part indicating the attenuation and the phase change of the corresponding wave across a unit cell, respectively. The k^{th} positive and negative going free wave characteristics are denoted as $[\mu_{\mathrm{p}k},\ \boldsymbol{\psi}_{\mathrm{p}k}]$ and $[\mu_{\mathrm{n}k},\ \boldsymbol{\psi}_{\mathrm{n}k}]$, respectively, where $\boldsymbol{\psi}$ is the displacement vector of dimension $n_{\mathrm{c}} \times 1$. Subscripts p and n represent the positive and negative going free waves, respectively. $\mu_{\mathrm{p}k}$ and $\mu_{\mathrm{n}k}$ are the propagation constants with $\mu_{\mathrm{p}k} = -\mu_{\mathrm{n}k}$ [7].

As an example, the free waves of K032R that can propagate at zone 3 at 40 Hz are calculated. Frequency independent hysteretic damping is added where the equation of motion becomes $(\mathbf{K} + i\eta\mathbf{K} - \omega^2\mathbf{M})\hat{\mathbf{u}} = \hat{\mathbf{F}}$ with η the hysteretic damping factor. η is initially taken as 0.02. The effective stiffness of the deck, column and piles are taken as $E_{\mathrm{deck}} = E_{\mathrm{column}} = 37$ GPa and $E_{\mathrm{pile}} = 34$ GPa. Three pairs of free waves with pronounced motion of the deck are plotted over several units in figure 6a-c. The first pair of free waves involves local bending of the deck, where the bending motion is approximately anti-symmetric around the longitudinal axis, while the second pair shows a local bending wave symmetric around the longitudinal axis. The third pair is a lateral wave with local bending of the deck. In figure 6d, a pair of longitudinal waves is plotted.

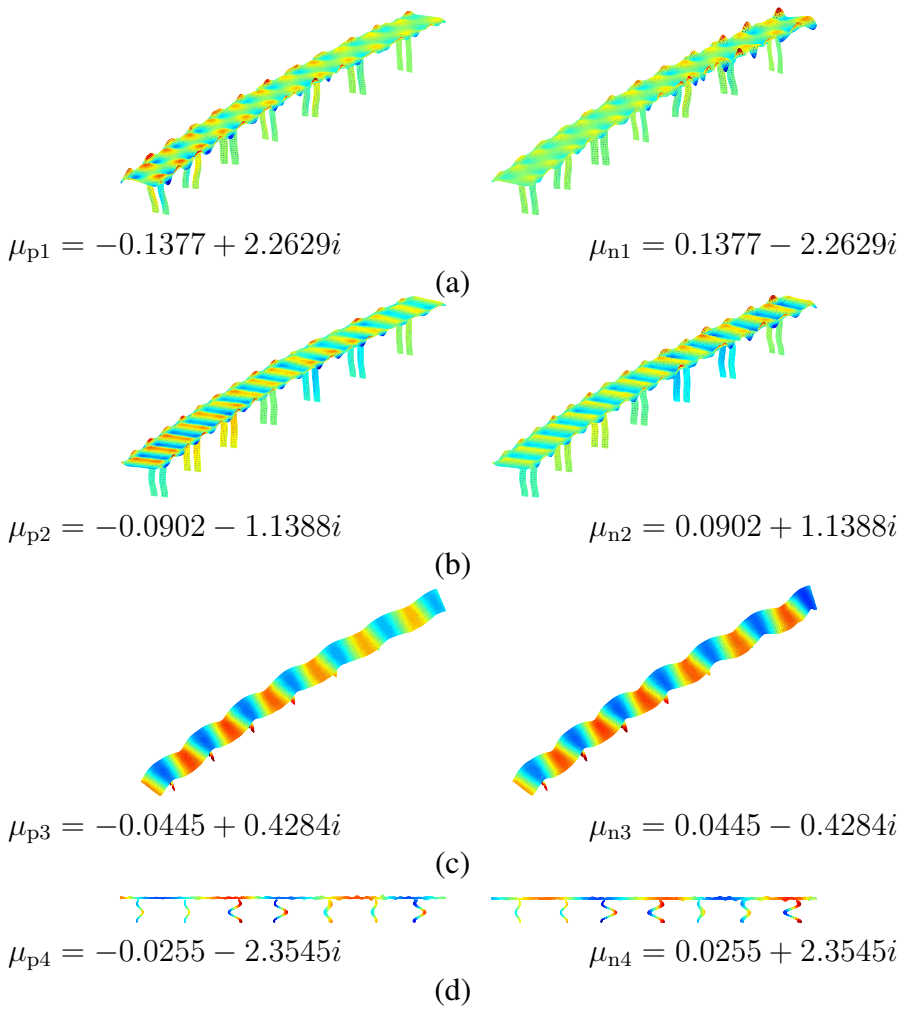


Figure 6: The calculated positive going (left) and the corresponding negative going (right) free waves at 40 Hz, (a)-(d): free wave pairs 1-4.

4 Free wave identification

First, the forced vibration of finite periodic structures is introduced based on the free wave analysis proposed by Mead [8]. Second, the inverse method of extracting the free waves from measured responses is briefly recapitulated [11]. This method is applied to K032R to identify the free wave characteristics, which will be used in the next section for model updating.

4.1 Forward problem

The forced vibration of periodic structures (forward problem) has been studied [6, 8] based on wave analysis. Mead [8] developed a method to calculate the forced harmonic motion of periodic structures by a linear superposition of all characteristic free waves. Figure 7 shows how the free waves propagate at zone 3 of K032R when the viaduct is excited at its right end. The negative going free waves are generated at the excitation point and propagate to the left though zone 3, the positive going free waves are reflected at the left end of zone 3 and propagate to the right. The responses at the left end of the first unit $\hat{\mathbf{u}}_1$ and second unit $\hat{\mathbf{u}}_2$ of zone 3 are

calculated as follows:

$$\hat{\mathbf{u}}_1 = \sum_{k=1}^{n_c} (\boldsymbol{\psi}_{pk}\alpha_{pk} + \lambda_{nk}^{-N}\boldsymbol{\psi}_{nk}\alpha_{nk}) = \sum_{k=1}^{n_c} (\boldsymbol{\psi}_{pk}\alpha_{pk} + \lambda_{pk}^{N}\boldsymbol{\psi}_{nk}\alpha_{nk}) \tag{6a}$$

$$\hat{\mathbf{u}}_2 = \sum_{k=1}^{n_c} (\lambda_{pk}\boldsymbol{\psi}_{pk}\alpha_{pk} + \lambda_{pk}^{(N-1)}\boldsymbol{\psi}_{nk}\alpha_{nk}) \tag{6b}$$

In equation (6a), $\boldsymbol{\psi}_{pk}\alpha_{pk}$ is the contribution of the k^{th} positive going free wave with α_{pk} the corresponding generalized coordinate, while $\lambda_{nk}^{-N}\boldsymbol{\psi}_{nk}\alpha_{nk}$ is the contribution of the k^{th} negative going free wave after propagation to the left through N units. In this case N is equal to 7. Since $e^{\mu_{pk}} = e^{-\mu_{nk}}$ and $\lambda_{pk} = \lambda_{nk}^{-1}$, the term $\lambda_{nk}^{-N}\boldsymbol{\psi}_{nk}\alpha_{nk}$ is re-written as $\lambda_{pk}^{N}\boldsymbol{\psi}_{nk}\alpha_{nk}$ in equation (6a). Similarly, the response $\hat{\mathbf{u}}_2$ is written in equation (6b). The responses at the other units can be obtained in the same way.

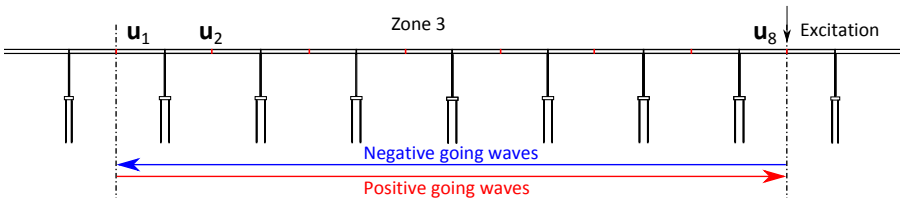

Figure 7: Waves propagating in zone 3 excited at its ends.

4.2 Inverse problem

The inverse problem, where the free waves are identified from measured responses, has been investigated by [5, 11]. It is briefly introduced in this subsection. The response at the left end of the first measured unit ($\bar{\mathbf{d}}_1$) is written in terms of the free wave contributions as follows:

$$\bar{\mathbf{d}}_1 = \mathbf{L}\hat{\mathbf{u}}_1 = \mathbf{L}\sum_{k=1}^{n_w} (\boldsymbol{\psi}_{pk}\alpha_{pk} + \lambda_{pk}^{N}\boldsymbol{\psi}_{nk}\alpha_{nk}) = \sum_{k=1}^{n_w} (\mathbf{x}_{pk} + \lambda_{pk}^{N}\mathbf{x}_{nk}) \tag{7}$$

where $\hat{\mathbf{d}}_1$ is the dynamic response at the measured DOFs at the left end of the first measured unit and $\mathbf{L}$ is a $n_m \times n_c$ selection matrix that selects the n_m measured DOFs from all n_c coupling DOFs. The vectors $\mathbf{x}_{pk} = \mathbf{L}\boldsymbol{\psi}_{pk}\alpha_{pk}$ and $\mathbf{x}_{nk} = \mathbf{L}\boldsymbol{\psi}_{nk}\alpha_{nk}$ are the k^{th} positive and negative going free wave component of size $n_m \times 1$ which need to be determined. The number of wave pairs that participate to the response is given by n_w.

Similarly, the measured response is obtained for the other units:

$$\begin{bmatrix} \sum_{k=1}^{n_w} (\mathbf{x}_{pk} + \lambda_{pk}^{N}\mathbf{x}_{nk}) \\ \sum_{k=1}^{n_w} (\lambda_{pk}\mathbf{x}_{pk} + \lambda_{pk}^{(N-1)}\mathbf{x}_{nk}) \\ \vdots \\ \sum_{k=1}^{n_w} (\lambda_{pk}^{N}\mathbf{x}_{pk} + \mathbf{x}_{nk}) \end{bmatrix} - \begin{bmatrix} \bar{\mathbf{d}}_1 \\ \bar{\mathbf{d}}_2 \\ \vdots \\ \bar{\mathbf{d}}_{(N+1)} \end{bmatrix} = \mathbf{0} \tag{8}$$

To solve this system of equations, Zhang et al. [11] have proposed a non-linear least-squares

method where the objective function is formulated as follows:

$$\mathbf{F}(\mathbf{x}_{\mathrm{p}k};\ \mathbf{x}_{\mathrm{n}k};\ \lambda_{\mathrm{p}k}) = \left\| \begin{bmatrix} \sum_{k=1}^{n_{\mathrm{w}}} (\mathbf{x}_{\mathrm{p}k} + \lambda_{\mathrm{p}k}^{N} \mathbf{x}_{\mathrm{n}k}) \\ \sum_{k=1}^{n_{\mathrm{w}}} (\lambda_{\mathrm{p}k} \mathbf{x}_{\mathrm{p}k} + \lambda_{\mathrm{p}k}^{(N-1)} \mathbf{x}_{\mathrm{n}k}) \\ \vdots \\ \sum_{k=1}^{n_{\mathrm{w}}} (\lambda_{\mathrm{p}k}^{N} \mathbf{x}_{\mathrm{p}k} + \mathbf{x}_{\mathrm{n}k}) \end{bmatrix} - \begin{bmatrix} \bar{\mathbf{d}}_1 \\ \bar{\mathbf{d}}_2 \\ \vdots \\ \bar{\mathbf{d}}_{(N+1)} \end{bmatrix} \right\|_2^2 \tag{9}$$

Data $\bar{\mathbf{d}} = [\bar{\mathbf{d}}_1; \bar{\mathbf{d}}_2; \cdots; \bar{\mathbf{d}}_{(N+1)}]$ can be directly measured (displacement, velocity or acceleration) responses or frequency response functions (FRFs). $\lambda_{\mathrm{p}k}$, $\mathbf{x}_{\mathrm{p}k}$ and $\mathbf{x}_{\mathrm{n}k}$ ($k = [1, 2, \cdots, n_{\mathrm{w}}]$) are the unknown free wave characteristics to be determined. The objective function is minimized to obtain the least-squares solution of the free wave characteristics:

$$[\mathbf{x}_{\mathrm{p}k};\ \mathbf{x}_{\mathrm{n}k};\ \lambda_{\mathrm{p}k}]^* = \min_{[\mathbf{x}_{\mathrm{p}k};\ \mathbf{x}_{\mathrm{n}k};\ \lambda_{\mathrm{p}k}]} \mathbf{F}(\mathbf{x}_{\mathrm{p}k};\ \mathbf{x}_{\mathrm{n}k};\ \lambda_{\mathrm{p}k}) \tag{10}$$

4.3 Free wave identification of K032

Measurements were conducted to identify the free waves of K032R. Twelve wireless recorders including 9 GeoSIG GMS-18 units and 3 GeoSIG GMSplus units were used. Each recorder measured the accelerations in 3 orthogonal directions x, y, and z, that are aligned with the LCS shown in figure 8. The GeoSIG GMSplus units have 3 additional channels, which were used to connected additional uni-axial accelerometers and the hammer. Repeated hammer impacts in the vertical direction z were applied at the right end of zone 3 to excite vertical bending or torsional free waves. In 2 setups, the locations in figure 8 are measured. The frequency response functions at the measured locations are calculated and used in the free wave identification.

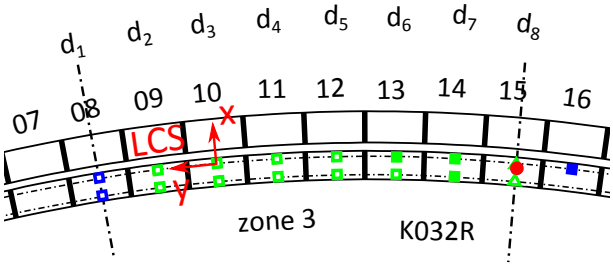

Figure 8: Sensor configurations for setup 1 (green) and setup 2 (blue) with the GeoSIG GMS-18 units (hollow squares), the GeoSIG GMSplus units (solid squares) and the uni-axial accelerometers (triangles) connected to the GeoSIG GMSplus units and the hammer excitation (circles).

One pair of stable torsional free waves is identified at each frequency in the range between 38 Hz and 44 Hz with an increment of 1 Hz. The negative going torsional free wave contributes most to the total response, while its positive going counterpart only has a small contribution. The stable torsional free wave pair identified here in fact corresponds to the local bending wave pair 1 computed from the preliminary FE model which was shown in figure 6a. The identified negative going free waves at the measured locations are shown in figure 10. The free waves calculated from the preliminary finite element model (Section 3) are also plotted over the measured locations. The corresponding propagation constants are listed in table 1. Discrepancies are found between the measured and predicted free wave characteristics. These discrepancies will be minimized to update the finite element model in the following section.

5 Model updating of the K032 viaduct

Deterministic model updating [9] is usually performed by minimizing a least-squares cost function quantifying the discrepancy between calculated and experimentally identified dynamic data. Based on the study in [11], free wave characteristics can be used as the data feature for the model updating of periodic structures. The eigenvalues $\lambda_{\mathrm{p}k}$ and $\lambda_{\mathrm{n}k}$, the positive and negative going free wave vectors $\boldsymbol{\psi}_{\mathrm{p}k}$ and $\boldsymbol{\psi}_{\mathrm{n}k}$, are used to construct the following least-squares cost function.

$$\mathbf{F}(\boldsymbol{\theta}_{\mathrm{M}},\omega)=\sum_{k=1}^{n_{\mathrm{w}}}a_k\frac{(\bar{\lambda}_{\mathrm{p}k}(\omega)-\lambda_{\mathrm{p}k}(\boldsymbol{\theta}_{\mathrm{M}},\omega))^2}{(\bar{\lambda}_{\mathrm{p}k}(\omega))^2}+\sum_{k=1}^{n_{\mathrm{w}}}b_k\frac{||\chi_{\mathrm{p}k}\bar{\boldsymbol{\psi}}_{\mathrm{p}k}(\omega)-\mathbf{L}\boldsymbol{\psi}_{\mathrm{p}k}(\boldsymbol{\theta}_{\mathrm{M}},\omega)||_2^2}{||\chi_{\mathrm{p}k}\bar{\boldsymbol{\psi}}_{\mathrm{p}k}(\omega)||_2^2}$$
$$+\sum_{k=1}^{n_{\mathrm{w}}}c_k\frac{(\bar{\lambda}_{\mathrm{n}k}(\omega)-\lambda_{\mathrm{n}k}(\boldsymbol{\theta}_{\mathrm{M}},\omega))^2}{(\bar{\lambda}_{\mathrm{n}k}(\omega))^2}+\sum_{k=1}^{n_{\mathrm{w}}}d_k\frac{||\chi_{\mathrm{n}k}\bar{\boldsymbol{\psi}}_{\mathrm{n}k}(\omega)-\mathbf{L}\boldsymbol{\psi}_{\mathrm{n}k}(\boldsymbol{\theta}_{\mathrm{M}},\omega)||_2^2}{||\chi_{\mathrm{n}k}\bar{\boldsymbol{\psi}}_{\mathrm{n}k}(\omega)||_2^2} \tag{11}$$

where n_{w} is the number of free wave pairs considered; ω is the considered frequency; $\bar{\lambda}_{\mathrm{p}k}(\omega)$, $\bar{\lambda}_{\mathrm{n}k}(\omega)$, $\bar{\boldsymbol{\psi}}_{\mathrm{p}k}(\omega)$ and $\bar{\boldsymbol{\psi}}_{\mathrm{p}k}(\omega)$ are the measured free wave characteristics at frequency ω, while $\lambda_{\mathrm{p}k}(\boldsymbol{\theta}_{\mathrm{M}},\omega)$, $\lambda_{\mathrm{n}k}(\boldsymbol{\theta}_{\mathrm{M}},\omega)$, $\boldsymbol{\psi}_{\mathrm{p}k}(\boldsymbol{\theta}_{\mathrm{M}},\omega)$ and $\boldsymbol{\psi}_{\mathrm{n}k}(\boldsymbol{\theta}_{\mathrm{M}},\omega)$ are the corresponding computed quantities; $\chi_{\mathrm{p}k}$ and $\chi_{\mathrm{n}k}$ are scaling factors which are introduced to obtain similar scaling of the free waves obtained from FE model and experiments. These scaling factors are calculated as $\chi_{\mathrm{p}k}=\dfrac{\bar{\boldsymbol{\psi}}_{\mathrm{p}k}^{\mathrm{H}}\mathbf{L}\boldsymbol{\psi}_{\mathrm{p}k}(\boldsymbol{\theta}_{\mathrm{M}})}{\|\bar{\boldsymbol{\psi}}_{\mathrm{p}k}\|_2^2}$ and $\chi_{\mathrm{n}k}=\dfrac{\bar{\boldsymbol{\psi}}_{\mathrm{n}k}^{\mathrm{H}}\mathbf{L}\boldsymbol{\psi}_{\mathrm{n}k}(\boldsymbol{\theta}_{\mathrm{M}})}{\|\bar{\boldsymbol{\psi}}_{\mathrm{n}k}\|_2^2}$. $\mathbf{L}$ is a selection matrix that selects the observed DOFs of the FE model; a_k, b_k, c_k and d_k are weighting factors, representing the importance of the corresponding terms.

When free wave characteristics at multiple frequencies are available, they can be considered simultaneously in the objective function:

$$\mathbf{F}(\boldsymbol{\theta}_{\mathrm{M}})=\sum_{j=1}^{n_{\mathrm{f}}}\mathbf{F}_j(\boldsymbol{\theta}_{\mathrm{M}},\omega_j) \tag{12}$$

where $\mathbf{F}_j(\boldsymbol{\theta}_{\mathrm{M}},\omega_j)$ contains the squared residuals at frequency ω_j and n_{f} is the number of frequencies considered. The cost function is minimized to obtain the model parameters:

$$\boldsymbol{\theta}_{\mathrm{M}}^{*}=\min_{\boldsymbol{\theta}_{\mathrm{M}}}\ \mathbf{F}(\boldsymbol{\theta}_{\mathrm{M}}) \tag{13}$$

For the updating of the preliminary unit model of the viaduct, 6 possible material related updating parameters are initially considered, including the effective stiffness of the concrete deck ($\theta_1 E_{\mathrm{deck}}$), the effective stiffness of the column ($\theta_2 E_{\mathrm{column}}$), the effective stiffness of the piles ($\theta_3 E_{\mathrm{pile}}$), the lateral stiffness provided by the soil ($\theta_4 k_{\mathrm{lateral}}^{)}$) and the axial and end bearing stiffness of the soil ($\theta_5 k_{\mathrm{axial,end}}^{\mathrm{s}}$) and the hysteretic damping factor ($\theta_6\eta$). The sensitivities of the free wave characteristics to these parameters have been studied. It is found that the free wave characteristics are more sensitive to the effective stiffness of the concrete deck ($\theta_1 E_{\mathrm{deck}}$) and the damping factor ($\theta_6\eta$) than to the other parameters. These two parameters are therefore considered in the updating with an initial value of 1. The identified negative going free waves are used in the updating. The weighting factors are taken as 1. The Levenberg-Marquardt algorithm is used to solve the least-squares problem. The residual of the objective function is shown in figure 9. The updated values of the parameters are $\theta_1 = 1.2408$ and $\theta_6 = 4.6430$. As expected, the effective stiffness of the deck is increased due to the pre-stressing of the steel

reinforcement. The updated propagation constants and free waves are shown in table 1 and in figure 10, respectively. A better agreement between the identified and updated free wave characteristics is obtained.

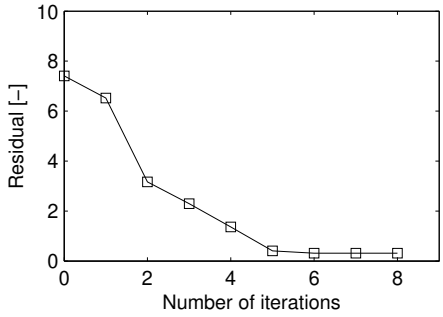

Figure 9: The residual of the objective function for the updating of the preliminary unit model.

Frequency	$\bar{\mu}_{\mathrm{N1}}$ [-]	μ_{N1} [-]	μ^*_{N1} [-]
38 Hz	$0.7330 + 2.0586i$	$0.1768 + 3.3010i$ (62.3%)	$0.7222 + 2.1786i$ (5.5%)
39 Hz	$0.6250 + 2.4098i$	$0.1378 + 3.6634i$ (54.0%)	$0.7235 + 2.5162i$ (5.8%)
40 Hz	$0.5591 + 2.8299i$	$0.1377 + 4.0203i$ (43.8%)	$0.7316 + 2.8446i$ (6.0%)
41 Hz	$0.6324 - 3.0734i$	$0.1488 - 1.9011i$ (40.4%)	$0.7479 - 3.1194i$ (4.0%)

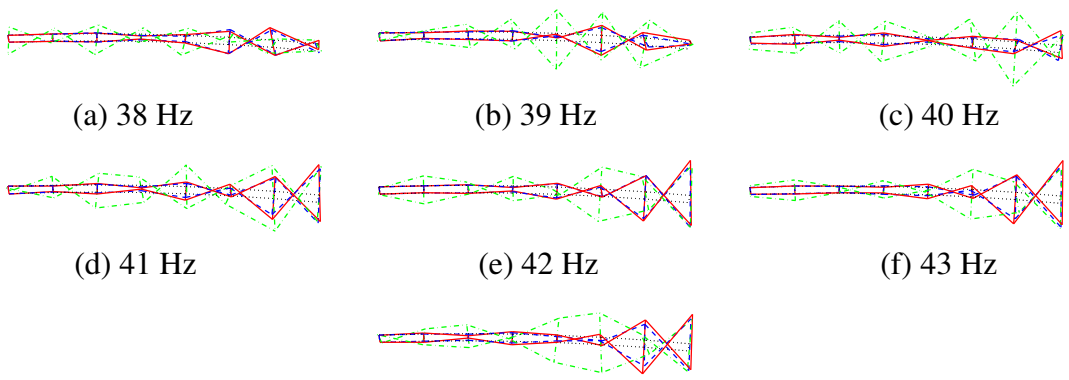
43 Hz	$0.6673 - 2.6902i$	$0.2926 - 1.4450i$ (46.9%)	$0.7973 - 2.5225i$ (7.7%)
44 Hz	$0.5653 - 2.3840i$	$0.1762 - 1.0256i$ (57.7%)	$0.8134 - 2.2329i$ (11.9%)

Table 1: The propagation constants of the negative going free waves identified from the experiment $\bar{\mu}_{\mathrm{N1}}$, calculated from the preliminary FE model μ_{N1} and the updated FE model μ^*_{N1}. The values between the brackets indicate the relative error between the identified and the calculated propagation constants.



(a) 38 Hz (b) 39 Hz (c) 40 Hz

(d) 41 Hz (e) 42 Hz (f) 43 Hz

(g) 44 Hz

Figure 10: The negative going free waves identified from the measurements (solid lines), calculated from the preliminary (dot-dashed lines) and updated model (dashed lines); (a)-(g): at frequencies 38 Hz to 44 Hz.

In order to validate the updating results, the frequency response functions (FRFs) representing the acceleration responses are calculated using the preliminary and updated finite element model and compared to the measured ones. The measurement was conducted where the hammer excitation was applied at the left side end of zone 3 and the responses were measured at few bays, as shown in figure 11. The measured and calculated FRFs at bay 08, 09 and 10 in the frequency between 0 Hz and 45 Hz are shown in figure 12. The FRFs zoomed between 0 Hz and 10 Hz are plotted in figure 13. At the measurement location on bay 08 closest to the excitation, the updated model gives a good prediction of the FRF. It also gives a good prediction of the FRFs at the other measured locations below 9 Hz. However, the preliminary and updated solid models do not predict very well the response on bays 09 and 10 above 9 Hz when the free waves propagate across one unit and two units, respectively. It is also observed that the FRFs on bays 09 and 10 calculated from the updated solid model are generally smaller than those of the preliminary solid model. One reason is that the damping factor used in the updated model is larger than the one in the preliminary model. In general, damping of bridges is difficult to be represented in numerical models. It varies with the vibration frequencies, which is not considered in the modeling. The inaccurate modeling of damping may be one reason for the discrepancies between the measured and calculated FRFs. It is also noted that the estimation of the experimental FRFs might not be accurate especially for the locations measured far away from the excitation due to the influence of noise.

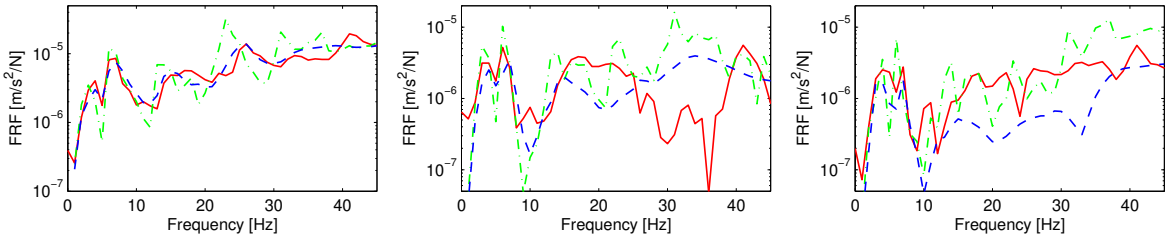

Figure 12: The frequency response function between 0 Hz and 45 Hz in z-direction measured from the experiment (solid lines), calculated from the preliminary (dot-dashed lines) and updated (dashed lines) solid model.

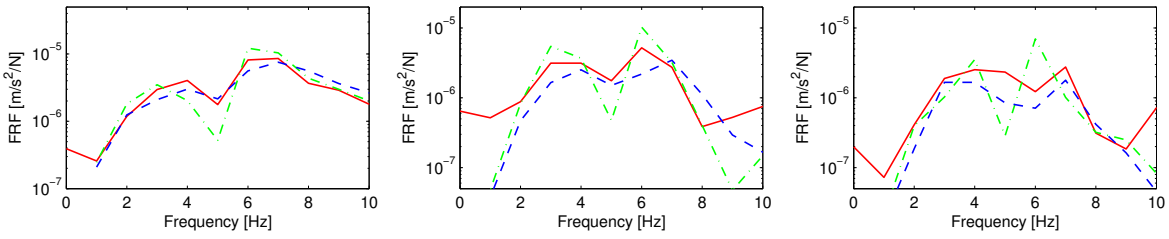

Figure 13: The frequency response function between 0 Hz and 10 Hz in z-direction measured from the experiment (solid lines), calculated from the preliminary (dot-dashed lines) and updated (dashed lines) solid model.

6 CONCLUSIONS

Following the method of free wave characteristics-based model updating for periodic structures, measurements have been conducted on the multi-span quasi-periodic viaduct. The free wave characteristics have been identified from the measurements and used to update the finite element model. It is found that the updated model leads to a much better prediction of the free wave characteristics that match well with the identified ones. It also gives generally good predictions on the frequency response functions. The feasibility of free wave characteristics-based model updating is validated though this case study.

ACKNOWLEDGEMENTS

The research presented in this paper has been performed within the framework of project OT/13/59 "Quantifying and reducing uncertainty in structural dynamics", funded by the Research Council of KU Leuven. The financial support of KU Leuven is gratefully acknowledged. The second, third and last author are members of the KU Leuven-BOF PFV/10/002 OPTEC-Optimization in Engineering Center. The authors would also like to thank Jeffrey Depauw and Dieter Van Boeckel of the THV KW A11 for providing access to the viaduct and their support in the practical organization of the measurements.

Keywords: suspension bridge, structural monitoring, force identification, Kalman filter.

Abstract. *The traditional wind load assessment for long-span bridges rely on assumed models for the wind field and aerodynamic coefficients from wind tunnel tests, which usually introduces some uncertainties. It is therefore desired to develop tools that can utilize full-scale vibration response data from existing bridges in order to study the wind loading in detail for in-situ conditions. This paper presents a novel case study of inverse identification of dynamic wind loads on the 1310 m long Hardanger bridge, a suspension bridge equipped with a network of accelerometers. The identification method used is an extented Kalman-type filter for joint input, state, and parameter estimation. A system model considering the still-air modes in addition to a quasi-steady submodel for the self-excited forces of the bridge is presente. The coefficients for self-excited lift and pitching moment are considered unknown and are jointly estimated with the buffeting forces.*

1 INTRODUCTION

For very long and slender bridges, aerodynamic performance often becomes the critical factor in the design [1]. Hence, it is important to understand the dynamic response behavior under wind excitation. In this arena, it is commonly accepted that the theories behind buffeting forces due to turbulence [2] and self-excited forces induced by the motion of structure [3] are governing. In addition to this comes static wind pressures and vortex-shedding [4, 5], but these are not the focus of this contribution. The calculation of the buffeting and self-excited forces involves the use of aerodynamic coefficients or functions, which in today's practice often are obtained from series of wind tunnel tests. Alternatively, simulations based on computational fluid dynamics can be performed [6, 7], with the drawback of requiring immense computational power. The numerical and small-scale experiments involve some uncertainties and simplifications, and sometimes it can be beneficial to learn directly from existing bridges in their operating environment.

In recent years, the focus on structural health monitoring (SHM) have given engineers an abundance of full-scale data from long-span bridges. This full-scale data can be valuable since it contains information on the behavior of the bridge in the complex conditions that occur in reality. It is therefore desired to use such data to explore the ability for testing and validation of the models for the wind loading and aerodynamic interaction. This can be a difficult task since the application of advanced signal processing methods can encounter some trouble due to uncertain or non-idealized conditions, disturbances, and data from limited sensors.

One available tool to reduce the dynamic load uncertainties is the use of inverse force identification methodologies. Herein, the excitation forces are considered unknown and are estimated from limited output response measurements, typically accelerations. Although many techniques have recently been proposed in the literature [8–18], the application of these inverse methods are not well-explored for long-span bridges. There is therefore a need to test the available methods to get experience on the actual performance under realistic conditions.

In this work, the apply the input and state estimator in [8] to study the estimation of wind loads. This Kalman-type algorithm, which is an extended version of earlier algorithms [19, 20], allows for an extension to estimation of unknown system parameters. The method is tested for measurement data from a long-span suspension bridge. In the presented framework, the states are the modal responses, the unknown inputs are the buffeting forces and the uncertain parameters are quasi-steady coefficients related to the self-excitation of the bridge box girder under wind loading.

2 THEORY

2.1 Equations for the wind-induced dynamic response

This section derives a state-space formulation for the bridge dynamics, taking into account a quasi-steady form of self-excitation leading to aerodynamic stiffness and damping. We assume the following equations of motion in a FE-format for the response $\mathbf{u}(t) \in \mathbb{R}^{\mathrm{n_{DOF}}}$:

$$\mathbf{M}_0\ddot{\mathbf{u}}(t) + \mathbf{C}_0\dot{\mathbf{u}}(t) + \mathbf{K}_0\mathbf{u}(t) = \mathbf{f}_{\mathrm{b}}(t) + \mathbf{f}_{\mathrm{se}}(t) \tag{1}$$

where $\mathbf{f}_{\mathrm{b}}(t)$ are the buffeting forces and $(\cdot)_0$ denotes still-air properties. The self-excited forces $\mathbf{f}_{\mathrm{se}}(t)$ depend on the displacement and velocity motion of the structure, and is dealt with later in this section. A modal truncation ($\mathbf{u}(t) = \mathbf{\Phi}\mathbf{z}(t)$) yields the reduced-order representation for the

modal coordinate vector $\mathbf{z}(t) \in \mathbb{R}^{n_m}$:

$$\ddot{\mathbf{z}}(t) + 2\boldsymbol{\Xi}\boldsymbol{\Omega}\dot{\mathbf{z}}(t) + \boldsymbol{\Omega}^2\mathbf{z}(t) = \boldsymbol{\Phi}^{\mathrm{T}}\mathbf{f}_{\mathrm{b}}(t) + \boldsymbol{\Phi}^{\mathrm{T}}\mathbf{f}_{\mathrm{se}}(t) \tag{2}$$

$\boldsymbol{\Omega}$ and $\boldsymbol{\Xi} \in \mathbb{R}^{n_m}$ are diagonal matrices that contain the still-air natural frequencies and damping ratios. By introducing the modal state variable $\mathbf{x}(t) = [\mathbf{z}(t)^{\mathrm{T}} \quad \dot{\mathbf{z}}(t)^{\mathrm{T}}]^{\mathrm{T}} \in \mathbb{R}^{2n_m}$, Eq. 2 can be cast into state-space form. Furthermore, the force vector $\mathbf{f}_{\mathrm{se}}(t)$ is set equal to $\mathbf{H}_{\mathrm{se,d}}(t,\boldsymbol{\epsilon})\boldsymbol{\Phi}\mathbf{z}(t) + \mathbf{H}_{\mathrm{se,v}}(t,\boldsymbol{\epsilon})\boldsymbol{\Phi}\dot{\mathbf{z}}(t)$, a transformation that is explained later. The time-evolution of the system then becomes:

$$\dot{\mathbf{x}}(t) = \Bigg(\begin{bmatrix} \mathbf{0} & \mathbf{I} \\ -\boldsymbol{\Omega}^2 & -2\boldsymbol{\Xi}\boldsymbol{\Omega} \end{bmatrix} + \begin{bmatrix} \mathbf{0} & \mathbf{0} \\ \boldsymbol{\Phi}^{\mathrm{T}}\mathbf{H}_{\mathrm{se,d}}(t,\boldsymbol{\epsilon})\boldsymbol{\Phi} & \boldsymbol{\Phi}^{\mathrm{T}}\mathbf{H}_{\mathrm{se,v}}(t,\boldsymbol{\epsilon})\boldsymbol{\Phi} \end{bmatrix} \Bigg)\mathbf{x}(t) + \begin{bmatrix} \mathbf{0} \\ \mathbf{I} \end{bmatrix} \boldsymbol{\Phi}^{\mathrm{T}}\mathbf{f}_{\mathrm{b}}(t) \tag{3}$$

or in compact notation:

$$\dot{\mathbf{x}}(t) = \mathbf{A}_{\mathrm{c}}(t,\boldsymbol{\epsilon})\mathbf{x}(t) + \mathbf{B}_{\mathrm{c}}\boldsymbol{\Phi}^{\mathrm{T}}\mathbf{f}_{\mathrm{b}}(t) \tag{4}$$

It is noted this results in a system which is linear, but time variant. When considering acceleration and displacement measurements, the output vector become:

$$\mathbf{y}(t) = \mathbf{S}_{\mathrm{a}}\ddot{\mathbf{u}}(t) + \mathbf{S}_{\mathrm{d}}\mathbf{u}(t) = \mathbf{G}_{\mathrm{c}}(t,\boldsymbol{\epsilon})\mathbf{x}(t) + \mathbf{J}_{\mathrm{c}}\boldsymbol{\Phi}^{\mathrm{T}}\mathbf{f}_{\mathrm{b}}(t) \tag{5}$$

with corresponding matrices:

$$\mathbf{G}_{\mathrm{c}}(t,\boldsymbol{\epsilon}) = \mathbf{S}_{\mathrm{a}}\boldsymbol{\Phi}\begin{bmatrix} -\boldsymbol{\Omega}^2 & -2\boldsymbol{\Xi}\boldsymbol{\Omega} \end{bmatrix} + \begin{bmatrix} \mathbf{S}_{\mathrm{d}}\boldsymbol{\Phi} & \mathbf{0} \end{bmatrix} + \mathbf{S}_{\mathrm{a}}\boldsymbol{\Phi}\begin{bmatrix} \boldsymbol{\Phi}^{\mathrm{T}}\mathbf{H}_{\mathrm{se,d}}(t,\boldsymbol{\epsilon})\boldsymbol{\Phi} & \boldsymbol{\Phi}^{\mathrm{T}}\mathbf{H}_{\mathrm{se,v}}(t,\boldsymbol{\epsilon})\boldsymbol{\Phi} \end{bmatrix} \tag{6}$$

$$\mathbf{J}_{\mathrm{c}} = \mathbf{S}_{\mathrm{a}}\boldsymbol{\Phi} \tag{7}$$

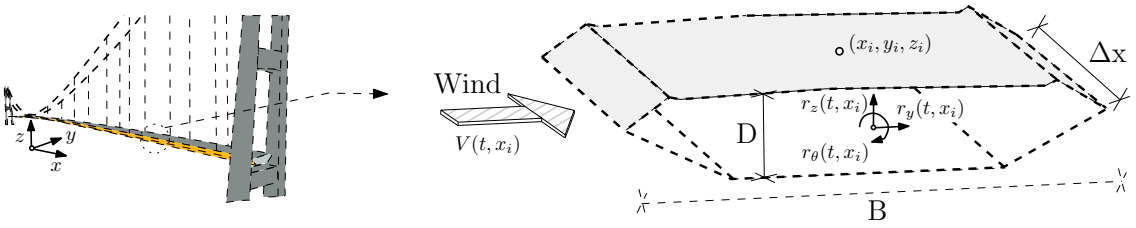

Figure 1: Suspension bridge and motion vectors of a segment of the box girder subjected to wind.

Next, the self-excited forces on the box girder are discussed. Although many model formulations are available [21], a simple memory-less model is adopted in this study for reasons of simplicity, implying the self-excited forces depend only on the structural displacement and velocity in the same time instant. Specifically, we employ a model called modified quasi-steady theory [22]. With reference to Fig. 1, the localized self-excited forces on a slice of the box girder with coordinate x_i are given in the form:

$$\begin{bmatrix} f_{\mathrm{se},y} \\ f_{\mathrm{se},z} \\ f_{\mathrm{se},\theta} \end{bmatrix} = \frac{1}{2}\rho V^2 B\Delta x\Bigg(\begin{bmatrix} p_4\frac{1}{B} & p_6\frac{1}{B} & p_3 \\ h_6\frac{1}{B} & h_4\frac{1}{B} & h_3 \\ a_6 & a_4 & a_3 B \end{bmatrix} \begin{bmatrix} r_y \\ r_z \\ r_\theta \end{bmatrix} + \begin{bmatrix} p_1\frac{1}{V} & p_5\frac{1}{V} & p_2\frac{B}{V} \\ h_5\frac{1}{V} & h_1\frac{1}{V} & h_2\frac{B}{V} \\ a_5\frac{B}{V} & a_1\frac{B}{V} & a_2\frac{B^2}{V} \end{bmatrix} \begin{bmatrix} \dot{r}_y \\ \dot{r}_z \\ \dot{r}_\theta \end{bmatrix} \Bigg) \tag{8}$$

or in compact notation:

$$\mathbf{f}_{\mathrm{se}}(t,x_i) = \mathbf{H}_{\mathrm{d}}(t,x_i,\boldsymbol{\epsilon})\mathbf{r}(t,x_i) + \mathbf{H}_{\mathrm{v}}(t,x_i,\boldsymbol{\epsilon})\dot{\mathbf{r}}(t,x_i) \tag{9}$$

where the parameter set $\boldsymbol{\epsilon} = [a_1 \dots a_6 \quad h_1 \dots h_6 \quad p_1 \dots p_6]^{\mathrm{T}}$ consist of 18 quasi-steady coefficients. This corresponds to modeling the well-established aerodynamic derivatives as functions proportional to $(\frac{B\omega}{V})^{-1}$ or $(\frac{B\omega}{V})^{-2}$ [22], where $\omega = 2\pi f$ is the angular frequency. In the presented framework, the mean wind velocity $V(t, x_i)$ is allowed to vary with time, although the notation V is used for brevity. The span is divided into M equally spaced nodal points with coordinates $\{x_1, \dots, x_M\}$. Using matrices $\mathbf{S}_i \in \mathbb{R}^{3\times \mathrm{n_{DOF}}}$ to select $\mathbf{r}(t, x_i)$ from the larger vector $\mathbf{u}(t)$, the vector $\mathbf{f}_{\mathrm{se}}(t)$ in Eq. 1 is now taken as the lumped sum of the contributions from all M nodes:

$$\begin{aligned}
\mathbf{f}_{\mathrm{se}}(t) = \sum_{i=1}^{M} \mathbf{S}_i^{\mathrm{T}} \mathbf{f}_{\mathrm{se}}(t, x_i) &= \sum_{i=1}^{M} \mathbf{S}_i^{\mathrm{T}} \big(\mathbf{H}_{\mathrm{d}}(t, x_i, \boldsymbol{\epsilon}) \mathbf{r}(t, x_i) + \mathbf{H}_{\mathrm{v}}(t, x_i, \boldsymbol{\epsilon}) \dot{\mathbf{r}}(t, x_i) \big) \\
&= \sum_{i=1}^{M} \mathbf{S}_i^{\mathrm{T}} \big(\mathbf{H}_{\mathrm{d}}(t, x_i, \boldsymbol{\epsilon}) \mathbf{S}_i \mathbf{u}(t) + \mathbf{H}_{\mathrm{v}}(t, x_i, \boldsymbol{\epsilon}) \mathbf{S}_i \dot{\mathbf{u}}(t) \big) \\
&= \sum_{i=1}^{M} \mathbf{S}_i^{\mathrm{T}} \mathbf{H}_{\mathrm{d}}(t, x_i, \boldsymbol{\epsilon}) \mathbf{S}_i \boldsymbol{\Phi} \mathbf{z}(t) + \sum_{i=1}^{M} \mathbf{S}_i^{\mathrm{T}} \mathbf{H}_{\mathrm{v}}(t, x_i, \boldsymbol{\epsilon}) \mathbf{S}_i \boldsymbol{\Phi} \dot{\mathbf{z}}(t) \\
&= \mathbf{H}_{\mathrm{se,d}}(t, \boldsymbol{\epsilon}) \boldsymbol{\Phi} \mathbf{z}(t) + \mathbf{H}_{\mathrm{se,v}}(t, \boldsymbol{\epsilon}) \boldsymbol{\Phi} \dot{\mathbf{z}}(t)
\end{aligned} \tag{10}$$

where the definitions of the (time and) parameter-dependent matrices $\mathbf{H}_{\mathrm{se,d}}(t, \boldsymbol{\epsilon})$ and $\mathbf{H}_{\mathrm{se,v}}(t, \boldsymbol{\epsilon}) \in \mathbb{R}^{\mathrm{n_{DOF}} \times \mathrm{n_{DOF}}}$ now are clear. A discretization in time ($t_k = k\Delta t$) of Eq. 4 and 5 now gives the following system equations:

$$\mathbf{x}_{k+1} = \mathbf{A}_{\mathrm{d}}(t_k, \boldsymbol{\epsilon}_k) \mathbf{x}_k + \mathbf{B}_{\mathrm{d}} \mathbf{p}_k \tag{11}$$

$$\mathbf{y}_k = \mathbf{G}_{\mathrm{d}}(t_k, \boldsymbol{\epsilon}_k) \mathbf{x}_k + \mathbf{J}_{\mathrm{d}} \mathbf{p}_k \tag{12}$$

where the substitution $\mathbf{p}_k = \boldsymbol{\Phi}^{\mathrm{T}} \mathbf{f}_{\mathrm{b}}(t_k)$ define the buffeting loads in the modal space. No parametric model is introduced for the buffeting loads or the turbulence. Provided that the wind velocity, the parameters, and the modal buffeting loads were known, the system output response could be straightforwardly solved from Eq. 11 and 12 for some given initial conditions. However, these are all, except the wind velocity, treated as unknown quantities; the estimation methodology is discussed in the next section.

2.2 Equations for the identification problem

The goal is to jointly estimate the inputs, states and the parameters for this system. The parameters are augmented into the state vector, resulting in the following final model of the dynamics:

$$\begin{bmatrix} \mathbf{x}_{k+1} \\ \boldsymbol{\epsilon}_{k+1} \end{bmatrix} = \begin{bmatrix} \mathbf{A}_{\mathrm{d}}(t_k, \boldsymbol{\epsilon}_k) & \mathbf{0} \\ \mathbf{0} & \mathbf{I} \end{bmatrix} \begin{bmatrix} \mathbf{x}_k \\ \boldsymbol{\epsilon}_k \end{bmatrix} + \begin{bmatrix} \mathbf{B}_{\mathrm{d}} \\ \mathbf{0} \end{bmatrix} \mathbf{p}_k + \begin{bmatrix} \mathbf{w}_k \\ \boldsymbol{\mu}_k \end{bmatrix} \tag{13}$$

$$\mathbf{y}_k = \begin{bmatrix} \mathbf{G}_{\mathrm{d}}(t_k, \boldsymbol{\epsilon}_k) & \mathbf{0} \end{bmatrix} \begin{bmatrix} \mathbf{x}_k \\ \boldsymbol{\epsilon}_k \end{bmatrix} + \mathbf{J}_{\mathrm{d}} \mathbf{p}_k + \mathbf{v}_k \tag{14}$$

According to principles from Kalman filtering, this model includes stochastic white noise on the modal states ($\mathbf{w}_k$) and on the measurements ($\mathbf{v}_k$), as well as a fictitious driving term for the parameters ($\boldsymbol{\mu}_k$). These vectors are all assumed mutually uncorrelated, zero-mean and with covariance relations:

$$\mathbb{E}[\mathbf{w}_k \mathbf{w}_l^{\mathrm{T}}] = \mathbf{Q}_{\mathrm{w}}\, \delta_{kl}, \quad \mathbb{E}[\mathbf{v}_k \mathbf{v}_l^{\mathrm{T}}] = \mathbf{R}\, \delta_{kl}, \quad \mathbb{E}[\boldsymbol{\mu}_k \boldsymbol{\mu}_l^{\mathrm{T}}] = \mathbf{Q}_{\mu}\, \delta_{kl} \tag{15}$$

Figure 2: The Hardanger bridge
(photo: Ø.W. Petersen/NTNU)

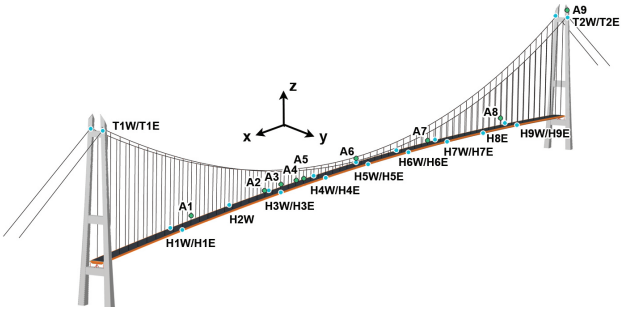

Figure 3: Positions of the installed anemometers (A) and accelerometers (H,T).

This is essentially a non-linear problem since the system matrices depends on the parameters in the augmented state. We apply a Kalman-type algorithm from [8], which is termed extended joint input-state (EJIS) estimation. This is an extension of previous algorithms [19, 20] that considers minimum-variance unbiased estimation in systems with unknown inputs.

Some necessary mathematical conditions for the estimation should be discussed. Firstly, $\text{rank}(\mathbf{J}_\text{d}) = \text{n}_\text{m}$ is required is order to identify all n_m modal forces [23]. This condition is fulfilled for the actual system model presented later in Section 3.1. As the system matrices changes with time, the observability should formally be checked according to the theory in reference [24], which is considered future work.

3 IMPLEMENTATION FOR THE HARDANGER BRIDGE

3.1 Data from the Hardanger bridge

The practical test of the methodology is applied to data from the Hardanger bridge, a suspension bridge shown in Fig. 2. In this study, the bridge is modelled with $\text{n}_\text{m} = 19$ vibration modes from a FE model [25, 26]. Fig. 4 shows the shape of the modes along the main span together with the natural frequencies and damping ratios, where the naming convention is according to the dominant motion of each mode: H1-H5 (horizontal), V1-V9 (vertical), T1-T2 (torsional), P1-P2 (pylon) and M1 (mixed). As discussed in [26, 27], the number of modes in the reduced-order model for long-span bridges (in inverse estimation) is mainly limited by the necessary criterion that $\text{rank}(\mathbf{J}_\text{d}) = \text{n}_\text{m}$; more acceleration sensors are needed to be able to identify more modal forces.

This bridge have 20 triaxial accelerometers for measuring the dynamic response, and eight anemometers that measures wind velocities in the main span [28], as shown in Fig. 3. The details of the sensors are given in references [26, 28].

A measurement data set with duration 60 min ($\Delta t = 0.1$ s) is studied. The direction of the wind is approximately normal to the bridge deck throughout this period. The span of the bridge is discretized into $M = 65$ points ($\Delta x \approx 20$ m). First, the mean wind velocity for the eight anemometer measurements is found by using 10 minute moving averages. Then, linear interpolation is used to estimate the field $V(x,t)$ between the anemometers, resulting in the time-spatial distribution in Fig. 5. Inhomogeneous features in the wind field is not uncommon for this bridge location [29], and in this case an apparent trend of higher velocities for one part of the bridge is observed. Although robust testing for (non-)stationarity of time series generally is difficult, the mean wind velocity could intuitively also be said to have weakly non-stationary features for this 60 minute period. This is not a direct problem, however, as no stationarity assumptions are imposed on the loading or dynamic behavior in the EJIS estimation.

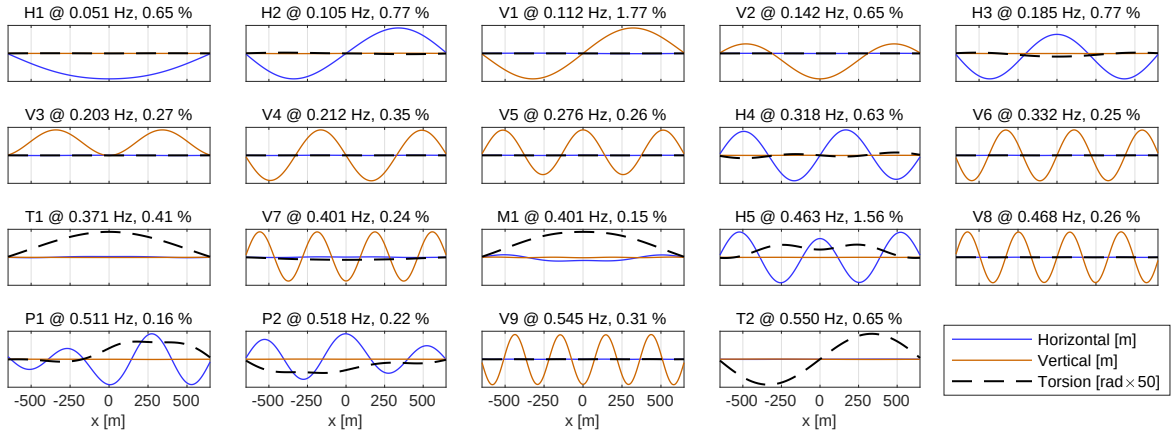

Figure 4: Horizontal, vertical and torsional deflection of the mode shapes along the main span.

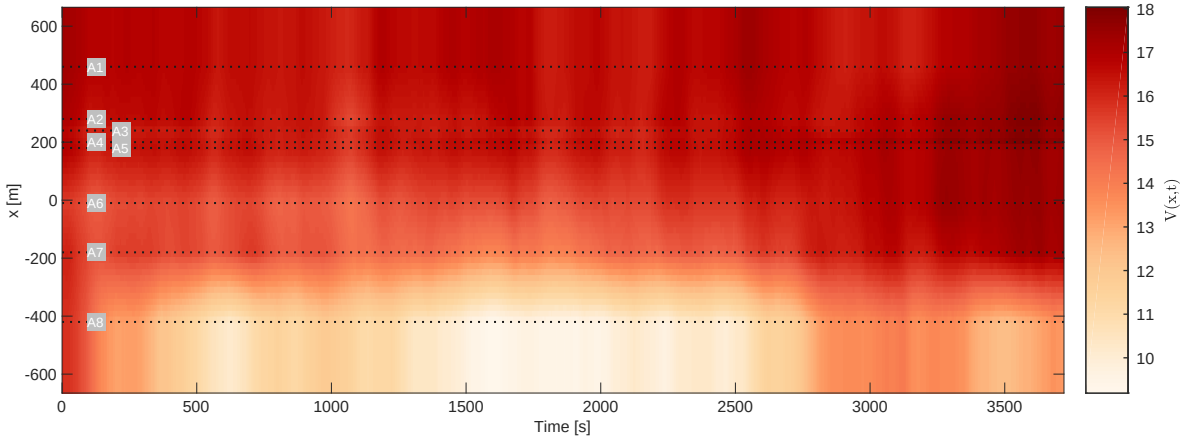

Figure 5: Estimated time-spatial distribution of the mean wind velocity along the main span. The horizontal lines indicate the positions of the anemometers A1-A8. Linear interpolation is used along the x-axis, with constant end values for extrapolation beyond A1 and A8.

Some pre-processing of the output response data is necessary. A low-pass filter is applied to mitigate the content above 0.6 Hz. A subset of the acceleration response data is shown in Fig. 6 for sensors in the quarter span. In addition to the acceleration data, displacements in the form of (offline) integrated accelerations are also included in the output vector to avoid instabilities in the estimation. This also involves high-passing the displacement data at 0.01 Hz.

3.2 Estimation of inputs, states and parameters

Some initial values for the unknown quantities are also needed for the first time step in the estimation. As the conditions at time t_0 are not practically determinable, the initial guess is set to $\mathbf{x}_0, \mathbf{p}_0 = \mathbf{0}$. For the parameters, the initial values ($\boldsymbol{\epsilon}_0$) are set to values given in Table 1, which are estimated from wind tunnel experiments [30]. The corresponding initial covariances are set to $\mathbf{P}_0^{\mathbf{x}} = \mathbf{I}$, $\mathbf{P}_0^{\boldsymbol{\mu}} = 10^{-2}\,\mathbf{I}$, $\mathbf{P}_0^{\mathbf{p}} = \mathbf{I}$.

After some trials, it was found that estimation of all 18 parameters lead to some unrealistic results. For this type of bridge, it is well-known that not all the self-excitation coefficients are

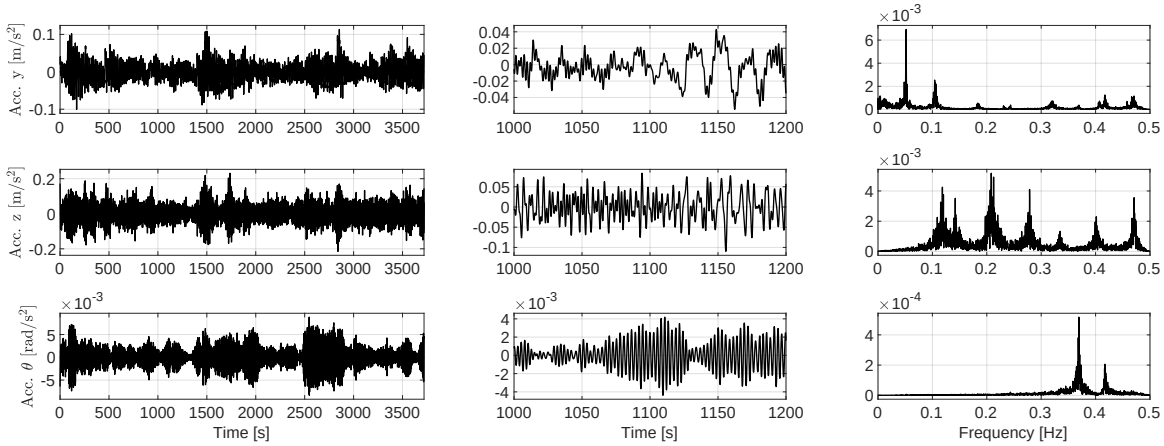

Figure 6: Acceleration response in the quarter span. The measurements have been transformed into the horizontal (y), vertical (z) and torsional (θ) motions of the box girder center to show the contributions of the different modes.

Quasi steady parameter					
$a_1 = -0.852,$	$a_2 = -0.312,$	$a_3 = 0.907,$	$a_4 = -0.048,$	$a_5 = -0.015,$	$a_6 = 0.007$
$h_1 = -2.870,$	$h_2 = -0.079,$	$h_3 = 3.062,$	$h_4 = -0.379,$	$h_5 = 0.813,$	$h_6 = -0.055$
$p_1 = -0.312,$	$p_2 = -0.051,$	$p_3 = -0.030,$	$p_4 = 0.004,$	$p_5 = -0.247,$	$p_6 = -0.024$

Table 1: Parameters values from wind tunnel testing of the bridge section.

equally important. It was therefore chosen to reduce the parameter set to the four coefficients a_1, a_2, h_1 and h_2 (i.e., the vertical-torsional coupled damping in Eq. 8). These are deemed the most important contributors for streamlined cross sections. The remaining 14 parameters were set to fixed values from Table 1.

An important aspect of the estimation is the choice of covariance matrices (Eq. 15). As noted in [10], the covariance magnitudes (noise levels) could influence the results quite considerably. $\mathbf{R} = 10^{-6}\,\mathbf{I}$ is used, a level which corresponds to $1-5\%$ of the output data standard deviations. For the process noise covariance, $\mathbf{Q}_{\mathrm{w}} = 10^{-1}\,\mathbf{I}$ is set. For the parameter covariance $\mathbf{Q}_{\mu} = c_{\mu}\,\mathbf{I}$, the two scalar values $c_{\mu} = 10^{-5}$, 10^{-7} are tested, which are much less than the expected parameter order.

The identified modal forces are shown in Fig. 7 in the frequency-domain by a fast Fourier transform (FFT) of the time series, where $c_{\mu} = 10^{-7}$ was used. Characteristic to ill-conditioned problems, identification of forces generally suffer from sensitivity in the solution to errors on the model or the output data. A known practical problem is that a few so-called cable-modes that could not be included in the state-space model in reality has a small contribution to the dynamic response in the box girder [27]. This leads to some unfortunate effects visible in Fig. 7, namely a spurious contribution around the frequencies 0.24, 0.37 and 0.41 Hz in the horizontal modes. Other than this, the modal loads appear to realistically resemble the frequency-domain characteristics of buffeting forces due to turbulence. A closer examination of the time-evolution of the modal loads in light of the wind data from the anemometers is deemed future work.

Next, the attention is shifted to the parameter estimation, as shown in Fig. 8. It is seen that for $c_{\mu} = 10^{-5}$, the dynamic response or loading tend to bleed into the parameter estimate, thus $c_{\mu} = 10^{-7}$ is deemed a more suitable choice. It is expected that the parameters should be quite constant, but small time-variations could happen for changes in environmental conditions such

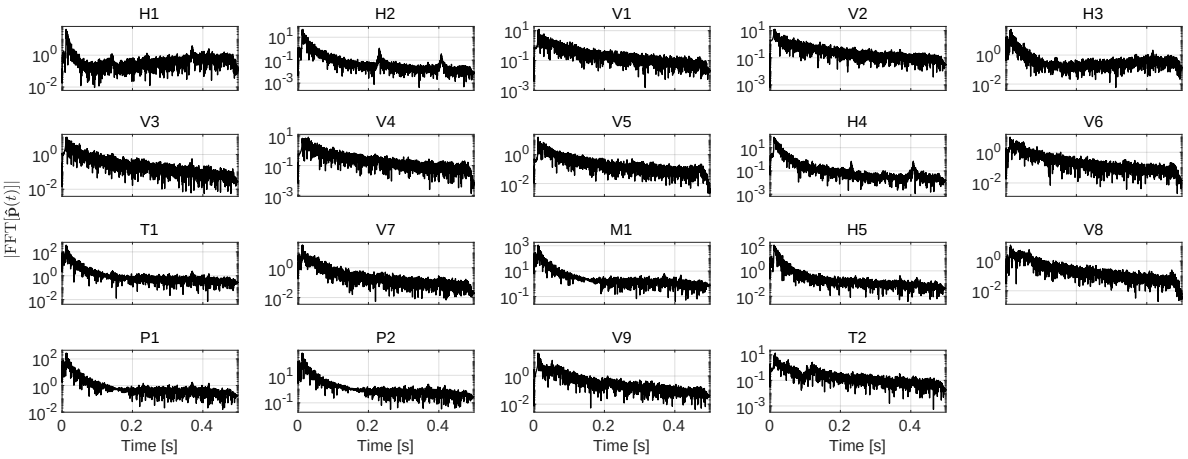

Figure 7: Estimated modal forces in the frequency-domain.

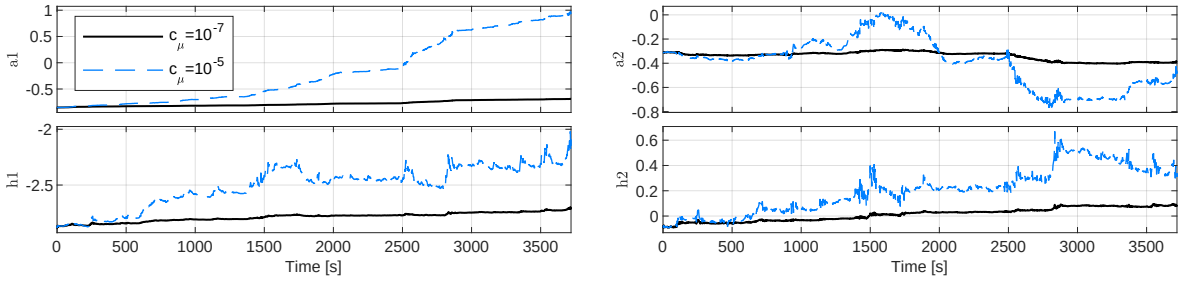

Figure 8: Estimated quasi-steady parameters.

as the wind yaw angle or mean the angle of attack. No formal convergence is achievable in the estimation, and the parameters tend to either stay at a relatively stable level or slowly change throughout the time period. A potential problem here is parameter magnitude differences, for which a shared c_μ-value introduces some compromise. As pointed out in [10], a correct parameter model is also necessary for convergence. The interpretation of the results should also factor in the individual parameter influence on the system dynamics. Generally, it is expected the most influential parameters for the system response are most accurately estimated, whereas parameters with a smaller influence could be more inaccurate since its deviations do not to the same degree affect the goodness of fit for the solution to the data. A sensitivity analysis could give some indications of the significance to trim out non-essential parameters.

3.3 Assessment of effective modal properties

A more intuitive way to assess the results is to study the effective natural frequencies and damping ratios of the system for the in-wind conditions. These can be solved from the eigenvalues of $\mathbf{A}_c(t, \boldsymbol{\epsilon})$, which are on the form $\lambda_j = -\xi_j\omega_j \pm i\omega_j\sqrt{1-\xi_j^2}$, $(\omega_j = 2\pi f_j)$. The modal properties will be time-varying since they are dependent on the mean wind velocity and the quasi-steady parameters, and Fig. 9 and 10 shows the evolution. Herein, it is the vertical and torsional modes that are most interesting, as changes in the horizontal modes mainly are driven by the assigned a priori values from Table 1.

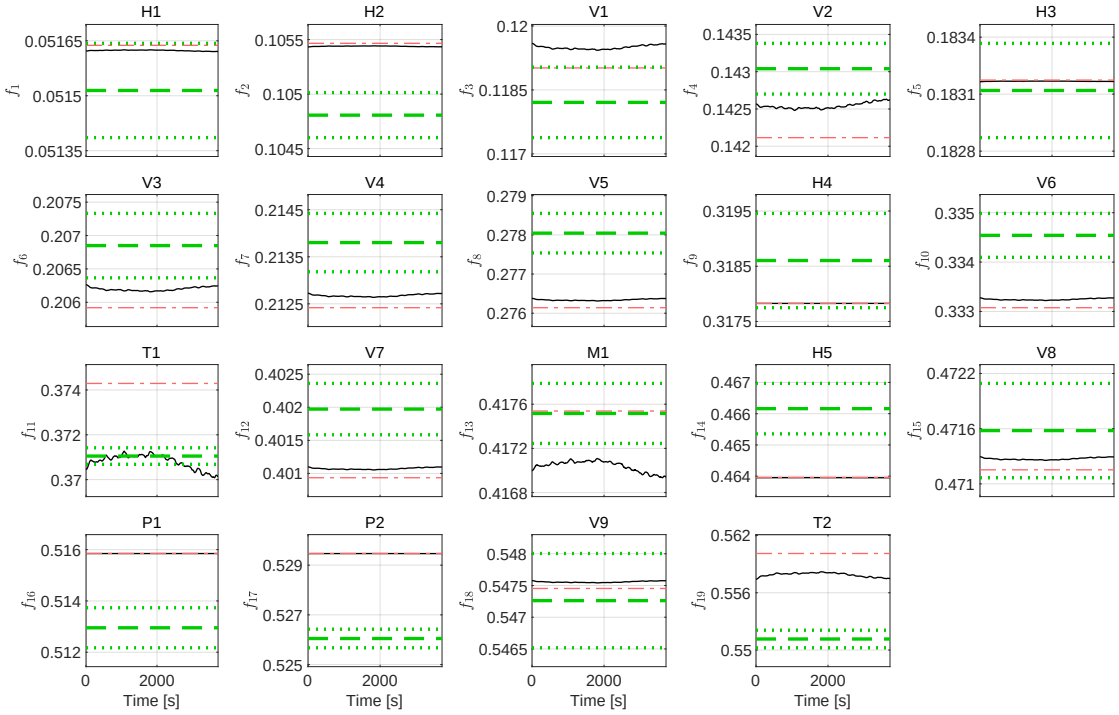

Figure 9: Evolution of natural frequencies (f in Hz) from the parameter estimation. The red lines denote the still-air modal properties, and the green lines denote modal properties from cov-SSI with an uncertainty interval of one standard deviation.

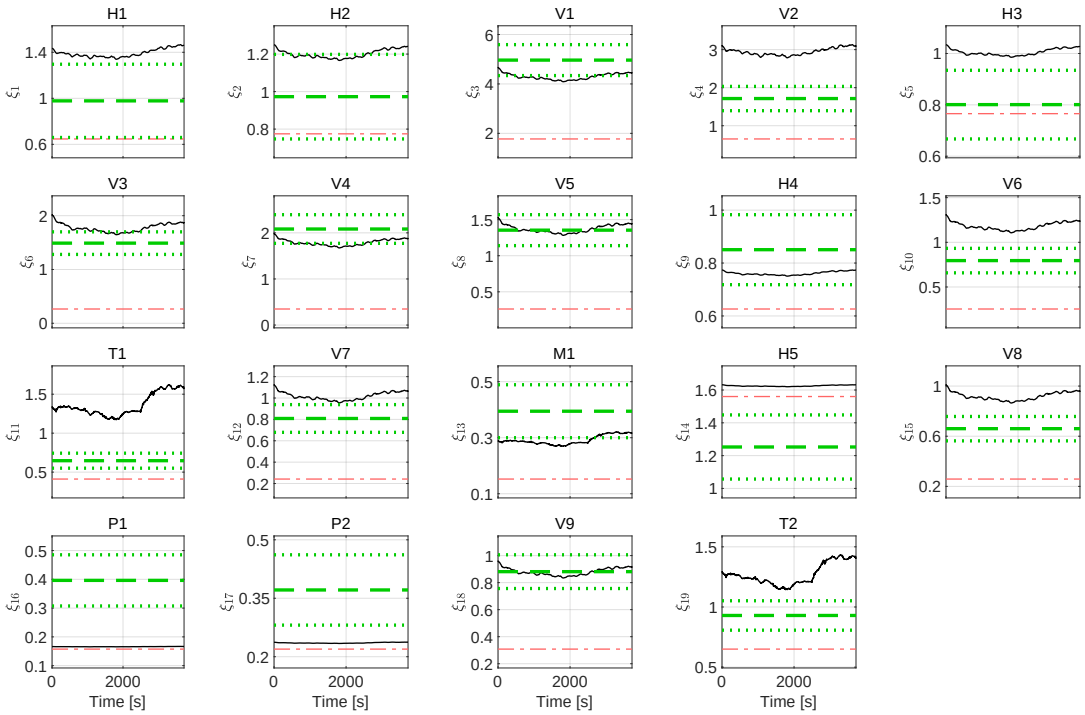

Figure 10: Evolution of damping ratios (ξ in %) from the parameter estimation. The red lines denote the still-air modal properties, and the green lines denote modal properties from cov-SSI with an uncertainty interval of one standard deviation.

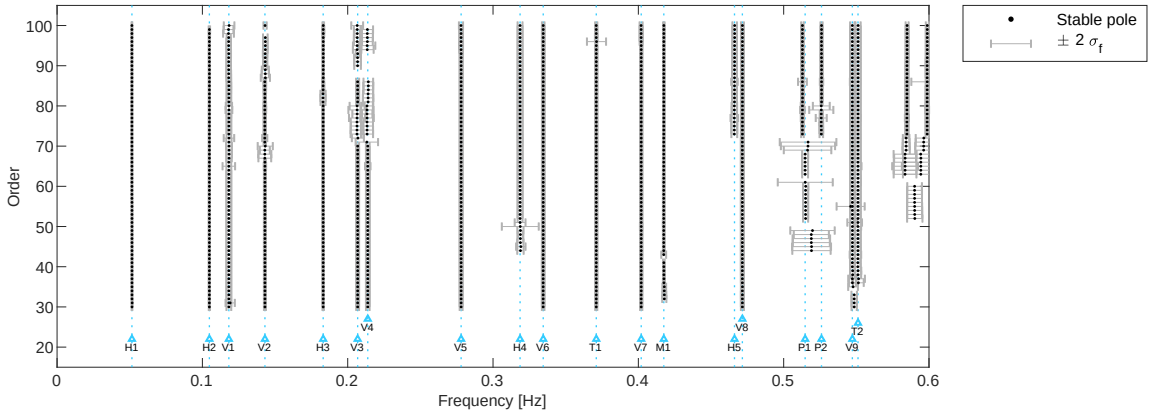

Figure 11: Stabilization diagram with uncertainty interval for the natural frequencies. Only poles with $\sigma_f/f < 0.02$ are shown. The vertical blue lines indicate the different modes.

As a reference solution, modal parameters with uncertainty bounds are identified using the tool covariance-driven stochastic subspace identification (cov-SSI) [31], supplemented by the fast implementation from [32]. Fig. 11 shows the poles and their frequency uncertainty range. These are also superimposed in Fig. 9 and 10. In general, the damping ratios for the vertical modes agree tend to agree between the inverse estimation and the cov-SSI. However, it does not for the torsional modes. The exact reason for this is hard to formalize, and these results could very well be case-dependent, as the performance of inverse estimation often highly depends on the sensor network as well as the quality of the system model. It is generally accepted that inverse estimation is difficult for systems with high-complexity dynamics, and the obtained results also support this notion.

The use of advanced computational methodology to full-scale bridge data always has some uncertainties that are difficult to eliminate. In this context, the following sources could be mentioned:

- Limited anemometer data leads to uncertainties in the interpolated wind field $V(x,t)$.
- A number of significant uncertainties can be related to the EJIS estimation itself. Herein, the Kalman-type algorithms always have an estimate uncertainty inherited from the white noise disturbance model. As shown, the noise covariance matrices influence to some degree the solution.
- Errors in the FE-based state-space model could give some incorrect estimates. Although the model is tuned [25], some temperature variations could affect the still-air natural frequencies and damping and thus also slightly the graphs in Fig. 9 and 10.
- The self-excitation of the cables could give some damping contributions. If the wind velocity at the elevation of the main cable was known, formulas similar to Eq. 8 could be included for the self-excitation of the main cable by letting its drag coefficient be an unknown parameter.
- Local traffic could give some small dynamic response contributions to the considered modes, although this would be small compared to strong winds.

4 CONCLUSIONS

The wind-induced dynamic response is an important but often uncertain aspect of long-span bridges due to uncertainties in the models for wind load prediction. This paper has presented a framework for state-space modelling of long-span bridges, taking into account the self-excited forces through a set of modified quasi-steady parameters. Using recently developed Kalman-type estimation schemes, this model can be applied for coupled input-state-parameter estimation to bridges with monitoring systems.

The methodology is tested to acceleration from the Hardanger bridge, which is modelled using 19 still-air vibration modes. Generally, the frequency-domain characteristics of the identified wind loads have features that resembles buffeting due to turbulence. Small errors on the state-space model, for example not including cable vibration modes, lead to some small but visible errors on the identified loads. A comparison with the wind measurement data could give better insight in the validity of the load estimates.

The parameter estimation for the self-excited damping works to some extent. Compared to the damping values from cov-SSI, the estimated parameters generally lead to similar effective damping for the vertical modes of the bridge deck, but not the torsional modes. Overall, the methodology show some promising results, but a robust application of inverse estimation to long-span bridges remains difficult.

Abstract

Tensile structural systems as for example cables nets, suspended bridges or membranes usually have nonneglecting p-delta effects under wind action. Consequently, great displacements give a geometrically nonlinear structural behavior. In addition, the wind action is nonlinear spatially and time depending. This closely affect the dynamic interaction between loads and structure. For this reason, the calculation process needs to take into account the time-depending nonlinear response of the structure. Finally, the wind action can be critical for structural and it can induce global or local instability. Analyses has to be able to capture and to describe the instability response in term of displacements, in the case of cables net, or rotations, in the case of suspended bridges. The paper is focused on the wind – structure interaction analyses carried out by wind tunnel experiments. The wind action is generally given by wind tunnel experiments, and it is time depending. For roofs, it generally is given as pressure time histories measured by some pressure taps on the roof. The process from experiments to structural response is described using a case of study of cables net. The dynamic geometrically nonlinear analyses were performed using the TENSO non-commercial program, which can execute dynamic step-by-step integration of the nonlinear three-dimensional structure with geometric nonlinearities by the Newmark-Beta method with Rayleigh damping.

Keywords: Tensile structural systems, Non-Linear analyses, cables.

1 INTRODUCTION

Light structures, as for example tensile structures or suspended bridges, has a small ratio between structural weight and environmental or live loads. For this reason, differently from traditional reinforced concrete structures [1], they are sensitive to the snow action and in particular the wind action dynamics. The dynamic wind action can give local or global instability due to great displacements and/or rotations.

However, recently, these structural typologies are more common than it was in the past because they have a convenient cost/benefit ratio. For example, light roof are often used to cover sport arenas, meeting rooms or concert halls [2, 3]. The large use of tensile structural systems (i.e. roof or bridges) would require simplifications of calculation methods. In addition, guidelines in codes should be improved and increased.

Contrarily, codes neglects cables structures and very few information are given for unconventional shapes as for example hyperbolic paraboloid, that are commonly used for roof tensile structures, or the closed box sections similar to the Great Belt , that is commonly used for suspended bridges [4-13].

For these reasons, the most of these structures need experimental campaign in wind tunnel to be designed. Wind tunnel experiments on in-scale models investigates the structure aerodynamics (i.e. on rigid models) and aero-elasticity (i.e. on flexible models).

Aerodynamics tests are focused on pressure coefficients acquisition on the building surfaces or on the vortex shedding distribution around the buildings that is simulated as a rigid body [14-16]. Aeroelastic measurements are focused on the wind-structure dynamically interaction. In particular, for roofs, these measurements are focused on the aerodynamic damping and added masses estimation [17, 18]. For bridge, aeroelastic tests are focused on the flutter derivatives estimation [19-21].

Generally, the scientific literature proposes simplifications of experimental tests as for example simplified maps of pressure coefficients [22, 23] or parametrical studies of the structural dynamics [19]. However, the most of literature examples are focused on specific cases of study [24-38] that sometimes are not generalizable.

Some studies discuss the structural design of tensile structures following a more general view [39-44] even if they do not discuss the complete process to design a tensile structure, that start from the architecture and it continues through experiments to the structural calculation.

Non-linear analyses have to be processed using time-depending experimental data through software able to calculate the wind-structure interaction. The complexity of calculation is crucial for these kind of structures and it affects negatively their development and dissemination.

This paper aims to describe the process of applying wind tunnel measurements for non-linear structural analyses using a case of study. Only aerodynamics results are discussed here. The case of study is a cable net with hyperbolic paraboloid roof and rectangular plane.

2 STRUCTURAL REMARKS

In order to discuss geometrically non-linear analyses the case of cables net was used as examples. In particular, the hyperbolic paraboloid cables net was assumed as significant examples of cables systems.

Hyperbolic paraboloid cables net have a double curvature with two order of cables (i.e. upward and downward) that can have a different lengths and curvatures. Consequently, cables can have different areas and initial pre-stresses.

These two order of cables assume a different role under gravitational (i.e. downward) and suction (i.e. upward) loads. In fact, under gravitational loads (i.e. dead, permanent loads

and snow action), the upward cables are load bearing and the downward cables are stabilizing, under suction (i.e. wind action) is opposite. The local instability occurs if stabilizing cables reduce their sag until almost to be horizontal or if the load bearing cables exceeds the stress limit of material.

The function adopted to describe the hyperbolic paraboloid is expressed by Eq.(1), where x, y and z are respectively the spatial variables; x_0, y_0 and z_0 are the coordinates of the origin of the axes *a*, *b* and *c* are the geometric coefficients of the function. The *c* parameter was set equal to 1, making all the parabolas that lying on the surface, parallel and of identical curvature.

$$\frac{(X-x_0)^2}{a^2} - \frac{(Y-y_0)^2}{b^2} = \frac{(Z-Z_0)}{c} \quad \text{where } 1/c = 1 \tag{1}$$

It's important to precise that the initial geometry is only an initial condition and that the real geometry of the net, whiteout environmental or live loads, is defined on bases of the initial cables pre-stress, dead and permeant loads.

The environmental and live loads effect modifies again the geometry. The goal is to predict the structural geometry under extreme loads in order to exclude instability phenomena. For this reason the preliminary design of cables areas and initial pre-stress is crucial.

The pre-sizing process has the aim to estimate an initial pre-stress and areas in order to minimize the shape between un-loaded and loaded condition. This is important because the pressure coefficients evaluated in wind tunnel are measured on a fixed geometry that generally correspond to the un-loaded shape.

The cables net preliminary design can be carried out using the simplified two dimensional model named "Rope Beam" illustrated in Fig.(1). The model consist in two cables with opposite curvature connected only by vertically.

The prefixed assumptions are:

1) vertical links, in tension or in compression, are treated as a continuous membrane between the two main cables;

2) the horizontal displacements are neglected compared to the vertical ones; pretension is considered as an equivalent distributed load;

3) the system congruence is required only in the central span node;

4) the mutual actions between cables are uniformly distributed as the external load, and consequently, load-bearing and stabilizing cable have a parabolic configuration also in elastic regime [43, 44].

Eq.(2) and Eq.(3), define the load-bearing cable (C_1) and stabilizing cable (C_2) stiffness coefficients, K_{c_1} and K_{c_2}. k_1 and k_2 are the stiffness of the load-bearing cable C_1 and the stiffness of the stabilizing cable C_2, respectively, defined in Eqs.(4) and (5). A_1 and A_2, f_1 and f_2, L_1 and L_2 are area, sag and span values of the cable C_1 and C_2, respectively.

$$K_{c_1} = \frac{k_1}{k_1 + k_2} \tag{2}$$

$$K_{c_2} = \frac{k_2}{k_1 + k_2} \tag{3}$$

$$k_1 = \frac{EA_1}{l\left[1 + \frac{8}{3}\left(\frac{\bar{f}_1}{l}\right)^2 - \frac{32}{5}\left(\frac{\bar{f}_1}{l}\right)^4\right]} \tag{4}$$

$$k_2 = \frac{EA_2}{l\left[1 + \frac{8}{3}\left(\frac{\bar{f}_2}{l}\right)^2 - \frac{32}{5}\left(\frac{\bar{f}_2}{l}\right)^4\right]} \tag{5}$$

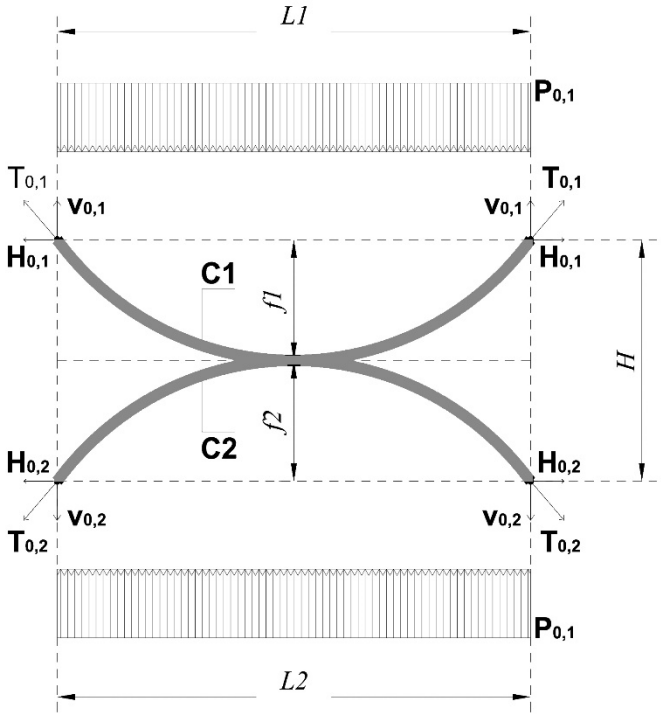

Fig.1: Rope beam, 2D structural system.

In Fig.1 $T_{0,1}$ and $T_{0,2}$ are the cables traction given by the initial pre-stress and $H_{0,1}$ and $H_{0,2}$ are their horizontal components. The horizontal components are generally much bigger than vertical ($V_{0,1}$ and $V_{0,2}$) because the curvature given by the sag/span ratio (i.e. *f1/L1* and *f2/L2*) is generally small. For this reason, cables nets need of very rigid support structures. In the preliminary design the initial pre-stress is approximated as an uniform distributed load applied on cables, upward for stabilizing cables (C2) and downward for load bearing cables (C1).

The design process almost takes into account the following load configuration:

1) Load condition 0, given by initial pre-stress only;

2) Load condition 1, given adding to condition 0 dead and permanent loads (i.e. gravitational);

3) Load condition 2, given adding to condition 1 the snow action (i.e. gravitational);

3) Load condition 3, given adding to condition 1 the wind action (i.e. upward action).

Cables areas $A_{0,1}$, $A_{0,2}$ and strain ($\epsilon_{0\ldots3,1}$, $\epsilon_{0\ldots3,2}$) are fixed iteratively matching results given by all loads conditions. In the following strain values for condition 2 are $\epsilon_{2,1}$, $\epsilon_{2,2}$ and for condition 3 $\epsilon_{3,1}$, $\epsilon_{3,2}$ for C1 and C2, respectively. The suffix "*i*" means a generic load condition, G_{p1} is the dead load, G_{p2} is the permanent load, S is the maximum snow action, W is the maximum wind suction. Like a start point the ratio $\frac{k_1}{k_2}$ between the cables stiffness is assumed equal to ΔP according Eq.(6).

$$\Delta P = \left[\frac{G_{p1} + G_{p1} + |W|}{G_{p1} + G_{p1} + S}\right] = \frac{\text{Load Condition (3)}}{\text{Load Condition (2)}} \tag{6}$$

The initial geometrical cables length $L_{0,1,geom}$ and $L_{0,2,geom}$ are given by Eqs.(7) and (8), as function of cables initial sag and span.

$$L_{0,1,geom} = L_1 \cdot \left[1 + \frac{8}{3} \cdot \left(\frac{f_1}{L_1}\right)^2 - \frac{32}{5} \cdot \left(\frac{f_1}{L_1}\right)^4\right] \quad (7)$$

$$L_{0,2,geom} = L_2 \cdot \left[1 + \frac{8}{3} \cdot \left(\frac{f_2}{L_2}\right)^2 - \frac{32}{5} \cdot \left(\frac{f_2}{L_2}\right)^4\right] \quad (8)$$

The initial cables internal traction $T_{0,1}$ and $T_{0,2}$ are given by Eqs.(9) and (10) and their horizontal component $H_{0,1}$ equal to $H_{0,2}$ are given by Eqs.(11) and (12).

$$T_{0,1} = H_{0,1}\sqrt{1 + 16\left(\frac{f_1}{L_1}\right)^2} \quad (9) \qquad T_{0,1} = H_{0,2}\sqrt{1 + 16\left(\frac{f_2}{L_2}\right)^2} \quad (10)$$

$$H_{0,1} = \frac{G_{p1}{L_1}^2}{8f_1} \quad (11) \qquad H_{0,2} = \frac{G_{p1}{L_2}^2}{8f_2} \quad (12)$$

The horizontal components $H_{i,1\ldots2}$ of traction for loads conditions 1, 2 and 3 varying as function of the cables traction and the deformed cables sag, according Eq.13. Cables are made of harmonic steel and the cables traction is in agreement with the Hook law.

$$H_{i,1} = \frac{T_{i,1}}{1 + 16\left(\frac{f_{i,1}}{L_1}\right)^2} \quad (13)$$

Step by step, cables stiffness vary as function of the deformed shape and cables strain given by loads. Eqs. (14) and (15) give the K_{C_1} and K_{C_2} expressions given by the balance between geometry deformation and applied loads ΔP.

$$K_{C_1} = \left\{\frac{\left[\frac{EA_1f_1^2}{L_1^4}\right]}{\left[\frac{EA_1f_1^2}{L_1^4}\right] + \left[\frac{E(A_2)f_2^2}{L_2^4}\right]}\right\} = \left\{\frac{1}{1 + \frac{\left[\frac{E(A_2)f_2^2}{L_2^4}\right]}{\left[\frac{EA_1f_1^2}{L_1^4}\right]}}\right\} = \left[\frac{1}{1 + \frac{1}{\Delta P}}\right] \quad (14)$$

$$K_{C_2} = \left\{\frac{\left[\frac{EA_2f_2^2}{L_2^4}\right]}{\left[\frac{EA_1f_1^2}{L_1^4}\right] + \left[\frac{E(A_2)f_2^2}{L_2^4}\right]}\right\} = \left\{\frac{1}{\frac{\left[\frac{EA_1f_1^2}{L_1^4}\right]}{\left[\frac{E(A_2)f_2^2}{L_2^4}\right]} + 1}\right\} = \left[\frac{1}{\Delta P + 1}\right] \quad (15)$$

Eq.(16) give the residue un-balance Δ that need to be iteratively minimized. As an example, Eq.(16) show the balance for condition 2.

$$\Delta = \left\{ P_{0,1} + \left[\frac{(G_{p1}+G_{p1}+S)}{\left(\frac{1}{K_{c_1}}\right)} - \frac{(G_{p1}+G_{p1})}{\left(\frac{1}{K_{c_1}}\right)} \right] \right\} - P_{2,1} = \left\{ \left[\left(\frac{8\varepsilon_{0,1} f_{0,1}}{L_1^2} \right) A_1 \right] - \left[\frac{(S)}{\left(\frac{1}{K_{c_1}}\right)} \right] \right\} - \left[\frac{8\varepsilon_{2,1} f_{2,1} A_1}{L_1^2} \right] = 0 \quad (16)$$

3 EXPERIMENTAL DATA ACQUISITION

Experimental data consist in pressure expressed in mmH_2O acquired by pressure transducers. A sampling frequency (F) and a time duration (T) of experiments are preliminary fixed based on the wind tunnel setup. Pressure series $p(P,t)$ are acquired using pressure taps distributed on the model. Teflon tubes measure pressure and send data to transducers. Transducers send electrical signals to the control system. Pressure coefficients $c_p(P,t)$ are calculated according to Eq.19. Results are pressure coefficients time histories with a number of time step equal to $T \cdot F$.

$$c_p(P,t) = \frac{p(P,t) - p_0}{\frac{1}{2}\rho V_m^2} \quad (19)$$

In Eq. 19, $p(P,t)$ is the measured pressure at point P of the roof surface, p_0 is the static pressure in the bare tunnel and ½ ρ V^2_m is the dynamic pressure measured by a pitot.

The pressure taps distribution is a crucial point of the experimental campaign. Each pressure tap represent a specific area of influence. It is obvious that a great number of pressure taps improve the aerodynamic study. However, the number of pressure taps depend on the wind tunnel setup.

The model surfaces were discretized in polygons surrounding each pressure taps. Generally, if the pressure taps distribution does not follow an orthogonal grid, Thiessen polygons are used to map surfaces. Thiessen polygons are polygons whose boundaries define the area that is closest to each point relative to all other points. The perpendicular bisectors of the lines between all points mathematically define them.

4 NON LINEAR ANALYSIS THROUGH EXPERIMENTAL DATA

For the case of cables net, the FE model is generally computed using cables elements and loads are applied on net nodes. It is important to precise that the wind tunnel pressure taps grid generally is different from the Finite Element (FE) structural models grid. Generally, the number of nodes in FE models are closely bigger than the number of pressure taps on wind tunnel models. This problem is far from negligible because it means that the numerical calculation is

affected by the experimental setup. In the case of cables net, there are two complementary approaches:

1) Experimental data sample given by pressure taps is numerically expanded make its size equal to the FE model nodes number.
2) Grid nodes (i.e. of the FE model) which are included in the same Thiessen polygon are loaded with the same experimental data.

If performed correctly, the first approach permits to obtain a more precise solution in term of lift and vertical displacements. However, the alteration of experimental data through numerical methods is not always correct. For the case of study discussed in the following, it was followed the second approach.

Cables net are non-linear structural systems and if the cables sag is between 1/10 and 1/6 of the cables span, the difference between the orthogonal direction and the vertical direction according the Cartesian System is neglected.

The wind action time history, $W(t)$, is calculated according to Eq.20.

$$W(t) = \left(\frac{1}{2}\rho V^2\right) c_p(P,t) Ai \tag{20}$$

In Eq.20 ρ is the air density assume equal to 1.25 kg/m^3, V is the wind speed in m/s, $c_p(P,t)$ is the pressure coefficient that varies on the roof and Ai is the surface of influence for the net node i-esimo.

Each node on his area of influence is loaded by a wind force time history to carry out non-linear analyses. The structural response is generally investigated estimating nodal vertical displacements time series [47].

The structural analysis program should be designed for static and dynamic analysis with step-by-step integration of nonlinear geometric three-dimensional structures. It has to contain cable and beam finite elements to permit the study of wind-structure interaction with generation of wind histories and simulation of aeroelastic phenomena [20, 48-51].

In this research, a not commercial software was used to carry out non-linear analyses though wind foresees time histories. It is named TENSO. Using TENSO, is possible to compute parabolic cables in two ways: in the first case, the cable can be divided in an appropriate number of elements that are rectilinear cable, in the second case elastic catenary configuration or parabolic cable can be used. The first case is applicable only with nodal loads. Possible applications of this methodology are suspension bridges with a distance between the hangers sufficiently small compared to the cable span length, and cables nets with a small spacing between cables compared to the maximum span length. For this kind of structures the global stiffness matrix is updated for each load step through the assembly of stiffness matrices of the elements varied according to the strain found in the previous step. In this way the software takes into account the geometric nonlinearity of the structure. As regards to the beam finite element, it is possible to choose among a beam with a uniform or a variable section. For each case it is possible to introduce prestressing actions or tractions as well as thermal loads. In particular, the beam finite element with variable section provides the calculation of ten coefficients in order to describe the area variation and the moment of inertia along the beam axis with a polynomial function. In order to evaluate the stiffness matrix, a numerical procedure based on the validity of the constitutive elastic low is used and six independent functions to describe the displacement field is used, too. At the beginning, the procedure computes the flexibility matrix of the element, applying a forces system and evaluating a displacement system using an algorithm that, step by step, computes the twelve conditions of kinematic compatibility and the balance evaluated in the previous step. The Gauss method is used for the numerical integration and Rayleigh

damping is implemented. In the case investigated a value of 5% of structural damping is used taking into account the membrane effect that increase the structural damping.

TENSO software simultaneously uses two solution methods to solve nonlinear analysis: the step by step incremental method and the interaction progressive method with the variable stiffness matrix as well as the secant method. The secant method can be thought of as a finite difference approximation of Newton's method. In TENSO, secant method is used as a check method that permits to stop the analysis with a unbalanced solution. Using the step by step incremental method, nonlinear problem can be transformed in a succession of linear problems. Each calculation step stores loads and strains history evaluated during the previous step. For each analysis step, a small enough part of load (ΔP) necessary to ensure that is possible to use the elasticity method is applied. However, this simple and classical approach presents the difficulty to evaluate the exact dimension of load step and so the exact step of analysis. A non-appropriate chosen range can cause an inexact solution. In order to solve it, TENSO uses the method with the variable stiffness matrix; this method is a vector version of the Newton-Raphson modified method about nonlinear equation systems. The Newton-Raphson procedure guarantees convergence if and only if the solution at any iteration is close to the exact solution. Therefore, even without a path-dependent nonlinearity, the incremental approach (i.e., for subsequent load steps) is sometimes required in order to obtain a solution corresponding to the final load level. If the displacements are large, the product between the stiffness matrix, evaluated on the basis of the solution of the previous step, and the displacements vector, give the internal force vector, not equilibrate with the external forces vector according to Eq.(21). In Eq.(21) K is the stiffness matrix, δ is the displacements vector, $\widetilde{P}$ is the external forces vector.

The difference between these two forces vectors (i.e. internal and external) represents the imbalance force vector, according to Eq. (22). R is the residual vector and P is the internal forces vector. Subsequently, R is applied as an external load modifying the displacement vector with a residual value of displacements $\Delta\delta$, according to Eq.(23).

$$[K]_{k+1}\{\delta\}_{k+1} = \{\tilde{P}\}_{k+1} \tag{21}$$

$$[R]_{k+1} = [\{P\} - \{\tilde{P}\}_{k+1}] \neq 0 \tag{22}$$

$$\{\Delta\delta\}_{k+1} = [K]_{k+1}^{-1}\{R\}_{k+1} \tag{23}$$

In order to solve nonlinear dynamic analyses, TENSO uses the Newmark-beta method, a numerical integration method used to solve differential equations. It is used in finite element analysis to model dynamic systems. In order to illustrate the use of this family of numerical integration methods, the solution of a linear dynamic system have to be firstly considered. In 1962 Newmark's method in matrix notation was formulated, stiffness and mass proportional damping was added, and the need for iteration by introducing the direct solution of equations at each time step was eliminated. The time dimension is represented by a set of discrete points each a time increment apart. The system is solved at each of these points in time using as data the solution at a previous time. The procedure follows these subsequent phases: reading of initial boundary conditions; assembly of the stiffness matrix, setting β and γ, Newmark method parameters that control the stability and the accuracy of the integration procedure. They are equal to ¼ and ½ respectively; assembly of the vector forces; step by step calculation with iterative process and convergence check. For each integration step, a check of the solution precision is done in order to evaluate if it is necessary to modify the integration step dimension. Generally, a more precise solution needs a very small integration step and so a higher computational work. Unbalanced loads are evaluated according to the Newmark's algorithm, as the difference between the reactions and the applied external loads. In TENSO, a correction

of this algorithm is implemented: the precision of solution is evaluated as a ratio between unbalanced loads and applied external loads for each unconstrained degree of freedom. At each integration step, unbalanced loads are added to the next load step, in order to obtain an optimal solution, [20].

5 CASE OF STUDY

The geometry discussed here as case of study is illustrated in Fig.2. Globally, it is 40 m wide and 80 m long, with a maximum height of 21.3 m. A Hyperbolic paraboloid roof made of a cable net and membrane covers the rectangular plane.

The l_1, f_1, l_2 and f_2 parameters are the upward and downward parabola sags and spans, respectively; H is the biggest height of the roof and was estimated at 1/10 of l_1 [16].

Data used to estimate the wind action on the roof, are given by aerodynamic tests carried out on a scaled model in the CRIACIV open circuit (Interuniversity Research Center on Building Aerodynamics and Wind Engineering) wind tunnel boundary layer. The CRIACIV test chamber size is 2.4 x 1.6 meters [16]. The model sizes are summarized in Table 1.

Table 1 Wind tunnel model sizes

model	l_1 [mm]	l_2 [mm]	f_1 [mm]	f_2 [mm]	H [mm]
1	400	800	27	53	213

The pressure series were acquired at a sample frequency equal to about 252 Hz for a period of nearly 30 s (i.e. 7504 time steps). The scaled wooden model was instrumented with Teflon 1.5 mm diameter tubes to acquire pressures. Totally, 95 pressure taps were located on the roof and sixteen wind angles were acquired. The cables net was dimensioned taking into account the local peaks factors distribution on the roof [46].

With the purpose of estimating the roof geometry variation when under wind action, structural analyses were performed on a FE model of cable net.

The wind forces time histories were calculated using [16] wind tunnel tests campaign and Eqs. (19) and (20). Following the second approach listed in Section 4, each node included in the same pressure tap area of influence was loaded using the same pressure coefficients time histories. Fig.2a shows the geometrical configuration of the building assumed as case of study and Fig.2b shows a FE model view. It is important to precise that the model took into account only the cable net and that it neglected the membrane (i.e. non-structural element).

The numerical model contains 861 nodes spaced according a 2 x 2 m square grid. The first ten natural frequencies estimated by modal analyses are between 0.25 to 0.43 Hz. Figs.2c and 2d show the first two modal shapes.

Fig.3 shows an example of forces time history (i.e. input), F, and an example of displacements time history (i.e. output), δv. In Fig.3, Negative values of F mean suction (i.e. upward) values, negative values of displacements mean gravitational (i.e. downward) displacements.

The time series applied in input were expanded with an initial ramp. The time length was 1800 s and it was calculated based the geometrical scale of the wind tunnel model size. The wind tunnel model geometrical scale was equal to 1/100. The tests were performed at a mean wind speed of 16.7 m/s at a height of 10 cm that in a 1:100 scale would be the standard reference height. Assuming that the prototype mean wind speed at 10 m of height is U = 27 m/s (design value for most of the Italian territory), then there results a velocity scale λ_v = 0.62,

which corresponds to a time scale $\lambda_t = 0.0162$. Therefore, the 30 s model scale acquisition time corresponds to a full scale time of approximately 1800 s [23].

Totally, 861 time history with 7504 time steps were applied on the model for a time equal to 1800 s.

6 CONCLUSION

The paper discussed the non-linear analyses of cables net carried out trough wind tunnel experimental data. The process of calculation was described discussing the cables net structural behavior, the wind tunnel data acquisition and the non-linear time history analyses on FE model. The paper give comments about the dynamic geometrically non-linear analyses of cables systems and their computing using a calculus software.

Keywords: Nonlinear Model Reduction, Damped Systems, Structural Dynamics, Complex Eigenmodes, Modal Derivatives, Large Deflection.

Abstract. *Finite element simulations of structures that undergo large deformations can imply high computation costs due to the nonlinearity of the resulting equations of motion and high numbers of degrees of freedom. Model reduction can encounter this burden by approximating the nodal displacements as a linear combination of some basis vectors and applying a Galerkin projection. The main challenge for this step is a proper selection of basis vectors that are able to capture the deformation states of the system.*

A prevalent selection of basis vectors for geometrically nonlinear systems is the combination of modes of the linearized system and so called modal derivatives. The modal derivatives describe the change of the modes when the system is perturbed and thus contain nonlinear information. However, modal derivatives are only defined for modes that are real. This makes this approach unusable for systems that have complex eigenmodes, such as nonclassically damped systems, i.e., systems with the damping matrix not fulfilling the Caughey condition.

This contribution shows how modal derivatives can be defined for nonclassically damped systems by extending the concept of modal derivatives to complex eigenmodes and how this can be used to build a reduction basis for geometrically nonlinear, nonclassically damped systems. A simple beam test case demonstrates that this approach can improve the accuracy of the reduced system slightly compared to the use of eigenmodes and modal derivatives of the underlying undamped system.

1 INTRODUCTION

One can find many applications in engineering that contain structural parts that undergo large deformations during operation, such as MEMS [14], wind turbine blades [15] or spring leafs for truck suspension [16]. Finite element analysis of such structures leads to the equations of motion

$$\boldsymbol{M}\ddot{\boldsymbol{u}}(t) + \boldsymbol{C}\dot{\boldsymbol{u}}(t) + \boldsymbol{f}(\boldsymbol{u}(t)) = \boldsymbol{F}^{\mathrm{ext}}(t)\,, \tag{1}$$

where $\boldsymbol{u} \in \mathbb{R}^N$ describes the displacements of the nodes of the finite element mesh, $\boldsymbol{M} \in \mathbb{R}^{N\times N}$ is the mass matrix, $\boldsymbol{C} \in \mathbb{R}^{N\times N}$ is the linear viscous damping matrix and $\boldsymbol{F}^{\mathrm{ext}} \in \mathbb{R}^N$ describes the external loads. N is the number of degrees of freedom. The term $\boldsymbol{f}(\boldsymbol{u})$ is the restoring force that is nonlinear for systems that undergo large deformations.

Due to a large number of degrees of freedom, which is typical for real world applications, and the nonlinearity of the restoring force term, simulation times can become very large. That makes design studies, in which the equation of motion must be solved several times, a tedious task. This burden can be faced by model reduction.

Model reduction in structural dynamics has been the focus of research for many years. Some techniques such as the Craig-Bampton method [3] or modal truncation have emerged to a standard and are implemented in many software packages. All these methods rely on the approximation of the displacement vector $\boldsymbol{u} \approx \boldsymbol{V}\boldsymbol{q}$ by a linear combination of some basis vectors that are column-wise stacked into a reduction matrix $\boldsymbol{V}$. The reduction is then carried out by a Galerkin projection onto the subspace that is spanned by the basis vectors. Different reduction methods only differ in how a proper reduction matrix is determined.

Most prominent reduction techniques use system properties of the undamped system for building the reduction matrix, such as the normal modes of the undamped system. This gives rise to the question if these techniques are also able to reduce systems that do not satisfy the Caughey conditions, i.e., systems whose eigenvalues are not equal to those of the underlying undamped system. This concern has been investigated in literature, too. Different methods for reduction of such systems as substructures can be found in [1, 2, 8, 4, 6].

These techniques can reduce linear systems, but they cannot be applied to geometrically nonlinear systems described by equation (1). Model reduction for this kind must overcome two additional issues: First, the reduction basis $\boldsymbol{V}$ must provide a subspace capturing large deformation states. Second, the evaluation of the nonlinear restoring force term must be accelerated. The reason for the second issue becomes clear by viewing the reduced equations of motion

$$\boldsymbol{V}^{\mathsf{T}}\boldsymbol{M}\boldsymbol{V}\ddot{\boldsymbol{q}}(t) + \boldsymbol{V}^{\mathsf{T}}\boldsymbol{C}\boldsymbol{V}\dot{\boldsymbol{q}}(t) + \boldsymbol{V}^{\mathsf{T}}\boldsymbol{f}(\boldsymbol{V}\boldsymbol{q}(t)) = \boldsymbol{V}^{\mathsf{T}}\boldsymbol{F}^{\mathrm{ext}}(t)\,. \tag{2}$$

The last term on the left hand side cannot be precomputed beforehand but must be evaluated in the full element domain. The acceleration of its evaluation is crucial to reduce computation time and can be gained by applying so called hyperreduction methods [16].

The first issue, namely the generation of a reduction basis, can be solved by two different classes of methods: The first class is 'simulation-based', which means that the basis is generated by data from full dynamic simulations of the high dimensional model. The most prominent example for this class is the Proper Orthogonal Decomposition [12, 10]. The second class is 'simulation-free'. These methods compute basis vectors from system properties. A common approach is to take the eigenmodes of the linearized system and augment them by modal derivatives [9]. Modal derivatives are the directional derivatives of the eigenmodes with respect to the displacements in the direction of the eigenmodes themselves. The use of these vectors as reduction basis for nonlinear systems is shown for example in [17, 18, 19].

The modal derivatives approach is able to include nonlinear information into the reduction basis without the need for dynamic simulations of the full high dimensional model. This makes this approach much more comfortable compared to the simulation-based methods. However, in contrast to methods for linear systems, there are no simulation-free basis generation techniques for geometrically nonlinear systems that consider damping properties. Available methods either do not consider damping or are limited to classically damped systems satisfying the Caughey condition, such as Rayleigh damping. But one can find many systems that do not satisfy this constraint in engineering. Thus, the question arises if available techniques can handle nonclassically damped systems or if better bases can be found by using the system's damping properties.

This contribution extends the modal derivative approach to complex eigenmodes which have been shown to be good candidates for nonclassic damped linear systems (cf. [7]). It is shown how a reduction basis for geometrically nonlinear systems can be built up from these vectors. A case study of a locally damped cantilever beam shows that their performance is slightly better than that of basis vectors computed from the properties of the underlying undamped system.

The remainder of this paper is organized as follows: First, the classic approach, i.e., the modal derivatives neglecting the damping properties of the system, is recapped in section 2. Section 3 summarizes the defintion of complex modes for the linearized equations of motion. Section 4 formulates a modal derivative for the complex modes with respect to the displacements $\boldsymbol{u}$. Section 5 shows how bases can be built by using the complex modes and modal derivatives. A case study demonstrates the new basis' performance in comparison to bases that neglect the damping properties of the system. This is illustrated in section 6. The results are summarized in section 7.

2 MODAL DERIVATIVES FOR UNDAMPED SYSTEMS

The equation

$$\boldsymbol{M}\ddot{\boldsymbol{u}}(t) + \boldsymbol{C}\dot{\boldsymbol{u}}(t) + \boldsymbol{K}\,\Delta\boldsymbol{u}(t) = \boldsymbol{F}^{\text{ext}}(t) - \boldsymbol{f}(\bar{\boldsymbol{u}}) \tag{3}$$

describes the linearization of equation (1) around $\boldsymbol{u} = \bar{\boldsymbol{u}}$ with the tangential stiffness matrix

$$\boldsymbol{K} = \left.\frac{\partial \boldsymbol{f}(\boldsymbol{u})}{\partial \boldsymbol{u}}\right|_{\boldsymbol{u}=\bar{\boldsymbol{u}}} . \tag{4}$$

In classic approaches, it is assumed that damping can either be neglected or the damping matrix satisfies the Caughey condition. The eigenmodes $\boldsymbol{\phi}_i$ can then be computed by solving the eigenproblem

$$(\boldsymbol{K}(\bar{\boldsymbol{u}}) - \omega_i^2\,\boldsymbol{M})\boldsymbol{\phi}_i = \boldsymbol{0}\,. \tag{5}$$

The modal derivatives that are used for reduction bases for nonlinear systems are defined by

$$\partial_{\boldsymbol{\phi}_j}\boldsymbol{\phi}_i = \lim_{h\to 0}\frac{\boldsymbol{\phi}_i(\bar{\boldsymbol{u}} + h\,\boldsymbol{\phi}_j) - \boldsymbol{\phi}_i(\bar{\boldsymbol{u}})}{h} \tag{6}$$

which is the directional derivative of a mode $\boldsymbol{\phi}_i$ with respect to the displacements in the direction of a mode ϕ_j. This derivative is not zero because the tangential stiffness matrix of the eigenproblem (5) is dependent on $\bar{\boldsymbol{u}}$ for geometrically nonlinear systems according to equation (4). There are several options to compute the derivative numerically. An extensive overview over different methods is given in [11].

3 COMPLEX MODAL DERIVATIVES FOR DAMPED SYSTEMS

Equation (3) can be transformed to implicit state-space form

$$\boldsymbol{E}\,\dot{\boldsymbol{x}} = \boldsymbol{A}\,\boldsymbol{x} + \boldsymbol{B} \tag{7}$$

with

$$\boldsymbol{x} = \begin{bmatrix} \Delta\boldsymbol{u} \\ \dot{\boldsymbol{u}} \end{bmatrix}, \qquad \boldsymbol{E} = \begin{bmatrix} \boldsymbol{C} & \boldsymbol{M} \\ \boldsymbol{M} & \boldsymbol{0} \end{bmatrix}, \qquad \boldsymbol{A} = \begin{bmatrix} -\boldsymbol{K}(\bar{\boldsymbol{u}}) & \boldsymbol{0} \\ \boldsymbol{0} & \boldsymbol{M} \end{bmatrix}, \qquad \boldsymbol{B} = \begin{bmatrix} \boldsymbol{F}^{\text{ext}} \\ \boldsymbol{0} \end{bmatrix}. \tag{8}$$

The damping matrix $\boldsymbol{C}$ is assumed to be symmetric but does not necessarily satisfy the Caughey condition. This constraint is often satisfied in practice except for systems with gyroscopic effects.

The eigenvectors of the generalized eigenvalue problem

$$(\boldsymbol{A} - \boldsymbol{\lambda}_i\,\boldsymbol{E})\;\boldsymbol{r}_i = \boldsymbol{0} \tag{9}$$

describe the complex mode shapes. The eigenvalues λ_i and eigenvectors $\boldsymbol{r}_i$ occur in complex conjugate pairs or are real (see for instance [5]). We normalize the eigenvectors such that

$$\boldsymbol{r}_i^{\mathsf{T}}\boldsymbol{E}\boldsymbol{r}_i = 1\,, \qquad \boldsymbol{r}_i^{\mathsf{T}}\boldsymbol{A}\boldsymbol{r}_i = \boldsymbol{\lambda}_i\,. \tag{10}$$

4 COMPLEX MODAL DERIVATIVES

The motivation is to extend the modal derivative approach from section 2 to complex modes that take the damping properties into account. Thus, we search for the directional derivative

$$\partial_{\boldsymbol{v}_j}\boldsymbol{r}_i = \lim_{h\to 0}\frac{\boldsymbol{r}_i(\bar{\boldsymbol{x}} + h\,\boldsymbol{v}_j) - \boldsymbol{r}_i(\bar{\boldsymbol{x}})}{h}\,. \tag{11}$$

with $\bar{\boldsymbol{x}} = [\bar{\boldsymbol{u}},\ \boldsymbol{0}]^{\mathsf{T}}$. There are several methods to compute the derivatives as outlined in [11]. One of these methods is Nelson's method [13]. This procedure will be transferred to the state-space eigenvalue problem (9) in this section. First, we apply a directional derivative to the eigenproblem (9)

$$\partial_{\boldsymbol{v}_j}(\boldsymbol{A}(\bar{\boldsymbol{x}}) - \lambda_i\,\boldsymbol{E})\boldsymbol{r}_i = \boldsymbol{0}\,. \tag{12}$$

The dependency on $\bar{\boldsymbol{x}}$ is omitted from now on for the sake of simplicity. The product rule leads to

$$(\boldsymbol{A} - \lambda_i\boldsymbol{E})\cdot\partial_{\boldsymbol{v}_j}(\boldsymbol{r}_i) + \partial_{\boldsymbol{v}_j}(\boldsymbol{A})\cdot\boldsymbol{r}_i - \partial_{\boldsymbol{v}_j}(\lambda_i)\cdot\boldsymbol{E}\boldsymbol{r}_i - \lambda_i\cdot\partial_{\boldsymbol{v}_j}(\boldsymbol{E})\,\boldsymbol{r}_i = \boldsymbol{0}\,. \tag{13}$$

The matrix $\boldsymbol{E}$ does not depend on the stiffness matrix and thus does not depend on $\bar{\boldsymbol{x}}$. Therefore, the last term cancels and one gets

$$(\boldsymbol{A} - \lambda_i\boldsymbol{E})\;\partial_{\boldsymbol{v}}\boldsymbol{r}_i = -\partial_{\boldsymbol{v}}(\boldsymbol{A})\,\boldsymbol{r}_i + \partial_{\boldsymbol{v}}(\lambda_i)\,\boldsymbol{E}\boldsymbol{r}_i\,. \tag{14}$$

The term $\partial_{\boldsymbol{v}}(\lambda_i)$ is unknown and needs to be expressed by other terms. We use the same trick as in Nelson's method and premultiply equation (14) by $\boldsymbol{r}_i^{\mathsf{T}}$ which leads to

$$\boldsymbol{r}_i^{\mathsf{T}}(\boldsymbol{A} - \lambda_i\boldsymbol{E})\,\partial_{\boldsymbol{v}}(\boldsymbol{r}_i) = -\boldsymbol{r}_i^{\mathsf{T}}\partial_{\boldsymbol{v}}(\boldsymbol{A})\,\boldsymbol{r}_i + \partial_{\boldsymbol{v}}(\lambda_i)\,\boldsymbol{r}_i^{\mathsf{T}}\boldsymbol{E}\boldsymbol{r}_i\,. \tag{15}$$

The left hand side vanishes because it satisfies the eigenproblem (9) due to the symmetry of $\boldsymbol{A}$ and $\boldsymbol{E}$. The equation simplifies to

$$\partial_{\boldsymbol{v}}(\lambda_i) = \boldsymbol{r}_i^{\mathsf{T}}\partial_{\boldsymbol{v}}(\boldsymbol{A})\,\boldsymbol{r}_i \tag{16}$$

due to the normalization condition $\boldsymbol{r}_i^\mathsf{T}\boldsymbol{E}\boldsymbol{r}_i = 1$. Inserting this into (14) gives

$$(\boldsymbol{A} - \lambda_i \boldsymbol{E})\, \partial_{\boldsymbol{v}}(\boldsymbol{r}_i) = \underbrace{-\partial_{\boldsymbol{v}}(\boldsymbol{A})\, \boldsymbol{r}_i + \left(\boldsymbol{r}_i^\mathsf{T} \partial_{\boldsymbol{v}}(\boldsymbol{A}) \boldsymbol{r}_i\right)\, \boldsymbol{E}\boldsymbol{r}_i}_{\boldsymbol{g}} \,. \tag{17}$$

This equation cannot be solved at hand because $(\boldsymbol{A} - \lambda_i \boldsymbol{E})$ is singular. The general solution

$$\partial_{\boldsymbol{v}}(\boldsymbol{r}_i) = \boldsymbol{\vartheta} + c\, \boldsymbol{r}_i \tag{18}$$

consists of a particular part $\boldsymbol{\vartheta}$ and a homogeneous part $c\,\boldsymbol{r}_i$ with an arbitrary scalar factor c. Similar to [13], a particular part is determined by setting one coordinate of $\boldsymbol{\vartheta}$ to zero. The system is then partitioned into

$$\left(\begin{bmatrix} \boldsymbol{A}_{11} & \boldsymbol{0} \\ \boldsymbol{0} & 1 \end{bmatrix} - \lambda_i \begin{bmatrix} \boldsymbol{E}_{11} & \boldsymbol{0} \\ \boldsymbol{0} & 0 \end{bmatrix} \right) \begin{bmatrix} \boldsymbol{\vartheta}_1 \\ \vartheta_2 \end{bmatrix} = \begin{bmatrix} \boldsymbol{g}_1 \\ 0 \end{bmatrix} \tag{19}$$

where the index 2 denotes the coordinate which is set to zero, the index 1 denotes the remaining coordinates and $\boldsymbol{g}$ is the right hand side from equation (17).

The homogeneous part is determined by using the normalization condition

$$\partial_{\boldsymbol{v}} \left(\boldsymbol{r}_i^\mathsf{T} \boldsymbol{E} \boldsymbol{r}_i\right) = 0 \qquad \Rightarrow \qquad \partial_{\boldsymbol{v}}(\boldsymbol{r}_i^\mathsf{T})\, \boldsymbol{E}\boldsymbol{r}_i = 0 \tag{20}$$

where we assumed $\boldsymbol{E}$ is symmetric and independent on $\bar{\boldsymbol{x}}$. The scaling factor c is then found by

$$(\boldsymbol{\vartheta} + c\, \boldsymbol{r}_i)^\mathsf{T} \boldsymbol{E} \boldsymbol{r}_i = 0 \qquad \Rightarrow \qquad c = -\boldsymbol{\vartheta}^\mathsf{T} \boldsymbol{E} \boldsymbol{r}_i \,. \tag{21}$$

5 BUILDING THE REDUCTION BASIS

The classic approach for building simulation-free reduction bases for geometrically nonlinear systems is to build up the basis from two parts

$$\boldsymbol{V} = [\boldsymbol{V}_{\text{lin}}\, \boldsymbol{V}_{\text{nl}}] \,, \quad \boldsymbol{V} \in \mathbb{R}^{N \times n} \,. \tag{22}$$

The first part $\boldsymbol{V}_{\text{lin}}$ contains modes $\boldsymbol{\phi}$ of the undamped system (eq. (5)), the second part $\boldsymbol{V}_{\text{nl}}$ contains their modal derivatives (eq. (6)). All vectors are orthogonalized to gain better numerical conditions.

We propose a new basis for damped systems by transferring this strategy to complex modes: The linear part $\boldsymbol{V}_{\text{lin}}$ is built by information from the complex modes $\boldsymbol{r}_i$ of the damped system. A complex mode $\boldsymbol{r}_i$ can be partitioned in

$$\boldsymbol{r}_i = \begin{bmatrix} \boldsymbol{d}_i \\ \boldsymbol{e}_i \end{bmatrix} \tag{23}$$

where the upper part describes displacements and the lower part velocities as defined in equation (7). The desired reduction basis $\boldsymbol{V}$ must suit to the dimension of the second order system (1) making the Galerkin projection described by (2) applicable. For this reason we use only the upper portion $\boldsymbol{d}_i$ of the eigenvectors $\boldsymbol{r}_i$. We propose

$$\boldsymbol{V}_{\text{lin}} = [\text{Re}(\boldsymbol{d}_1)\;\; \text{Im}(\boldsymbol{d}_1)\;\; \text{Re}(\boldsymbol{d}_2)\;\; \text{Im}(\boldsymbol{d}_2)\;\; \ldots\;\; \text{Im}(\boldsymbol{d}_m)] \tag{24}$$

as linear part. It contains the real and imaginary parts of the displacement portion of the first m complex modes belonging to the linearized system. The nonlinear part

$$\boldsymbol{V}_{\mathrm{nl}} = [\, \cdots \ \mathrm{Re}(\partial_{\boldsymbol{r}_j} \boldsymbol{d}_i) \ \mathrm{Im}(\partial_{\boldsymbol{r}_j} \boldsymbol{d}_i) \ \cdots \,] \quad \text{for } i,j \in \{1,\dots,m\} \tag{25}$$

consists of the real and imaginary parts of the complex modal derivatives. Again only the displacement portion $\boldsymbol{d}$ is contained. The derivatives $\partial_{\boldsymbol{v}} \boldsymbol{A}$ that appear during the computation of the complex modal derivatives, such as in equation (17), are computed via central differences. The relation

$$\partial_{\boldsymbol{v}} \boldsymbol{A} = \frac{\partial \boldsymbol{A}}{\partial \bar{\boldsymbol{x}}} \cdot \boldsymbol{v} = \frac{\partial \boldsymbol{A}}{\partial \bar{\boldsymbol{x}}} \cdot \mathrm{Re}(\boldsymbol{v}) + \mathrm{i}\, \frac{\partial \boldsymbol{A}}{\partial \bar{\boldsymbol{x}}} \cdot \mathrm{Im}(\boldsymbol{v}) \tag{26}$$

gives the central difference scheme

$$\partial_{\boldsymbol{v}} \boldsymbol{A} = \frac{\boldsymbol{A}(\bar{\boldsymbol{x}} + h \cdot \mathrm{Re}(\boldsymbol{v})) - \boldsymbol{A}(\bar{\boldsymbol{x}} - h \cdot \mathrm{Re}(\boldsymbol{v}))}{2h} + \mathrm{i}\, \frac{\boldsymbol{A}(\bar{\boldsymbol{x}} + h \cdot \mathrm{Im}(\boldsymbol{v})) - \boldsymbol{A}(\bar{\boldsymbol{x}} - h \cdot \mathrm{Im}(\boldsymbol{v}))}{2h}\,. \tag{27}$$

The full reduction basis

$$\boldsymbol{V} = [\boldsymbol{V}_{\mathrm{lin}}\ \boldsymbol{V}_{\mathrm{nl}}] \tag{28}$$

is stacked together from the linear and nonlinear part. All vectors are orthogonalized to each other by using a singular value decomposition. Vectors that are almost linear dependend are removed by truncating vectors belonging to small singular values. After orthogonalization the full reduction matrix $\boldsymbol{V}$ has the dimension $N \times n$.

6 CASE STUDY

The performance of the proposed reduction basis is tested by means of a case study. Figure 1 shows the finite element model of a cantilever beam that is used for this purpose. The beam is fixed on the left and excited through a harmonic excitation on the tip. The amplitude of the excitation force is chosen so that the beam undergoes large deflection. The beam is slightly damped by a Rayleigh damping. Additionally, a linear viscous damper is applied at a variable position x_d. We consider two positions x_d, namely $30.0\,\mathrm{mm}$ and $50.0\,\mathrm{mm}$. The system has $N = 7,184$ degrees of freedom. The eigenvalues of the linearized system are listed in Table 1.

Three reduction bases are compared against each other. First, the new proposed reduction basis is generated. Four complex modes ($m = 4$) are used to build the reduction basis, namely $1, 2, 3$ and 5. Mode number 4 is not included because it is the complex conjugate pair to the third mode. Thus, its real and imaginary part is linear dependend and does not contribute new information. All complex modal derivatives to the chosen modes are computed. Their real and

5	-0.003-0.052i	-0.001-0.082i
6	-0.003+0.052i	-0.001+0.082i
7	-0.003-0.147i	-0.009+0.118i
8	-0.003+0.147i	-0.009-0.118i
9	-0.004-0.256i	-0.001-0.262i
10	-0.004+0.256i	-0.001+0.262i

Table 1: First 10 complex eigenvalues of the linearized eigenvalue problem of the full cantilever beam model in $\mathrm{rad}/(10^{-4}\,\mathrm{s})$.

imaginary parts are stacked into the reduction matrix as described by equation (25). This results in 8 basis vectors for the linear part and 32 for the nonlinear part. However, after orthogonalization some vectors are removed because they show approximately linear dependence. This is done by truncating vectors belonging to singular values smaller than 10^{-9} times the largest singular value. This leads to a smaller dimension n than expected, namely $n = 31$.

Second, two classic reduction bases are computed for comparison. The first part $\boldsymbol{V}_{\mathrm{lin}}$ consists of undamped modes according to eq. (5), the second part $\boldsymbol{V}_{\mathrm{nl}}$ contains their modal derivatives according to eq. (6). They neglect the damping properties of the system. One of these bases contains the same number of modes ($m = 4$) and all modal derivatives. After orthogonalization and truncation using the same tolerance as above, the basis' dimension is $n = 14$. The other classic reduction basis contains $m = 7$ modes and their modal derivatives. This leads to a dimension of $n = 35$ after orthogonalization which is comparable to the dimension of the first basis. All linearization points $\bar{\boldsymbol{x}}$ and $\bar{\boldsymbol{u}}$ are chosen to be zero for all bases. This linearization point describes the static rest position of the beam.

Figures 2 and 3 show the tip displacements of the full simulations over time and their error generated by the reduced systems. The plotted error describes the absolute error Δu_{tip} normalized by $|u_{\mathrm{tip}}|_{\max}$ which is the maximum tip displacement over time. It can be seen that the new proposed basis performs better than the classic bases for $x_d = 30.0\,\mathrm{mm}$. It also performs better for $x_d = 50.0\,\mathrm{mm}$ compared to the classic basis computed with the same number of modes. However, the error is approximately the same as for a classic basis with almost same number of basis vectors. When using the same dimension for the basis, the new proposed method does not enhance the accuracy for this case.

7 CONCLUSION

Model reduction for geometrically nonlinear systems is used to reduce computation times for design studies. A crucial part for successful reduction is a proper chosen reduction basis. The basis can either be computed simulation-based by relying on training sets from full dynamic simulations or can be computed by simulation-free methods that are much more comfortable. So far, available simulation-free methods do not take the system's damping properties into account or at least assume a viscous damping matrix that satisfies the Caughey condition. The fact, that damping can drastically change the dynamic behavior of a system, motivates to develop

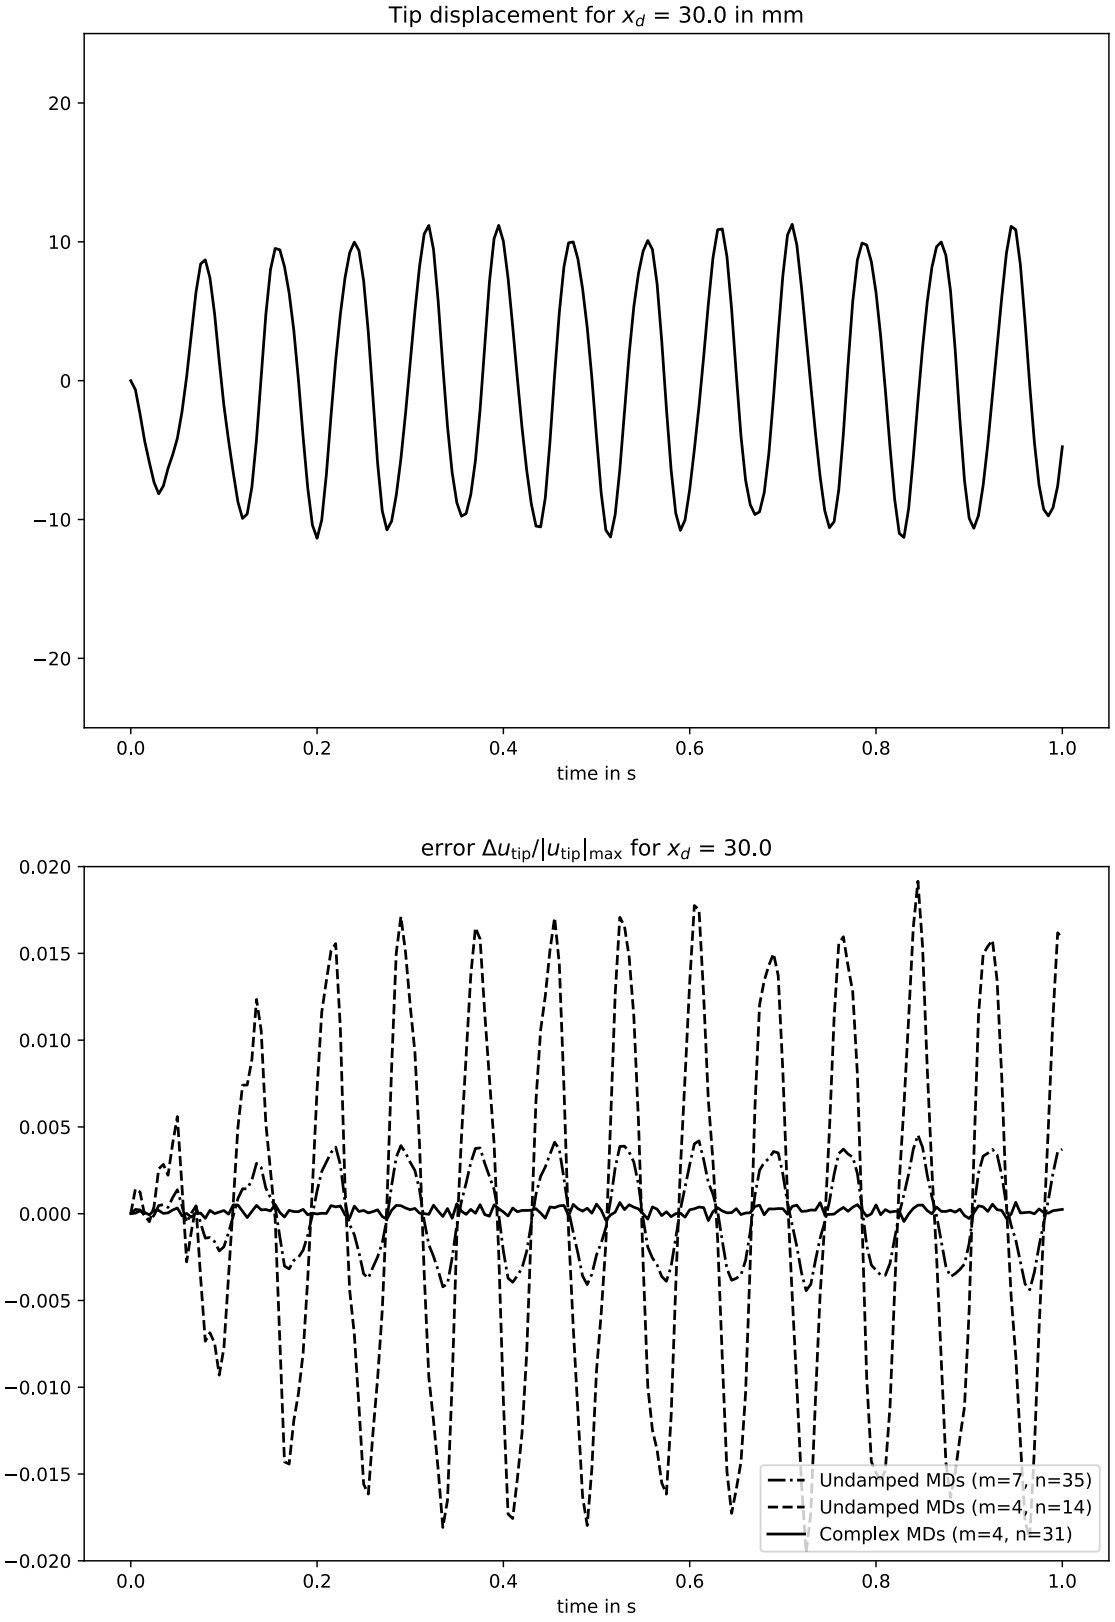

Figure 2: Tip displacement and error.

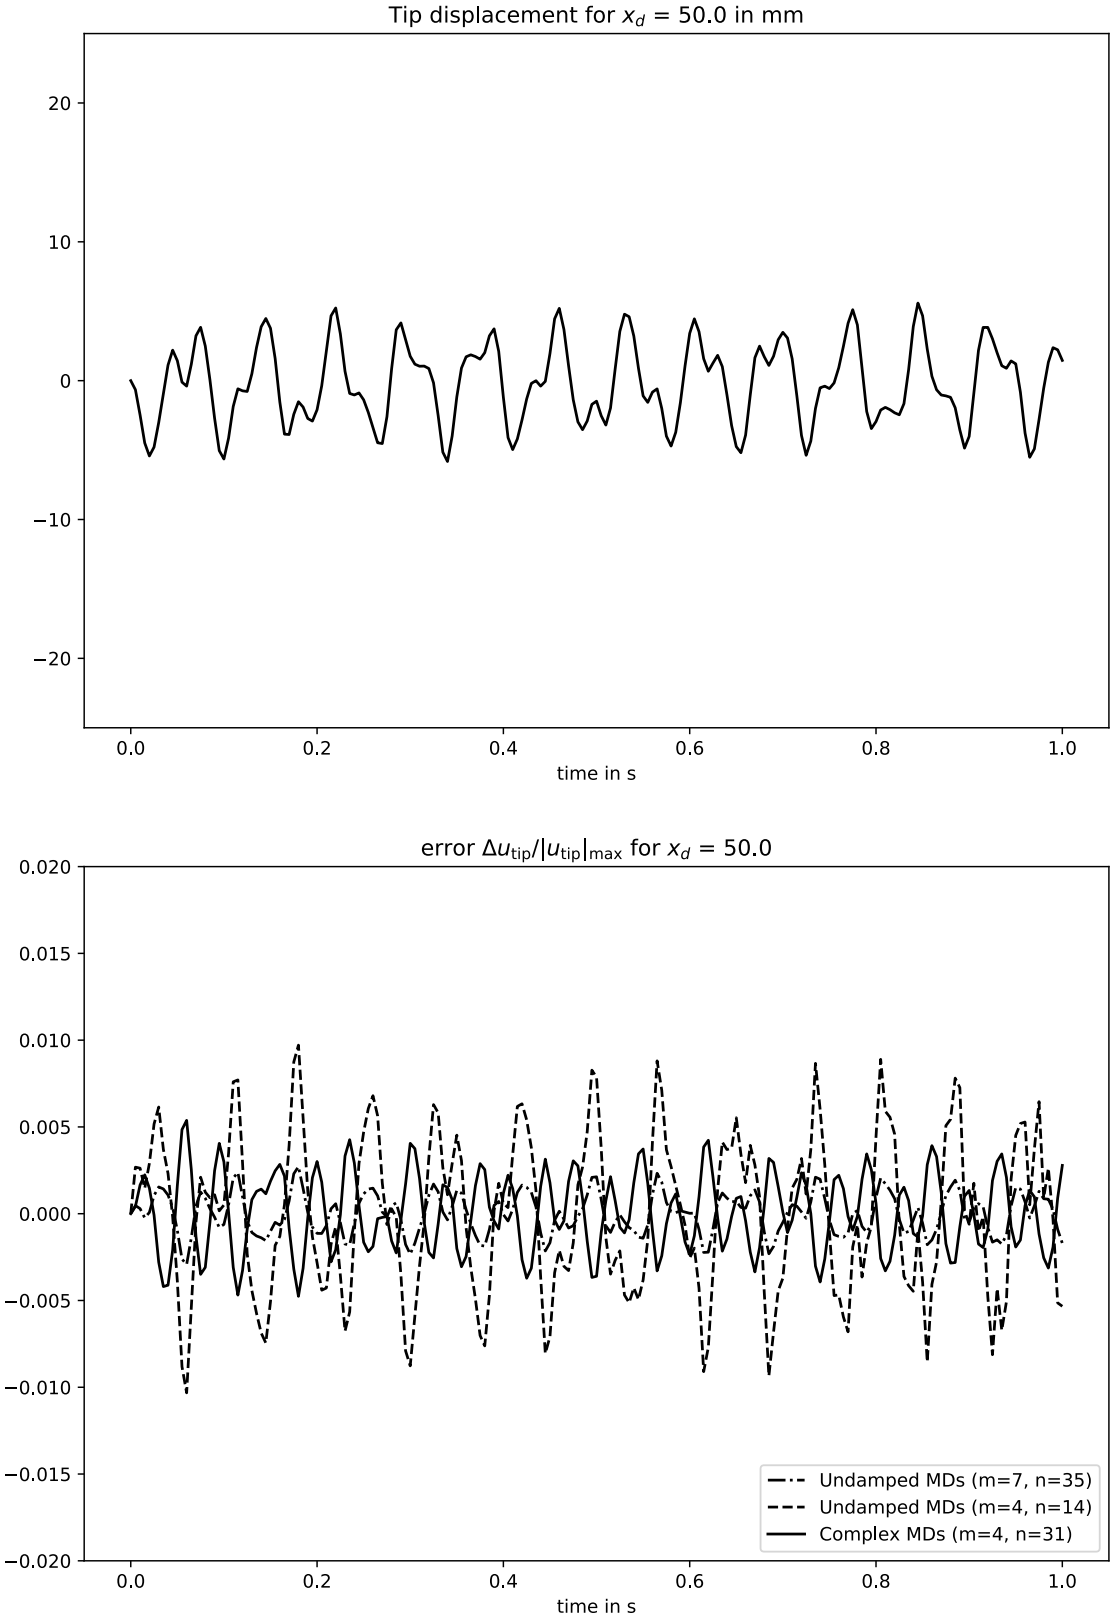

Figure 3: Tip displacement and error.

simulation-free bases that take the damping properties into consideration.

This contribution provides a simulation-free basis that is based on complex modes of the damped linearized system. The idea of modal derivatives is transferred to the complex modes formulation. Nelson's method is applied to derive modal derivatives for the complex modes. A reduction basis is built by using the real and imaginary parts of the modes and their modal derivatives. A case study on a cantilever beam is carried out to evaluate the performance of the new proposed basis. The results show a slight improvement compared to classic bases. But this improvement is small. The higher computation costs associated with the new basis do not outweigh its improvement. Further case studies are necessary to evaluate if there are systems where the improvements are greater and their use more reasonable or if the new basis fails for specific systems.

Abstract

Tensile membrane structures are part of a unique technology that gives designers the capability to experiment new forms and new solutions to conventional design problems. These structures are extremely efficient for long span application and allows considerable savings in the foundations and supporting structure costs. Cable stayed masts are integral part of this structure typology and consists of a inclined elements supported by several layers of pre-tensioned cables. Generally their dynamic loading is not a concern in the design of tensile structures, nevertheless in case of massive shafts, their dynamics can play a fundamental role for global behaviour of the structure. Therefore pre-tensioning force on supporting cables system is an important issue since the internal force distribution, significantly affects their structural dynamic behaviour. A non-linear cable model, combined with the taut-cable theory has been employed to simulate the non-linearity conditions in the stays and cables, by using a restoring-force equivalent spring model to replicate the behaviour of each cable. In the present paper a simplified based displacement technique is utilized to examine the non-linear dynamics of the system. The proposed approach, based on energetic method Equivalent Linearization method (ELM), shows a robust simplified technique capable to linearize the non-linear system, taking into account of slackening effects of pre-tensioned stays. It is concluded that performance coefficient and linearized frequency, may possibly be used as useful indicators for designing pre-tensioned cable stayed masts where a suitable selection of the initial pre-tensioning force can effectively improve dynamic performance of the system.

Keywords: Tensile fabric structures, cable stayed masts; cable response, non-linear effects.

1 INTRODUCTION

Guyed masts are tall structures whose function is to support tensile fabric structures. Pre-tensioning has a beneficial effect on these structures, since it increases the stiffness of the system and improves their dynamic performances [1, 2], on the other hand, a high level of pre-stressing can lead to undesirable yielding of the cables of fabric structures or to high compression strengths on the mast which can lead to buckling of the system.

A suitable configuration of the pre-tensioning force in the cable system can be considered an important issue since the internal force distribution, emerging from the interaction with mast, significantly affects the structural dynamic behavior of the tensile structure [2-5]. The study of the structural optimization of these systems has recently received attention by the researches. Innovative approaches to study the dynamics and the modal response of frames and similar structures are considered in recent papers [6-8]. Furthermore new approach to evaluate the equivalent dynamic stiffness these structures is examined in a recent work [9].

In past years, the several authors have been investigating the dynamics of similar systems, installed on cable-stayed bridges [10-15], furthermore a similar approach suitable for simulating slackening on Pre-Tensioned-Cable Cross-Braced Structures is been recently devel-

oped [16, 17]. This paper proposes, capitalizing from the recent works on non-linear cable dynamics, a new approach to analyze, in pre-tensioned cable stayed masts, the non-linear behavior of the cables, which could lead to a complete loss in the pre-tensioning force imparted to the cables (cable-less structure). A new "linearized solution" is presented to directly simulate the non linear behavior *i* o in the stays on the dynamics of the structural system. Even though other similar approaches have been considered to study the nonlinear dynamics, (e.g. [18, 19]), the proposed method is simple and may be considered attractive for practical engineering design.

2 BACKGROUND

A generalized configuration of cable mast is studied in the present paper, as a typical prototype example of pre-tensioned cable stayed masts configuration present in many existing tensile structures. The structure is modeled as lumped-mass system connected to the rest of the tensile structure through an equivalent cable which simulate the interaction with the fabric structure. Figure 1 illustrates the model geometry, employed for the free vibration dynamics. In the considered case, a 2D plane model has been considered, accounting for a symmetric in-plane configuration of the stays. Constitutive equation of non linear spring (Figure 1c) illustrate a simplified constitutive model of the reaction of a tensile fabric structure around the equilibrium shape. It must be noted that the configuration is general and the proposed preliminary model could easily be extended to a more complex systems (different constitutive models). A set of various lumped masses are utilized in the model to simulate both the main mast mass and additional equivalent masses to simulate the presence of the fabric structure. In the present stage the axial stiffness of the primary structure and dynamic mast-cable interactions are not considered. The mass of the mast has been considered uniformly distributed along its elevation with density ρ_j and is been simulated through a lumped mass discretization of each element $m_j=m=\rho_j \Delta H$. Each lumped mass is associated with a transverse horizontal degree of freedom (x_j). In order to perform a parametric study, generalized mass properties of the prototype system in Fig. 1 are expressed as function of the constant distributed mass m of the antenna, with $\mu_k=M_k/m$ being the mass ratio of the *i-th* fabric structure and $\xi_k=H_k/H$ the dimensionless geometric constants designating the mass position with H being the total height of the mast.

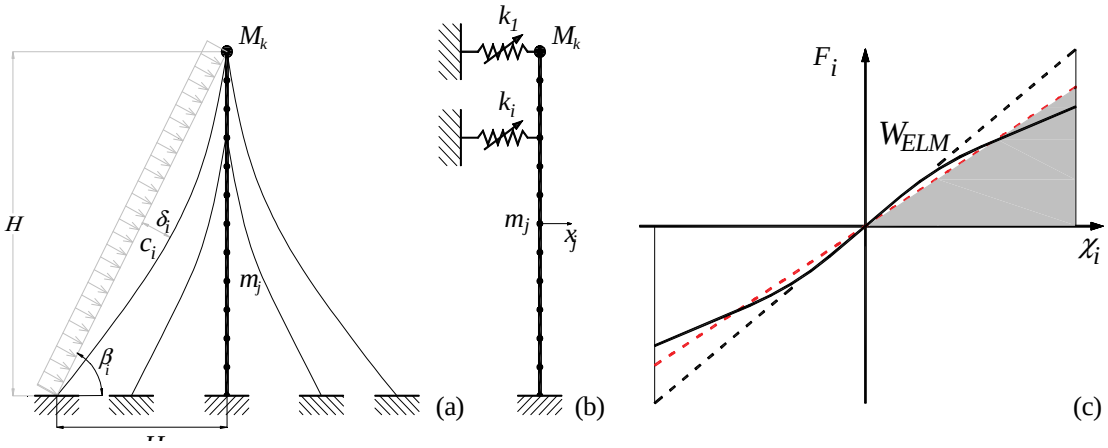

Fig.1 (a) Cable stayed mast, simulated as a lumped-mass model (descriptive example) (b) Lumped mass model with non-linear springs (c) Constitutive equation of non-linear springs and corresponding work performed by: linearized spring (red line) (WELM).

Generalized stiffness properties of the structure are defined through the diameter ratio $\delta_d=d/H$ where d represents the characteristic size of an equivalent constant circular cross-section with area $A_c=\pi(d^2/4)$ and moment of inertia $I=\rho_g^2 A_c$, being ρ_g is the radius of gyration of the cross-section defined as $\zeta=\rho_g/d$. Axial stiffness of the cables are defined as function of their normalized area $\eta_{s,i}=A_{s,i}/A_c$ where $A_{s,i}$ is the cross-sectional area of the *i-th* cable, horizontal normalized distance between the mast and the connection of the *i-th* cable to the ground is been defined by the parameter κ_i. The presence of the fabric pre-tensioned system are definedin the *i-th* cable, through the parameter $v_i=q_i c_i/T_i$.

In the case of linear (or linearized) dynamic free vibration of the system in Fig. 1, the lumped-mass dynamic equilibrium equations can be solved by setting $\mathrm{Re}\left|\mathbf{\Phi}e^{i\omega t}\right|$, with $\mathbf{\Phi}$ generalized amplitude vector and ω a generic unknown pulsation. A homogeneous algebraic system of equations can be consequently derived, after proper manipulation, as $[\mathbf{S}-\omega^2=\mathbf{0}\ \mathbf{I}]\mathbf{\Phi}$ with $\mathbf{S}$ being a N_{dof} by N_{dof} matrix and $\mathbf{\Phi}$ a vector containing vibration amplitudes A_j. More details on the derivation of the system and corresponding equilibrium equations are provided in Section 3.

3 DESCRIPTION OF THE LINEAR MODEL FOR DYNAMIC EQUILIBRIUM

The dynamic equilibrium equation at each mass level, described by each mass element (Fig. 1), accounts for the effects of the inertial force related to M or m_j and the effects of the generalized restoring force effect F due to the stiffness effect of the main shaft and to the axial stiffness of the cables connected to the mast. The global dynamic equilibrium of the system can be expressed through the following

$$\mathbf{M}\ddot{\mathbf{x}}+\mathbf{K}\mathbf{x}=\mathbf{0} \tag{1}$$

with $\ddot{\mathbf{x}}=d^2\mathbf{x}/dt^2$ for $j=1,...,N_{dof}$ where N_{dof} is the total number of DOFs. The presence of the unilateral internal force effect is not discussed at this point but is introduced in the next section. A dynamic system is obtained from Eq. (1), conveniently rewritten in matrix form for the *j-th* mass m_j as function of a non-dimensional time $\tau=\omega_0 t$, non-dimensional displacements $\chi_j=x_j/H$ and non dimensional acceleration, $\mathrm{d}^2\chi_j/\mathrm{d}t^2=\omega_0^2\left(\mathrm{d}^2\chi_j/\mathrm{d}\tau^2\right)=\omega_0^2\chi_j''$.

$$\omega_0^2 M_1\mathbf{M}_N\boldsymbol{\chi}''+k_1\mathbf{K}_N\boldsymbol{\chi}=\mathbf{0} \tag{2}$$

The quantity $\omega_0=(k_{ref}/m_{ref})^{0.5}$ is a reference pulsation of a 1DOF system with mass $m_{ref}=m$, and stiffness $k_{ref}=3EI/H^3$ being E and I respectively elastic modulus and moment of inertia of the mast cross section. In Eq. (2) $\mathbf{M}_N$ is a dimensionless mass matrix and $\mathbf{K}_N$ is a normalized stiffness matrix. Eq. (2) can be further simplified as

$$\mathbf{M}_N\boldsymbol{\chi}''+\mathbf{K}_N\boldsymbol{\chi}=\mathbf{0} \tag{3}$$

The linear discrete eigen-value/eigen-vector problem is derived by postulating that the free-vibration solution of the differential system (3) is converted to an algebraic homogeneous matrix system, which can be numerically solved to determine the frequencies α and the non-trivial modes $\mathbf{\Phi}$ from$[-\alpha^2\mathbf{M}_N+\mathbf{K}_N]\mathbf{\Phi}=\mathbf{0}$. As shown in previous works [11, 20], the ELM can be used to derive an approximate solution in the case of non-linear restoring effects in a cable-cross-tie system.

The ELM (Equivalent Linearization Method) is an energy approach requiring the derivation of the work performed by an equivalent linearized spring element (W_{ELM}) and the actual

work performed by the non-linear component of the spring (W_{SLK}), related to each mass $m_j$or M_k of the system in Fig. 1.

In this preliminary step, the presence of the pre-tensioned tensile fabric structure apparatus, is simulated through the equivalent uniformly distributed load q which act on the mast stays, load q simulates the presence of the fabric pre-tensioning apparatus, which at the present stage can be considered uniformly distributed as shown in Fig. 1a. The static configuration of the *i-th* cable can be written as:

$$y_i(\chi) = \frac{q_i}{2T_i}\left(c_i \cdot \chi - \chi^2\right) \tag{4}$$

Where the sag δ_i of the cable can be written as:

$$\delta_i = \frac{q_i \cdot c_i^2}{8T_i} \tag{5}$$

And T_i is the *i-th* axial component of the equilibrium tension of the main cable.

The pre-tensioning parameter represents the initial deformation pre-assigned to the *i-th* pair of stays $\varepsilon_{0,j}$. The work performed by the linearized and non linear pair of stays experiencing slackening ("SLK"), depends on the (still) unknown frequency α. The work becomes espressed in terms of the dimensionless time τ becomes for both cases:

$$W_{ELM,j} = \frac{2\alpha}{\pi}\int_0^{\pi/(2\alpha)} \left\{\chi_j'(\tau)\cdot\chi_j(\tau)\cdot k_{N,ELM,j}\right\} \mathrm{d}\tau \;,\; W_{SLK,j} = \frac{2\alpha}{\pi}\int_0^{\pi/(2\alpha)} \left\{\chi_j'(\tau)\cdot\chi_j(\tau)\cdot k_{N,j}(\chi_j)\right\} \mathrm{d}\tau \tag{6,7}$$

Where the stiffness of the spring of the *j-th* pair of cables corresponding to the lumped mass m_j,or M_j in the model (Fig. 1); it is defined as a function of the dimensionless displacement χ_j .

After imposing $W_{ELM,j}=W_{SLK,j}$ and postulating $A_{E,j}\approx A_j$ (e.g. [12, 15]), the equivalent frequency can be expressed as a function of the equivalent linearized dimensional stiffness of the spring model with slackening of the pair of cables can be determined as

$$k_{N,ELM,j}(\lambda, \varepsilon_{0,j}) = k_{N,j}(W_{ELM,j}, W_{SLK,j}) \tag{8}$$

Were $A_j(\lambda)$ represents the amplitude of the considered eigenvector at the *j-th* mass re-scaled in terms of a reference dimensionless maximum amplitude $A_{max}=\lambda$.

The nonlinear behavior of the tho pair of cables, lead to a "fictitious" reduction of the equivalent spring stiffness $0<k_{N,ELM,j}<k_{N,j}$. In order to quantify the level of "malfunctioning" of the considered pair of stays, a relative "performance coefficient" ΔK can be defined. The ΔK quantity expresses the ratio between the reduced stiffness of the non-linear cable, due to slackening, and the total stiffness which tends to a perfectly linear behavior:

$$\Delta \mathrm{K}_j(\lambda, \varepsilon_{0,j}) = \frac{k_{N,ELM,j}(\lambda, \varepsilon_{0,j})}{k_{N,j}} \tag{9}$$

The quantity ΔK_j does not depend on the frequency α; it is a positive real number be which varies between 0 and 1. The upper and lower limits of ΔK_j refer to two different specific conditions. The upper limit (ΔK_j=1.0) correspond with a approximately linear behavior; the pre-tensioning parameter $\varepsilon_{0,j}$ is sufficiently large to avoid slackening of the of the considered pair of cables for the the considered vibration amplitude λ, ensuring linear response at the pre-selected mode (Full-Stiffness System). The lower limit (ΔK_j=0.0) for the pre-tensioning parameter $\varepsilon_{0,j}$=0, corresponds to the case of cable less structure with and to a practically absence of stiffening effects due to the stays.. The ELM generalized equivalent eigen-value/eigen-vector problem can be formulated in compact matrix form as $\mathbf{Q}(\lambda,\varepsilon_{0,j})\mathbf{\Psi}=\mathbf{0}$,; the linearized eigen-vector $\mathbf{\Psi}=[A_{E,1}, A_{E,2}...A_{E,n}]$ ($\mathbf{\Psi}\neq\mathbf{\Phi}$) collects the modal amplitudes in the case of ELM. Results obtained by ELM were verified through a direct integration approach of the discrete dynamic equations by imposing, mode by mode, suitable boundary conditions in terms of displacement.

4 PARAMETRIC STUDY BY ELM

A special case, derived from the cable stayed mast illustrated in Fig. 1, is investigated; distributed masses are considered as constant $m_j=m=\rho_j \Delta H$ and $M_j=\mu_j m$ (μ_1= 7.7) simulates the masses of the fabric structure of the fabric structure located in in ξ_1=1, ξ_2=0.9 as shown in Fig.1. Presence of the load q was simulated through the non-dimensional parameter $\nu_1=\nu_2$=0.01. Stiffness and geometrical properties of the mast are the described by δ_d=0.002, ζ= 1.0854 with the normalized area of each cable $\eta_{s,i}=\eta_s$=0.00225, $\kappa_1=\kappa_2$=0.8. A parametric study was carried out to examine the effect of internal pre-tensioning force in the cables of the system; the first three of the in-plane modes of the system were analyzed. The presence of non-linearity in the pair of cables produces a reduction in their performance coefficient ΔK and consequently of the equivalent frequency α_E, these parameters are function of the pre-tensioning level $\varepsilon_{0,i}$ imparted to the *i-th* pair of stays and of the vibration parameter λ>0. The numerical results by ELM are presented as a function of the level of the pre-tensioning force $\varepsilon_{0,i}$. The structural response is non-linear due to the alternate slackening in the cables. Various levels of amplitude λ were selected to evaluate different vibration regimes: moderate vibration (λ=0.002, corresponding to 0.2% lateral drift), large vibration (λ=0.004 and λ=0.005) and unrealistically large vibration (λ=0.010).

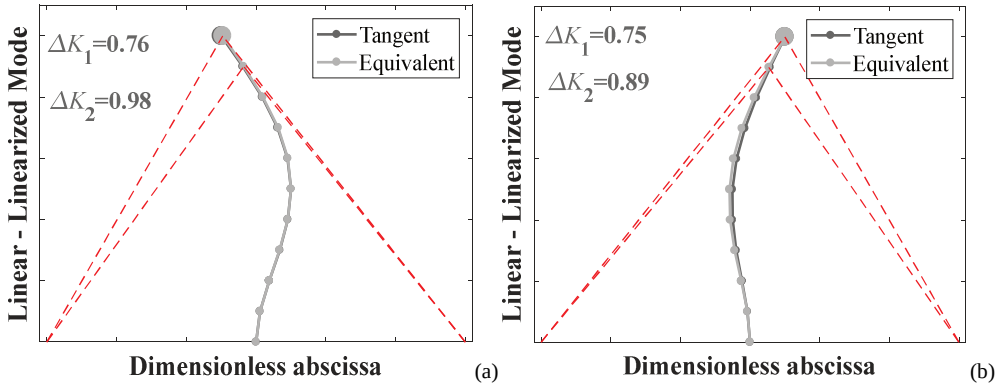

Fig. 2 Comparison between linear and linearized mode shapes for the LM system system depicted in Fig.1with amplitude parameter λ=0.005, experiencing alternate slackening in the *two* pair of cables with pre-tensioning level (a) $\varepsilon_{0,1}=\varepsilon_{0,2}$=0.0005 for the first mode, (b) $\varepsilon_{0,1}=\varepsilon_{0,2}$=0.0005 for the second mode.

In Fig. 2 is illustrated a comparison between linear and linearized mode shapes of the structural system for the first two modes relative to an amplitude λ=0.005, a low level of pre-

tensioning force ($\varepsilon_{0,i}$=0.0005) is been assigned (mode by mode) to both pair of cables identified by the index i (i=1,2); Fig. 3 shows performance coefficients of the two pair of stays of the system illustrated in Fig.1a, in the case of slackening occurring in the first pair (i=1) and linear behavior for the second pair(i=2) and

Has to be noted that for both cases, for the same amplitude λ=0.005, a low pre-tensioning level $\varepsilon_{0,i}$=0.005 can ensure a linear behavior.

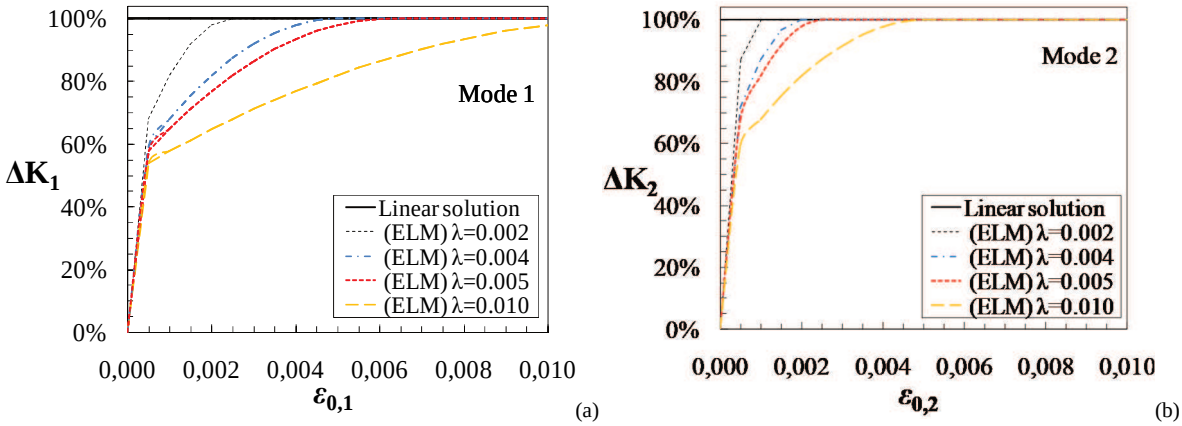

Fig. 3 Performance coefficient ΔK_i of the LM system, as a function of the pre-tensioning level of the *i-th* pair of cables $\varepsilon_{0,i}$ and vibration amplitude parameter λ with slackening in the cables simulated at: (a) first cable for the first mode, (b) second cable for the second mode .

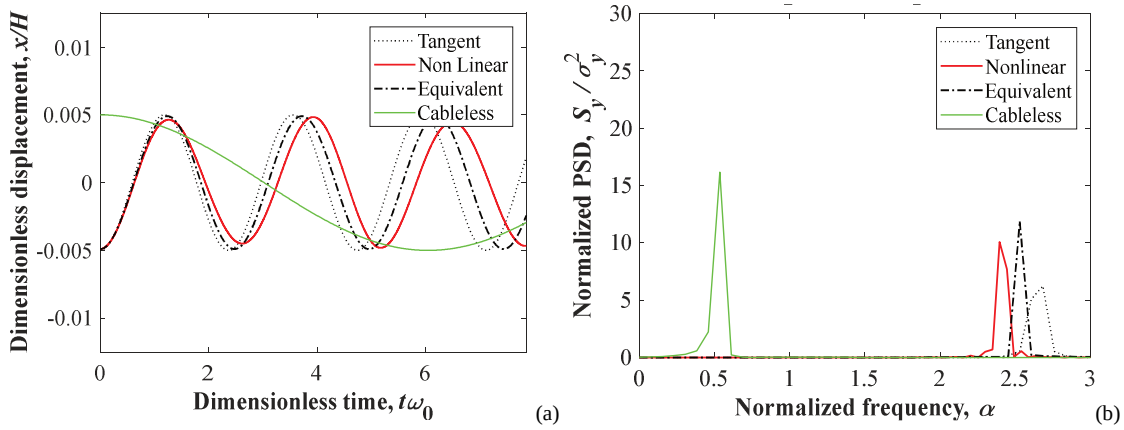

Fig. 4 Time history analysis for the first-mode vibrations of the system for an amplitude parameter λ=0.005, $\varepsilon_{0,1}$=0.0005 and linear behavior in the remaining cables: (a) time history of the horizontal in-plane displacements at the top obtained by direct integration approach , (b) power spectral density of the displacements at the top.

In Fig.3 is shown the parametric study conducted for the first two modes of the mast, performance coefficient ΔK_i is illustrated as function of the pre-tensioning level $\varepsilon_{0,i}$ of the *i-th* stay, results are shown for different values of the amplitude parameter λ, Fig.4a shows that for a chosen amplitude (λ=0.005) the first mode reaches the linear behavior (ΔK_1=1) for a pre-tensioning level $\varepsilon_{0,1}$ =0.006, on the other hand second mode requires a lower pre-tensioning level of the second stay ($\varepsilon_{0,2}$ =0.002). Figure 4 presents the results obtained through a direct integration approach, linearized frequency α_E is shown in comparison with α_{NL} (peak frequency of the non-linear system) for the pre-tensioning parameter $\varepsilon_{0,1}$=$\varepsilon_{0,2}$=0.0005.

5 DISCUSSION AND CONCLUSIONS

The present paper examined a generalized model of pre-tensioned-cable stayed mast of tensile fabric structure, with non-linear dynamic behavior caused by the slackening in the stays. The effects were analyzed by varying the pre-tension imparted to the cables. The ELM was used to study a simplified model of the system, which simulates the dynamic response. A performance coefficient was introduced to describe the dynamic behavior of each pair cables. If no slackening occurs and linear behavior is present in the cables, the performance coefficient is equal to one. On the other hand a performance coefficient smaller than one means the presence of slackening in the supporting cables. The performance coefficient can reach a lower limit of 0 in case of total absence of pre-tensioning force in the cables. The performance coefficient depends on the considered mode, on the level of pre-tensioning force assigned to the cables and on the initial conditions (reference vibration amplitude λ). Performance coefficient could be considered as helpful designing tool for setting a suitable pre-tensioning level in the cables. A concept of linearized frequency is been introduced aimed to characterize the dynamic non-linear behavior of the considered system.

Abstract. *Non-linear calculation results can be significantly different when considering monotone or cyclic analyses. The crack opening and re-closing phenomena are quite difficult to represent with non-linear constitutive models using finite elements methods. The comparison between seismic time-history and pushover analyses is performed in this paper using GLRC_HEGIS non-linear global model for reinforced concrete mono-layer shell elements. It takes into account four different dissipative phenomena: concrete cracking, concrete damage, steel-concrete slip and steel yielding, by means of an analytical multi-scale analysis. This stress-resultant model is formulated for cyclic calculations in the framework of the thermodynamics of irreversible processes, in order to allow efficient numerical computations of earthquake engineering applications of RC buildings. This paper explores the validity range of this constitutive law through cyclic time-history analyses (that consider the crack opening and re-closing phenomena) and monotone pushover static analyses on asymmetric structures of CASH and SMART benchmarks. Pushover analysis is a nonlinear static procedure for evaluating the seismic margin of buildings accounting for their non-linear behavior. The pushover method used in this paper is the so-called Enhanced Direct Vectorial Addition (E-DVA) which defines the load pattern for the pushover analysis as a linear combination of load patterns proportional to the mode shapes. As this method is based on the application of a static force field with constant shape and increasing amplitude, only monotone non-linear phenomena are taken into account. The pushover and time-history analyses are performed (i) on the CASH benchmark model representing a multi-storey shear wall of a real nuclear power plant building structure and (ii) on the SMART benchmark mock-up representing a typical RC building of a nuclear facility. Several numerical comparisons are made at both global and Gauss points levels and are focused on the global mechanical behaviour and the computation of crack opening.*

1 Introduction

In many applications, RC structural analysis is usually realized by design offices using Finite Element (FE) models accounting for a structural linear elastic behaviour. However, in some cases (e.g. nuclear buildings), structural verifications have to be performed under extreme seismic solicitations; in this case, a non-linear behaviour is needed for RC cyclic calculations. Moreover, from a structural and earthquake-resistant point of view, when the bracing system of a structure essentially consists in shells connected to each other and to the slabs by heavily armed chaining, the contribution of RC slabs and walls have to be well represented.

The non-linear behaviour at the global scale of a RC element can be defined by the apparition and the evolution of different non-linear physical phenomena that dissipate energy. In this paper, the RC walls and slabs of the analyzed structures are modelled by GLRC_HEGIS [1] constitutive model. This thermodynamic admissible law accounts for four non-linear mechanisms: concrete cracking, concrete damage (or stiffness reduction), steel-concrete relative slip and steel yielding. It allows an efficient global modelling using a mono-layer shell FE, since the multiscale analysis has been performed analytically and the model implementation only accounts for the formulation at the global scale (macro-scale). A lot of information is available at the end of a FE calculation with GLRC_HEGIS since many results of interest (as crack width, steel plastic strain...) are internal variables of the model. More details about this constitutive model are presented in chapter 2.

In this paper, the seismic action is taken into account by two different methods: nonlinear time-history and nonlinear pseudo-static pushover analyses. The basic (or classical) version of the pushover method is based on three main assumptions: (i) the structure has a plane of symmetry; (ii) there is a single horizontal earthquake component, parallel to the plane of symmetry; (iii) the dynamic behavior is governed by a dominant mode of vibration (with high effective mass). Therefore, the basic pushover analysis cannot be applied for the assessment of global torsion, local effects or influence of high frequency modes, and asymmetric buildings cannot be analyzed. For that reason, in this paper the Enhanced Direct Vectorial Approach (E-DVA) [2] is used to take into account many modes of irregular buildings under a multi-component earthquake. The load pattern for the pushover analysis is defined as a linear combination of modal load patterns using the modal weighting factors (called α-factors), which are calculated using the elliptical response envelopes. The details of this pushover method are presented in chapter 3.

These two seismic nonlinear methods (time-history and pushover analysis) are compared with each other by application to two different structures in chapter 4. First, a four-story framed in-plane irregular asymmetric wall extracted from the CASH benchmark is analyzed in section 4.1. Then, the three-story RC building of SMART benchmark is considered in section 4.2, accounting for the nonlinear behavior of its RC walls and slabs. Comparisons are done at the global (force, displacements) and local (crack width, steel yielding...) scales to analyze the pertinence and the interest of each of these two different nonlinear methods for seismic structural analysis.

2 Constitutive model: GLRC_HEGIS law for RC walls and slabs

An efficient and realistic material cyclic constitutive model is necessary for the comparison between the different seismic calculation approaches. Since the applications in chapter 4 are RC structures composed by walls and slabs, the GLRC_HEGIS model [1] is used for the material modelling. As shown in [3], this model is adapted to nonlinear seismic applications.

The model is implemented in the FE software Code_Aster [4] and allows an efficient global modelling and computation since it is implemented in mono-layer shell FE, accounting for an equivalent "reinforced concrete material". In order to obtain a stress-resultant model accounting for many nonlinear cyclic local phenomena which are at the origin of the nonlinear global behavior of RC elements, an analytical multi-scale analysis has been performed in [1]. Therefore, there is no need of time-costly numerical multi-scale analysis at each Gauss point and at each load step. The resulting model is formulated in the framework of the Thermodynamics of Irreversible Processes; the detailed formulation can be found in [5]. The four different local nonlinear cyclic mechanisms taken into account by GLRC_HEGIS are the following ones:

- Concrete cracking is the development of concrete displacement discontinuities (or macro-cracks) caused by tensile stresses. At each Gauss point, a constant average stabilized crack pattern characterized by the crack spacing s_r (obtained with Vecchio and Collins [6] formula) and orientation θ_r (perpendicular to the principal tensile strength) appears when tensile forces reach the concrete tensile strength f_{ct}. After this cracking onset, these two parameters remain known and constant (fixed crack model), where only the normal (crack width) w_n and tangential w_t crack displacements evolve with the applied force by following the retained bridging stress and aggregate interlock local laws respectively. Four family of cracks are considered: for each layer (top and bottom) of the RC shells, the typical crack pattern of RC walls submitted to cyclic in-plane shear loading can be reproduced by two family of cracks characterized by two different crack orientations.

- Concrete damage is assumed to be associated with the onset and development of homogeneous diffuse micro-cracking, which results in a concrete stiffness reduction. This degradation of concrete stiffness only takes place at high strain levels, above the limit value in tension f_{ct}/E_c. Therefore, concrete damage is supposed to be associated to compressive concrete behaviour. GLRC_HEGIS considers concrete damage as isotropic and it is introduced as an internal damage variable d scalar (two values, defined for both top and bottom layers of the RC shell), positive, non-decreasing in time and which can evolve only at high stress states.

- Relative slip between concrete and steel bars originates bond stresses for each x and y and top and bottom steel reinforcement layers. As stresses are transmitted from steel to concrete between consecutive cracks, this phenomena is at the origin of the tension stiffening effect. GLRC_HEGIS model uses an inelastic steel-concrete slip variable to limit the average tension stiffening effect to values given by the codes like [7].

- Steel reinforcement yielding is supposed to be concentrated at the crack crossings due to the steel-concrete stress transfer by bond. GLRC_HEGIS model considers that reinforcement bars only carry longitudinal forces and that the constitutive law is elastic-perfectly plastic characterized by a constant threshold equal to the steel yielding stress f_{sy}.

3 Pushover method: the Enhanced Direct Vectorial Approach (E-DVA)

The pushover analysis is a seismic nonlinear calculation method based on the application of a static force field with constant pattern and increasing amplitude on a nonlinear structural model. In the basic versions, the pattern of the applied load is generally chosen as proportional to the deformed shape of the dominant vibration mode for a given earthquake component. Other conventional patterns are constant or triangular, or more complex when choosing the vector of the CQC (Complete Quadratic Combination) of the pseudo-accelerations for a given earthquake component. Some adaptive approaches exist, where the load pattern is updated to account for the effects of the non-linear phenomena.

As presented in section 1, the basic version of the pushover analysis does not reproduce accurately the seismic behavior of no-perfectly regular and no-perfectly symmetric structures. For that reason and for the numerical comparisons of this paper, more advanced pushover methods are needed in order to account for interesting and conclusive results. When doing a pushover analysis, the loading pattern selection is likely more critical than the accurate determination of the target displacement.

Several generalizations of the basic pushover analysis have been proposed in the past years, in particular by Chopra and co-workers [8, 9, 10, 11], Fajfar and co-workers [13, 12, 14] and Penelis and Papanikolaou [15]. Some of these approaches take into account the possible multi-modal structural behavior, but all assume that the earthquake is mono-component. The Direct Vectorial Addition (DVA) (Kunnath [16], Lopez-Menjivar [17]) extends the pushover method to the case of multi-component earthquake by application of a load pattern obtained by a linear combination on the modes and earthquake directions.

The E-DVA pushover method is used in this work. It is based on the DVA approach and a rigorous definition of the weighting factors (α-factors) is provided, based on the notion of response envelopes of Menun and Der Kiureghian ([18]). This definition for the load pattern was first proposed by Erlicher et al. [20], which allows imposing an a priori chosen response of the structure. The pertinence of this pushover approach when comparing to time-history non linear analysis has been shown in [21]-[22].

3.1 The load pattern as a linear combination of modes

On the global axes (x, y, z) of the FE model of a structure, the mass $\underline{\underline{M}}$ (assumed diagonal) and the stiffness matrix $\underline{\underline{K}}$ are defined. It is supposed that the seismic input may have 1, 2 or 3 translational components, whose corresponding ground accelerations are named $a_{g,x}(t)$, $a_{g,y}(t)$ and $a_{g,z}(t)$, which act in the directions given by the influence vectors $\underline{\Delta_k}$ corresponding to the translation in the $k = x, y, z$ direction.

The non-adaptative pushover analysis are defined by a nodal force vector $\underline{q}_{pushover}(t)$ with constant shape and increasing amplitude:

$$\underline{q}_{pushover}(t) = c(t)\underline{Q} \tag{1}$$

where $c(t)$ is a scalar increasing pseudo-time function and $\underline{Q}$ is the constant vector defining the pattern of the nodal force field (a displacement-driven is also equivalently possible). The E-DVA approach defines this load pattern as:

$$\underline{Q} = \sum_{k=1}^{n_{ec}} \sum_{i=1}^{n} \alpha_{i,k} \underline{\underline{M}} \cdot \underline{A}_{max,i,k} \tag{2}$$

where $\alpha_{max,i,k}$ is the linear combination factor and $\underline{A}_{max,i,k}$ is the maximum pseudo-acceleration vector for the for the n retained modes i and n_{ec} earthquake directions k:

$$\underline{A}_{max,i,k} = (2\pi f_i)^2 S_{d,k}(f_i, \xi_i)\gamma_{i,k}\underline{\Phi}_i \tag{3}$$

where $S_{d,k}(f,\xi)$ is the response spectrum, f_i ,ξ_i and $\underline{\Phi}_i$ are respectively the modal frequency, damping ratio and deformed shape of mode i, and $\gamma_{i,k}$ is the participation factor of mode i with respect to earthquake direction k.

3.2 Different pushover analyses for different load cases

It can be shown that any response vector any any time $\underline{f}(t)$ (vector containing forces and/or displacements and/or stresses...) can be written as a linear combination of modal responses with the weighting factors $\alpha_{i,k}(t)$ [20]. Actually, only some response vectors are of interest when comparing to time-history analyses, those that maximize the value of parameters of interest, e.g. that maximum force in the x direction at the basis of a building or the maximum displacement in the y direction of a point of the roof. These response vectors corresponding to the load cases that maximize the interest parameters can be obtained using the notion of elliptical responses, as done in [21].

Once the response vector $\underline{f}(t)$ is known, the vector of modal combination $\underline{\alpha}$ is calculated following Erlicher et al. [20]:

$$\underline{\alpha} = \underline{\underline{\tilde{H}}} \cdot \underline{\underline{R}}_f \cdot \underline{\underline{X}}_f^{-1} \cdot \underline{f} \tag{4}$$

where $\underline{\underline{\tilde{H}}}$ is the modal coefficient correlation matrix, $\underline{\underline{R}}_f$ is the modal response vector matrix and $\underline{\underline{X}}_f = \underline{\underline{R}}_f^T \cdot \underline{\underline{\tilde{H}}} \cdot \underline{\underline{R}}_f$ is the matrix which defines the elliptical domain of the concomitant values of $\underline{f}$ by:

$$\underline{f}^T \cdot \underline{\underline{X}}_f^{-1} \cdot \underline{f} \leq 1 \tag{5}$$

Finally, in Erlicher et al. [24] a method is proposed to choose several dominant modes to reach the searched response. As the total value of the response vector is $\underline{f} = \underline{\underline{R}}_f^T \cdot \underline{\alpha}$, the value of the parameter of interest of the response vector is compared to the cumulative contribution of each mode (and earthquake direction) by means of the sum of the products between α_{ik} and the corresponding line of $\underline{\underline{R}}_f$, for the column corresponding to the parameter of interest.

3.3 The equivalent seismic spectrum for multi-direction earthquakes

A difficulty exists when trying to define the response spectrum for an earthquake acting in the direction of the earthquake $\underline{t}$, which is identified as the direction of the resultant of the load pattern $\underline{Q}$. By considering the deformed shape $\underline{U}$ under $\underline{Q}$ load $\underline{U} = \underline{\underline{K}}^{-1} \cdot \underline{Q}$, the participation factor of $\underline{U}$ in the $\underline{t}$ direction can be defined. In this direction, the structure vibrates with an equivalent frequency f^* and damping ratio ξ^*.

For a single-component earthquake, the maximum displacement can be easily calculated from the corresponding spectrum. For example, for single-component earthquake in direction $k = x$, one has $\gamma_{U,t} = \gamma_{U,x}$ and the response spectrum is $S_{d,x}(f^*, \xi^*)$. Analogous formulas can be written for earthquake components y and z. Based on the assumption of non-correlation between accelerograms in the x, y and z directions, the SRSS combination is used to define s_{max} for a multi-component earthquake:

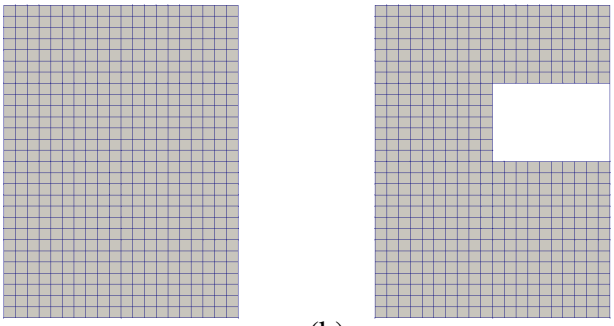
$$S_{d,t}(f^*, \xi^*) := \frac{1}{|\gamma_{U,t}|}\sqrt{(\gamma_{U,x}S_{d,x}(f^*,\xi^*))^2 + (\gamma_{U,y}S_{d,y}(f^*,\xi^*))^2 + (\gamma_{U,z}S_{d,z}(f^*,\xi^*))^2} \tag{6}$$

4 Numerical Applications

4.1 Irregular wall from CASH : Benchmark on the beyond design seismic capacity of reinforced concrete shear walls

CASH is an international benchmark organised by the OEDC-NEA (Nuclear Energy Agency). The main purpose is to evaluate the accuracy of tools and prediction methods used in civil engineering for the estimation of the seismic capacity of shear reinforced concrete walls in "beyond design" seismic situation (important seismic excitation). The benchmark study focuses on two different multi-storey shear walls representative of a real NPP building structure. The results presented in the article are those obtained for the irregular structure (Figure 1-b) and the following post-treatment results are not those presented to the benchmark but are only examined for the purpose this article.

4.1.1 Model description



(a) (b)

Figure 1: CASH Finite Element models on Code_Aster

The structure represents the facade of a building with four floors, the studies are done in the plane (2D) of the wall. The height of the structure is 16m for 12m width and 0.40m thick. Slabs and out-of-plane walls are represented by beams and columns with strong depths. In-plane walls are modelled with shell elements using the GLRC_HEGIS global constitutive law and beams and columns are modelled with multifiber beams elements using the MAZARS constitutive law [23] for concrete fibers and an elastic-plastic model (with kinematic hardening) for steel fibers.

4.1.2 Modal and spectral analyses

The purpose of this section is to evaluate the linear response of the considered irregular structure for a given pseudo-acceleration spectrum. First, the modal analysis is performed and the corresponding spectral values are calculated.

The results of the modal analysis performed on the FE model are summarized in Table 1. The 5 retained modes account for 99% of the total mass for x and z directions.

4.1.3 Pushover analysis

The objective of this analysis is to evaluate the non-linear response of the wall under an increasing horizontal load proportional to a specific profile. The E-DVA method procedure described in [24] is applied step by step.

Modes	**Frequency [Hz]**	**Effective mass in X [kg]**	**Effective mass in Z [kg]**	$S_{a,X}$ $[m/s^2]$	**Damping factor [%]**
1	4.21	1730	0	4.06	2.00

Table 3: Number of modes and corresponding percentage of the total response needed

(e) The procedure is applied to determine the dominant modes: based on the $\alpha_{i,k}$ factors calculated at step (d),the products $\alpha_{i,X}\underline{F}_{i,X}^T$ are computed for the two load cases. The cumulative sum of the products according to the order defined in Table 3 is normalized according

to the maximum response (second row of Table 2). For instance, when taking $C_d = 0.90$ as suggested in [25] at chapter 4.3.1(b), the first ik_{max} modes are dominant since their contribution to the response $F = \underline{f}^T \cdot \underline{b}$ is 90% of the total response. Table 3 shows that only the first mode is needed to fulfill this condition.

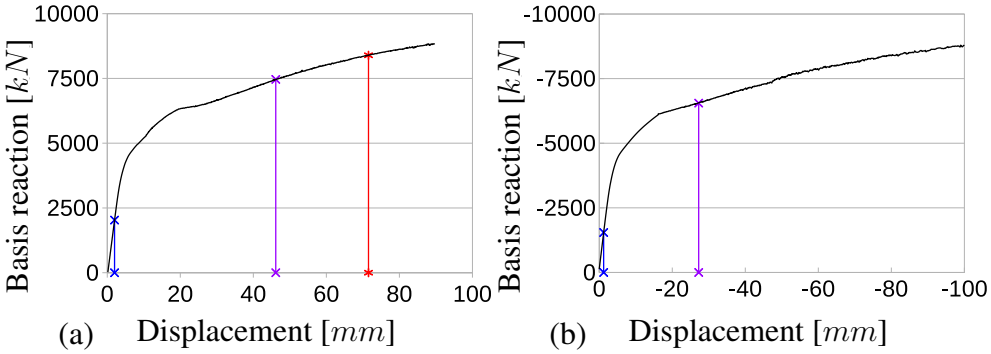

Figure 2: Pushover curve (Force-Displacement) for (a) +Fx and (b) -Fx load cases

The application of incremental unidirectional loading for pushover analysis gives global force-displacement curves which can be analyzed to distinguish the evolution of the activated non-linear phenomena. First, in Figure 2, a linear segment describe the non-cracked phase (before the blue line), then there is creation of several cracks. When the crack pattern is stabilized, the crack width increase and the steel reinforcement can yield (purple line) and finally a "tension-stiffening" effect can be observed. As shown in Figure 2, the concrete ultimate limit in compression is reached for a displacement of +72 mm (red line) and corresponds to a strain level of $\epsilon_u = 3.5‰$. It can be explained by the fact that the concrete developed too many micro-cracks in compression and can't bear more stress. The structure only reach its ultimate capacity in compression in the direction +Fx.

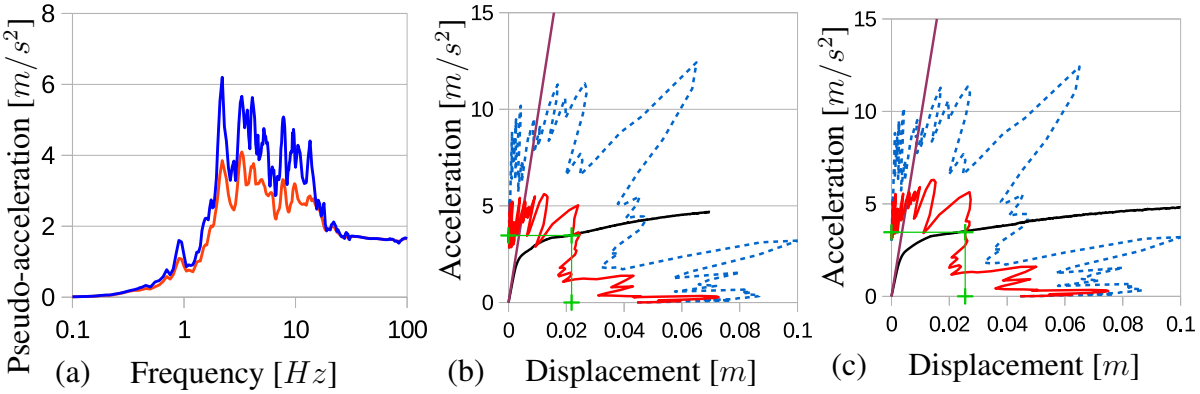

Figure 3: (a) Spectra and graphical results in the ADRS plane for the cases (b) +Fx (c) -Fx

Then, the coordinates of each target point are determined at the intersection of the capacity spectrum with the Acceleration Displacement Response Spectrum (ADRS) given by Eq. (6). The damping ratio $\tilde{\xi}^*$ of ADRS after iteration accounts for the hysteretic damping (Figure 3). The target point coordinates are shown in Table 4, with F_X and V_X corresponding to the obtained target global reaction and displacement of the structure, respectively.

Direction	+Fx	-Fx
$S_a(m/s^2)$	2.78	2.81
$S_d(mm)$	7.79	8.08
$\tilde{\xi}^*(\%)$	12.6	8.80
F_x(kN)	5257	-5272
V_x(mm)	10.18	-10.25

Table 4: Obtained target points for the considered load cases

4.1.4 Time history analysis

To evaluate the non-linear response of the irregular specimen under a horizontal seismic loading, a accelerogram whose spectrum corresponds to the one used in the pushover analysis is imposed to the structure. The chosen seismic input data is scaled to a $PGA = 0.16g$ intensity earthquake.

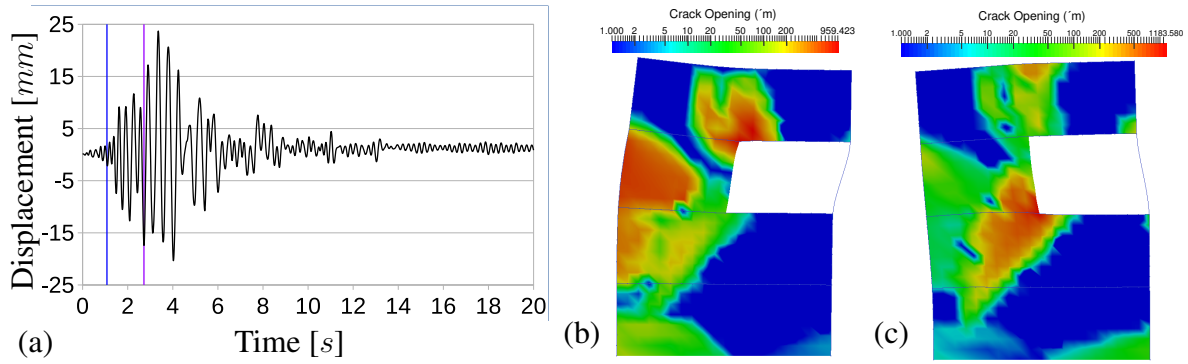

Figure 4: (a) Time-history roof displacement and obtained crack opening at (b) maximal displacement +Vx and (c) maximal displacement -Vx

The graphical results are shown in Figure 4 (a). Two non-linear indicators are given : the first concrete crack (blue line) and the first steel reinforcement yielding (purple line). The crack pattern at the maximal displacements in both directions are shown in Figure 4 (b) and (c).

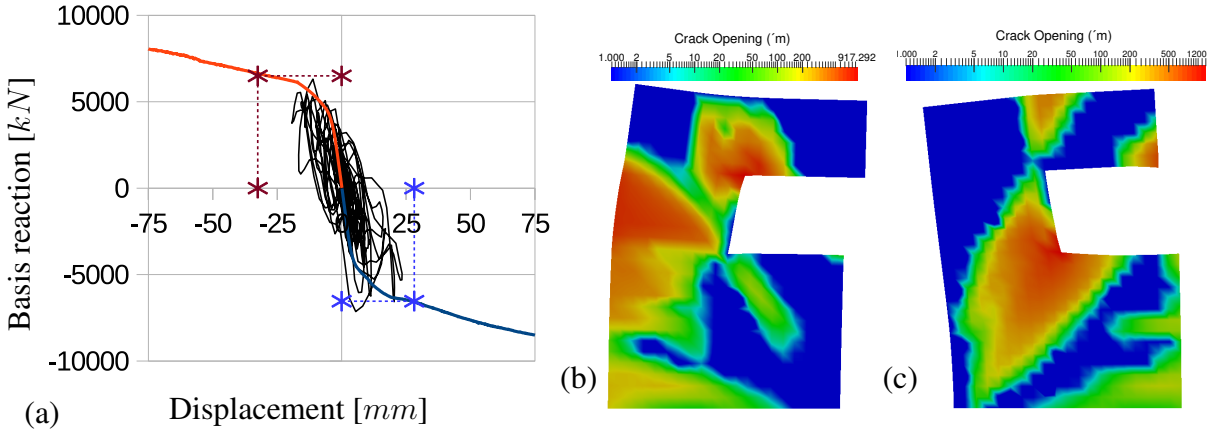

Figure 5: (a) Comparison of the capacity curves and obtained crack opening during the pushover analyses at (b) target point +Vx and (c) target point -Vx

4.1.5 Comparison between time history and pushover analyses

The graphical comparison of Figure 5 (a) shows that the dynamic results (black lines) are mostly inside the envelope area defined by the obtained target points (red and blue) and that the calculated forces that are presented in Table 4 are well estimated by the pushover (Figure 5 (a)) compared to the time-history results. The pushover results given by the E-DVA approach provide a suitable and accurate envelope of the maximum roof displacements and global forces at the basis of the building.

In order to compare the obtained crack pattern, the crack opening values using GLRC_HEGIS are plotted at the pushover target point. The results of Figure 5 (b) and (c) show that the crack patterns obtained by the pushover analyses are very close of the one obtained by time-history analysis showed in Figure 4 (b) and (c).

4.2 SMART: Seismic design and best-estimate Methods Assessment for Reinforced concrete buildings subjected to Torsion and non-linear effects

The experimental program SMART [26] was supported by the French companies Commissariat l′Energie Atomique et aux Energies Alternatives (CEA) and Electricite de France (EDF) and partially by the International Atomic Energy Agency (IAEA). The goals of the benchmark are to compare and to validate the used methods to evaluate the seismic responses of reinforced concrete structures under a seismic loading that induce 3D effects such as torsion and out-of-plane shear and to check the accuracy of prediction approaches of advanced calculation methods used in earthquake engineering.

4.2.1 Model description

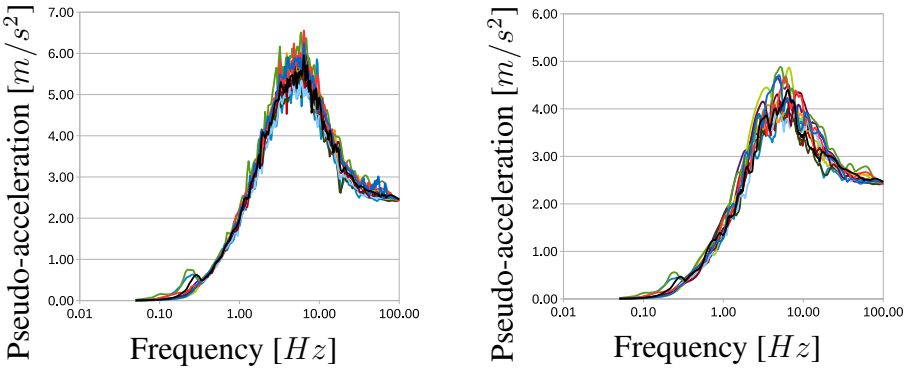
The program concerns a $1/4$ scale mock-up of a representative asymmetric RC multi-storey building in nuclear power plants. The experimental moke-up was tested under seismic loadings applied by the shaking table with 6 degrees of freedom AZALE at CEA Saclay. The tested structure corresponds to SMART 2013 international benchmarks [26], but the foundation conditions are not respected in this article and all the comparisons to experimental results are out-of-scope of this paper. The structure shown in Figure 6(a) represents a asymmetric 3 storey reinforced

(a)  (b) 
Figure 6: SMART (a) experimental moke-up and (b) used FE model on Code_Aster

concrete building and consists of RC slabs, walls, beams and columns. In the FE model of Figure 6(b), only the two first types of structural elements are modelled with the developed GLRC_HEGIS constitutive model, while beams and columns are modelled with a linear elastic

law. Therefore, all the non-linearities are originated by the nonlinear response of the developed model. The full building is 3.650 m height for 3.100 m width, walls are 10 cm thick and beams and columns are 15 cm and 20 cm thick respectively. In order to check the performances of the constitutive law GLRC_HEGIS, several studies were carried in parallel of the benchmark to compare the obtained results in the same way than those of the previous numerical application. Therefore, the shaking table was not taken into account here to save computation time but the benchmark will be fully conducted in a second time and the shaking table will be added.

For preliminary studies carried on the SMART building, several sets of seismic input data were generated. There particularity is that they all were generated from a unique aimed spectrum. Therefore, spectral, pushover and time-history results can be compared between each seismic input sets. The obtained pseudo-acceleration spectra were compared to only keep those which don't exceed a 10% error from the aimed spectrum, see Figure 7. All the generated accelerograms are different but the modes of the structure can be excited in a comparable way. The seismic intensity of the aimed spectrum is given by PGA$= 2.45m/s^2$.



(a) Spectra at 5% damping

(b) Spectra at 10% damping

Figure 7: Chosen spectra associated to the seismic pseudo-acceleration inputs for the preliminary SMART studies

4.2.2 Modal and spectral analyses

First, the modal analysis is performed and the corresponding spectral values are calculated. The nine first modes are calculated for the structure. The results of the modal analysis performed on the FE model are summarized in Table 5. The 9 retained modes account for 83% of the total mass for x and y directions. The presented pushover method allows to choose along these modes which really need to be considered.

4.2.3 Pushover analysis

The E-DVA method procedure previously applied in section 4.1.3 is also applied to this 3D structure. The pushover directions are chosen here following 8 horizontal directions given by the Newmark combinations, as explained in [2].

Then, the coordinates of each target point are determined at the intersection of the capacity spectrum with the ADRS spectrum given by Eq. (6). The damping ratio $\tilde{\xi}^*$ of ADRS spectra

after iteration accounts for the hysteretic damping (Figure 8). The target point coordinates are shown in Table 8, with F_t and V_t corresponding to the obtained target global reaction and displacement of the structure in the considered direction t.

4.2.4 Time history analysis

To evaluate the non-linear response of the irregular specimen under a horizontal seismic loading, accelerograms whose spectra correspond to those of Figure 7 used in the pushover analysis are imposed to the structure. The seismic input data are all scaled to a $PGA = 2.45m/s^2$ intensity earthquake. For the sake of brevity, only two time-history results are showed here.

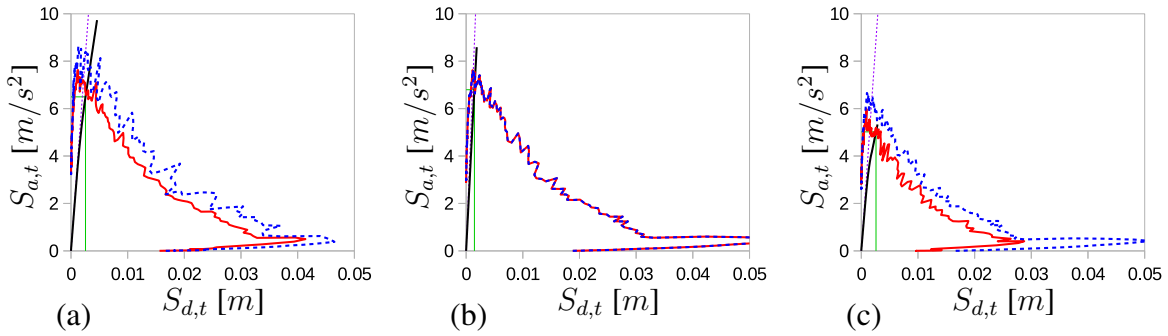

Figure 8: Capacity curves vs. spectrum in the ADRS plane for three of the load cases

Direction	12.9°	51.9°	122°	168°	−167°	−128°	−57.6°	−12.5°
$S_a(m/s^2)$	6.50	6.80	5.02	5.26	6.84	6.68	5.69	6.06
$S_d(mm)$	0.256	0.146	0.260	0.211	0.273	0.149	0.215	0.267
F_t(kN)	357	395	428	374	359	383	410	363
V_t(mm)	8.14	7.92	7.89	8.03	8.38	8.02	8.34	8.08
$\tilde{\xi}^*(\%)$	3.37	3.39	7.11	2.41	3.56	3.39	4.12	4.33

Table 8: Obtained target points for the considered load cases

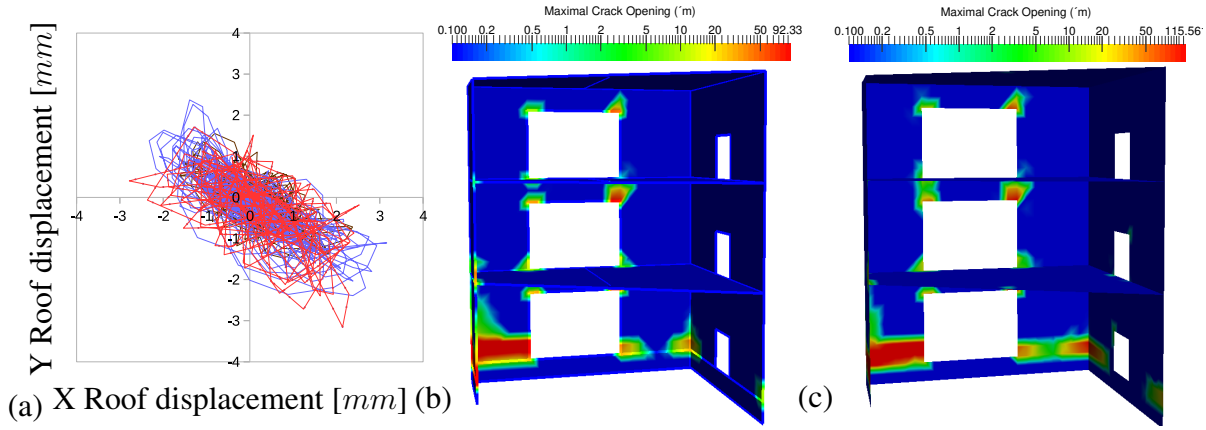

Figure 9: (a) Time-history roof displacement and maximal obtained crack opening during (b) a first seismic input and (c) a second one

The roof displacements shown in Figure 9 (a) are characteristic of an asymmetric structure with a dominant torsion mode. In Figures 9 (b) and (c), the maximal values of the crack opening during two whole earthquakes are plotted and represent the obtained crack patterns. When analyzing the results, it can be observed that the cracks are localized near the openings. The structure is heavily cracked at its left basis corner and steel reinforcement yielded.

4.2.5 Comparison between time history and pushover analyses

In order to compare the obtain results, the pushover results are plotted at their target point steps. The graphical comparison of Figure 10-a shows that the dynamic results obtained by all performed time-history analyses are mostly inside the envelope area defined by the obtained target points. The results show that the calculated forces that are presented in Table 7 are well

estimated (Figure 10-a). The pushover results given by the E-DVA approach provide a suitable and accurate envelope of the maximal global forces at the basis of the building.

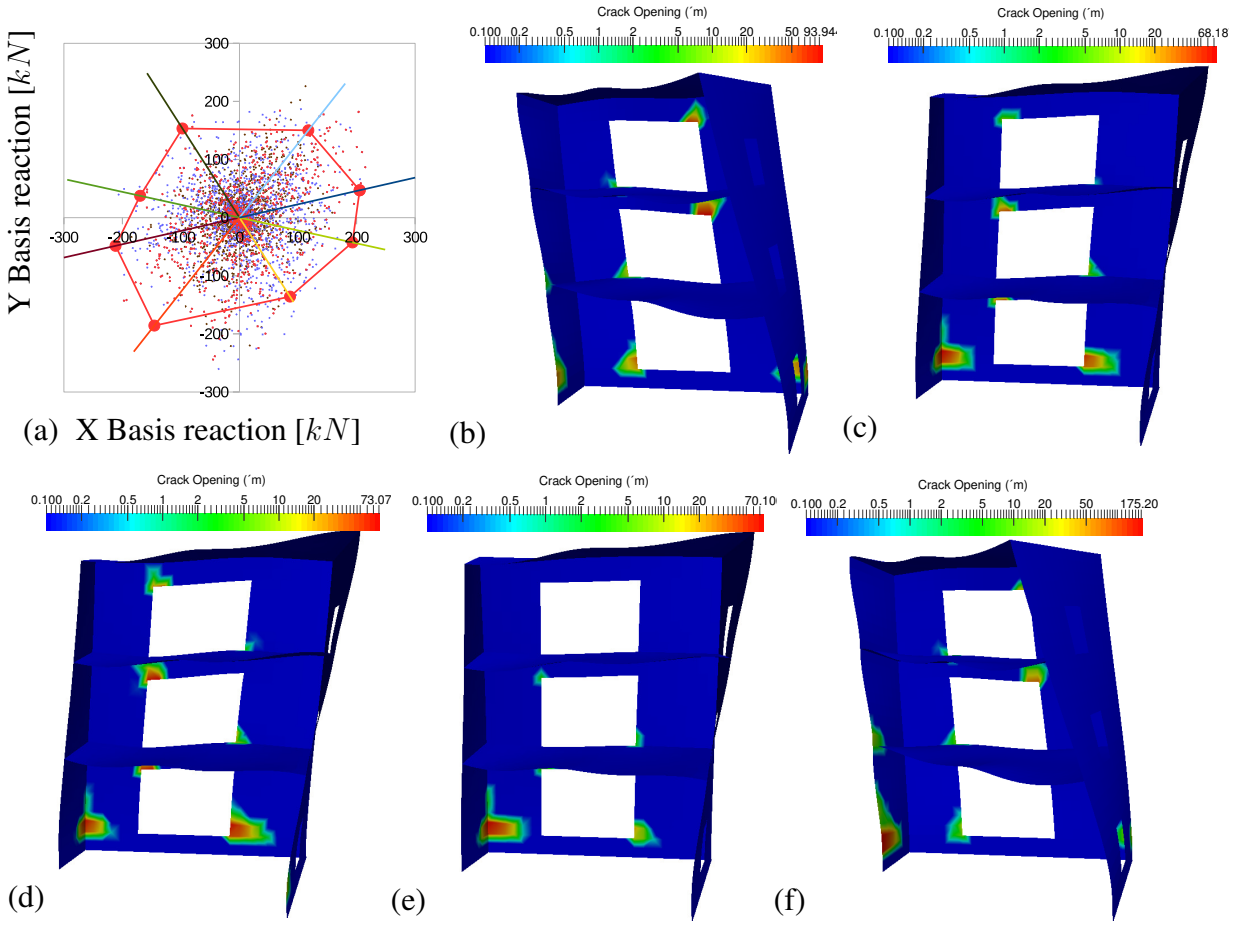

Figure 10: (a) Comparison of the capacity curves and obtained crack opening during the pushover analyses at (b) target point $12.9°$, (c) target point $168°$, (d) target point $-167°$, (e) target point $-57.6°$ and (f) target point $-12.5°$

The crack patterns obtained the pushover analyses (Figure 10-b-c-d-e-f) show that the crack opening are well estimated near the openings compared to the two time history crack opening pattern showed in Figure 9-b-c. As the time history analysis is a cyclic loading, the phenomena of cracking and reclosing cannot be reproduced by monotonic pushovers therefore several pushovers are needed to reproduce the crack pattern. The maximum obtained crack opening values obtained with the pushover analyses (Figures 10) give a quite accurate localization and value of the maximal crack opening obtained by time-history analyses (Figures 9). However, the severally cracked left basis corner due to the torsion behaviour of the structure cannot be fully predicted by pushover analyses that maximize basis reactions but it can be interesting in another study to perform multi-modal and multi-component pushover analyses that maximize the torsion (global torsion moment of the building M_{zz}).

5 Conclusions

The GLRC_HEGIS [1] model for RC plates (walls and slabs) is implemented for shell finite elements in Code_Aster [4] software and is applied to incremental static pushover and transient dynamic structural analyses corresponding to the same seismic intensity level. The structures which have been studied in this paper consisting of RC walls and slabs and the possibilities offered by this thermodynamic admissible law accounting for non-linear mechanisms have been used to compare available crack patterns at the end of a FE calculation since many results of interest (as crack width, steel plastic strain...) are internal variables of the with GLRC_HEGIS constitutive model.

In this paper, the seismic action has been taken into account by two different methods: non-linear time-history and nonlinear pseudo-static pushover analysis. In this paper the Enhanced Direct Vectorial Approach (E-DVA) [2] is used to take into account many modes of irregular buildings under a multi-component earthquake. The load pattern for the pushover analysis has been defined as a linear combination of modal load patterns using the modal weighting factors (called α-factors), which have been calculated using the elliptical response envelopes. The results obtained by time-history and pushover analyses have been compared.

First, a four-story framed in-plane irregular asymmetric wall extracted from the CASH benchmark has been analyzed in section 4.1. Then, the three-story RC building of SMART benchmark has been considered in section 4.2, accounting for the nonlinear behavior of its RC walls and slabs. Comparison between obtained results shows a relatively good fitting both at the local (e.g. crack width) and global (structural behavior) scales. The capabilities of the model to show the evolution of variables (crack width, steel reinforcement plastic strain, energy dissipation...) fields at every load step, and to estimate in a relatively accurate manner the RC section strength, have been also demonstrated. Comparisons have shown that forces and displacements can be estimated by pushover analyses and that time-history analyses have given a lot of local results (crack width, steel yielding...) that show the interest of each of these two different nonlinear methods for seismic structural analysis.

A SIMPLE MODEL FOR INVESTIGATING THE NON-LINEAR DYNAMIC BEHAVIOR OF ELASTIC SYSTEMS SUBJECTED TO STICK-SLIP MOTION

S. Bennati[1], R. Barsotti[2], and G. Migliaccio[3]

Abstract

The stick-slip phenomenon is the typical jerking motion that may occur when two objects are forced to slide with friction over each other. There are several situations in which this motion can be observed in practice, for example, between the components of different kinds of seismic protection systems, like the slabs of some friction dampers or the sliding elements of some base isolation systems. These kinds of systems are generally designed to work in a smooth, flawless manner. However, it cannot be excluded that in particular situations undesired jerking motions might develop. Similar situations are widespread in all areas of engineering and may result in complex dynamic behavior, even when only a small number of degrees of freedom are involved. A well-known simple scheme for problems of this kind consists of a rigid block connected elastically to one support while its base is in contact with a second, moving rough surface. This model, despite its apparent simplicity, can provide useful indications on the main features of many physical systems. This contribution illustrates an analytical study conducted to better understand the non-linear dynamic behavior of such systems, with the objective of identifying conditions that may disrupt their proper functioning. In particular, the equations of motion are solved analytically, the sticking and sliding phases are studied, the influence on the solution of the system's main parameters is investigated, and some typical long-term system responses are discussed. Lastly, some results obtained by means of a specifically developed numerical procedure are illustrated.

Keywords: Non-linear dynamics, stick-slip motion, friction dampers, seismic isolators.

1 INTRODUCTION

Dynamic systems containing components that slide with friction over others are widespread in many engineering applications. Systems in which friction forces play a significant role are encountered in mechanical, aerospace and automotive engineering, for instance in brakes, wiper blades, and so on. In civil engineering, several examples can be found by looking at the damping devices and base-isolation devices developed to protect buildings from earthquakes. In this regard, several devices exploiting friction have been effectively proposed and used as a means for increasing a building's capacity to dissipate energy or isolating it from the oscillating ground.

Systems of this kind are generally designed to work in a smooth, steady manner. However, it cannot be excluded that in particular conditions undesired jerking motions may develop. Over the years, several studies have been conducted to better understand the dynamic behavior of systems in which two components are forced to slide with friction over each other, the objective being to identify any conditions that may disrupt their proper functioning, and to optimize their performance. Generally speaking, the body of literature on the topic may be subdivided into two main categories. The first category is represented by numerical studies, performed by means of finite element models [6]. The second approach, to which this paper belongs, applies simplified models which regard the system as a mechanical system endowed with a small number of degrees of freedom [4].

Over the last century particular attention has been devoted to the single degree-of-freedom (DoF) system subjected to elastic and friction forces. The first studies on systems of this kind are contained in the work by Den Hartog [7], after which similar problems have been considered by other researchers [9-16]. Although the full list of contributions is too lengthy to cite here, we recall the relevant works by Parnes [8], Hong [9], Shaw [10], Butikov [11], and Andreaus and Casini [12].

The present work addresses the dynamic response of a simple model composed of a rigid block connected elastically to a first rigid support while in frictional contact with a moving second rigid support. The paper is organized as follows. The mechanical model is introduced in Section 2. A description of the different types of motion that the considered system may undergo is provided in Section 3. Subsequently, we focus attention on some limit cycles – continuous sticking or sliding – that the system may undergo (Section 4). In particular, we show that it is possible to foresee some features of the system's long-term response, provided its mechanical parameters are known. In this regard, some reference maps are illustrated, which provide useful indications on possible long-term system responses. Finally, in Section 5, some results from an application example are shown.

2 THE MECHANICAL MODEL

The mechanical problem addressed here concerns the motion of a structure that is connected elastically to a moving support, while its base can slide over a moving rough surface (Figure 1). The single degree-of-freedom system is composed of a rigid block with mass m attached to a spring with elastic constant k. The other end of the spring is connected to point A, which may move according to a prescribed law, $x_A(t)$. The block is restrained so as to remain in contact with a rough rigid support whose reference point B moves according to the prescribed motion law, $x_B(t)$. The friction force acting on the block is F_a; the position of the block's center of gravity, G, with respect to a suitable (inertial) reference frame, is $x(t)$. The equation of motion reduces simply to

$$m\ddot{x} + k(x - x_A) = F_a \tag{1}$$

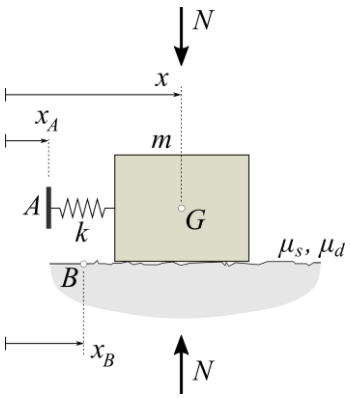

Figure 1: A schematic representation of a rigid body (mass m) connected elastically to a rigid support A (spring constant k) and with friction to a rigid support B (static and kinematic friction forces F_s and F_k)

The friction force, F_a, which the support exerts on the block when the relative velocity between the two is not zero is given by the following relation:

$$F_a = -\mathrm{sgn}(\dot{x}_{rel})F_k \tag{2}$$

where $\dot{x}_{rel} = \dot{x} - \dot{x}_B$ is the relative velocity between the block and support, and $sgn(\dot{x}_{rel})$ is the sign of the relative velocity; moreover, when the relative velocity between the block and the support is zero:

$$|F_a| \le F_s \tag{3}$$

A well-known property of such systems is that at the beginning of a sticking phase it will take some short time to actually establish a contact condition (see, for example, the studies by Sampson [13]). Hence, the standard version of Coulomb's law is modified as follows:

- in any *sliding phase* the friction force is equal to the kinematic value (2);
- at the *beginning of a sticking phase* the friction force cannot exceed the kinematic value ($|F_a| \le F_k$);
- at any time *within a sticking phase* the friction force cannot exceed the static value ($|F_a| \le F_s$).

In the following we will consider the special case in which point A is kept fixed (i.e., x_A = constant), while B moves according to the law $x_B = A_b sin(\omega_b t)$, where A_b and ω_b are the amplitude and angular frequency, respectively.

3 STICKING AND SLIDING PHASES

In the general case, the motion of the system may involve a sequence of sticking phases, during which the block follows the motion of the underlying moving support, and sliding phases, during which the mass moves with respect to the base support. As the friction force is non-smooth, the equation of motion has to be solved separately in each of the two phases, and the time lapse between one phase and the other has to be determined.

A sticking phase following a sliding phase will begin if both the block and the support have the same velocity, and if the magnitude of the friction force on the block does not exceed the kinematic value, F_k. Vice versa, a sliding phase following a sticking phase may begin if and only if the magnitude of the friction force on the block reaches the maximum static value, and a friction force greater than F_s would be required to keep the block sticking to the support.

3.1 The sticking phase

The law of motion for the block during the sticking phase reduces to

$$x(t) = A_b \sin(\omega_b t) + C \tag{4}$$

The sticking phase will persist until the magnitude of the friction force reaches the maximum static value, F_s. After some algebraic manipulation, such condition can be expressed as

$$|\alpha| + |\lambda| \le 1 \tag{5}$$

where $\alpha = a(1-\Omega^2)$, $a = A_b / x_s$, $x_s = F_s / k$, $\Omega = \omega_b / \omega$, $\omega = \sqrt{k/m}$, and $\lambda = C / x_s$.

Condition (5) enables distinguishing the α, λ pairs corresponding to systems that may be in a sticking condition up to a certain time, as well as those which cannot initially be in a sticking condition. Figure 2 (left) shows the partition of the α, λ plane produced by condition (5).

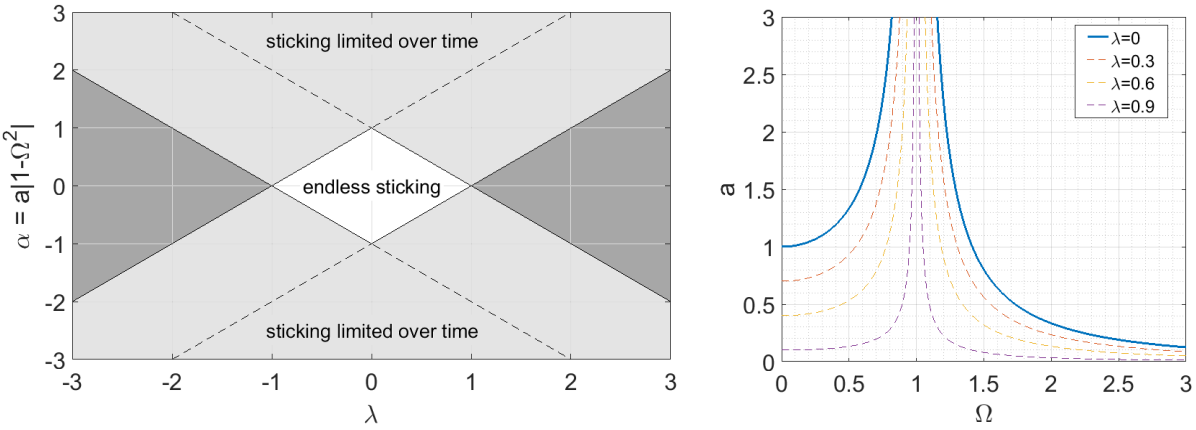

Figure 2: Sticking regions in the α, λ plane (left), and a, Ω plane (right)

Condition (5) can be recast in an alternative form in order to determine the set of values a, λ, Ω, corresponding to systems that may undergo a sticking phase. Such alternative condition can be expressed as:

$$a \le \frac{1-|\lambda|}{|1-\Omega^2|} = f(\Omega, \lambda) \tag{6}$$

The interesting feature of the curve $a = f(\Omega,0)$ is that it enables distinguishing the systems for which endless sticking motion is impossible regardless of the initial conditions (region above the thick curve on the right of Figure 2), from those systems for which such motion is possible.

We conclude this section by observing that it is possible to determine *a priori* the time, t_{SL}, at which a sticking phase will end. A simple, though nonlinear equation, not displayed for the sake of brevity, enables determining t_{SL} for a given system from the very start of the sticking phase.

3.2 The sliding phase

Let us assume that the block is sliding at a certain instant. The block's equation of motion in the sliding phase reads

$$m\ddot{x} + kx = \pm F_k \tag{7}$$

where the sign depends on that of the relative velocity during the sliding phase. Integration of equation (7) yields the law of motion

$$x(t) = c_1 \cos(\omega t) + c_2 \sin(\omega t) \pm x_k \tag{8}$$

where $x_k = \eta x_s$ and $\eta = F_k / F_s$.

The necessary condition for a sliding phase to stop at time t_{ST} is that the relative velocity between the block and the surface become zero. According to the rules introduced in section 2, a sticking phase may actually begin at t_{ST} only if the following condition holds

$$\left| -a\Omega^2 \sin(\omega_b t_{ST}) + x(t_{ST}) / x_s \right| \le \eta \tag{9}$$

Condition (9) ensures that the magnitude of the friction force on the block at the beginning of a sticking phase does not exceed the kinematic friction, F_k. If such inequality is not satisfied, the friction force would be greater than F_k and a sticking phase could not actually begin.

4 LIMIT CYCLES

Limit cycles are periodic solutions to the equation of motion characterized by a balance between the energy dissipated by and that supplied to the mass-spring system. Different possible limit cycles may be observed for systems like those considered here [9,13], depending on the values chosen for the system's initial conditions and mechanical parameters a, Ω, and η.

In broad terms, the limit cycles that a system may reach after a transient phase can be subdivided into three main categories, in which the block:

1) slides indefinitely,
2) sticks indefinitely,
3) periodically alternates sliding and sticking phases.

In this section, we concentrate our attention on limit cycles corresponding to pure sticking and on some kind of limit cycles corresponding to pure sliding.

4.1 Sticking limit cycles

If condition (5) is fulfilled, it is straightforward to conclude that periodic solutions to the equation of motion characterized by continuous sticking to the surface become possible. All these periodic solutions may be expressed in the form

$$x / x_s = a \sin(\omega_b t) + \lambda \tag{10}$$

where the parameter λ represents the dimensionless relative initial position between the block and point B.

4.2 Sliding limit cycles

In this section we study particular sliding limit cycles, in which the block undergoes a periodic motion and slides over the moving support, B, without ever sticking to it. In addition, we restrict the analysis to motion satisfying the following constraints:

$$\begin{aligned} x(0) &= x(T_b / 2) = x(T_b) = 0 \\ \dot{x}_{rel}(0) &= \dot{x}_{rel}(T_b / 2) = \dot{x}_{rel}(T_b) = 0 \end{aligned} \tag{11}$$

Moreover, as an additional condition, we assume that the component of the friction force in the direction of the x axis has a prescribed sign (for example, $+F_k$) over one half of the period and the opposite sign over the other half-period (*relative velocity sign condition*).

By imposing that the velocity of B be equal to that of the block at the beginning of any half-period, and by requiring that the friction force have a specified sign during a half-period and the opposite sign during the subsequent one, we obtain an inequality that must be verified for the validity of the considered limit cycle motion. After some manipulations, such inequality can be expressed as:

$$a > \eta g(\Omega) \tag{12}$$

where

$$g(\Omega) = \sqrt{\frac{M_\Omega^2}{\Omega^4} + \frac{1}{\Omega^2}\tan^2\left(\frac{\pi}{2\Omega}\right)} \tag{13}$$

$$M_\Omega = \max\left\{1; \sup_{z\in(0,1)} \left|h_\Omega(z)\right|\right\}, \quad \text{for a given } \Omega \tag{14}$$

$$h_\Omega(z) = \frac{\Omega}{\sin(\pi z)}\left[\tan\left(\frac{\pi}{2\Omega}\right)\left(\cos\left(\frac{\pi z}{\Omega}\right) - \cos(\pi z)\right) - \sin\left(\frac{\pi z}{\Omega}\right)\right] \tag{15}$$

4.3 The influence of the system parameters on its long-term response

The motion of the single degree-of-freedom system considered in this paper is fully determined if the values of its mechanical parameters, a, Ω, η, and initial conditions are given. Moreover, it is reasonable to believe that it should be possible to forecast some features of the system's long-term response regardless of its initial conditions. For example, if a, Ω and η satisfy inequality (5), the system will undergo continuous sticking, otherwise at least one sliding phase will take place.

Inequalities (5) and (12) enable making some predictions on the system's long-term response, provided the system parameters, a, Ω, η, are assigned. For example, if such parameters satisfy inequality (5), *i.e.*, if the corresponding point belongs to the dashed area below the blue curve in Figure 3, the system will undergo continuous sticking. Instead, if condition $a>f(\Omega,0)$ is verified, an endless sticking motion is not possible, regardless of the initial condition. In addition, for a given η, if condition (12) is not verified, *i.e.* if the corresponding point is below the red curve in Figure 3, the system cannot undergo the limit slipping motion defined in section 4.2. Instead, if a system verifies the assumptions discussed in section 4.2, and its parameters comply with the discussed constraint (12), then such a system may actually undergo the periodic limit motion discussed in section 4.2.

That said, it is worth noting that the illustrated study of the long-term response of systems like those considered in this paper is not conclusive. Further studies are needed and will be discussed in future works to carry out an exhaustive or, at least, wider examination of the possible limit cycles and the corresponding conditions of existence. Nevertheless, the results illustrated in this work are promising, and the introduced reference maps already furnish important information.

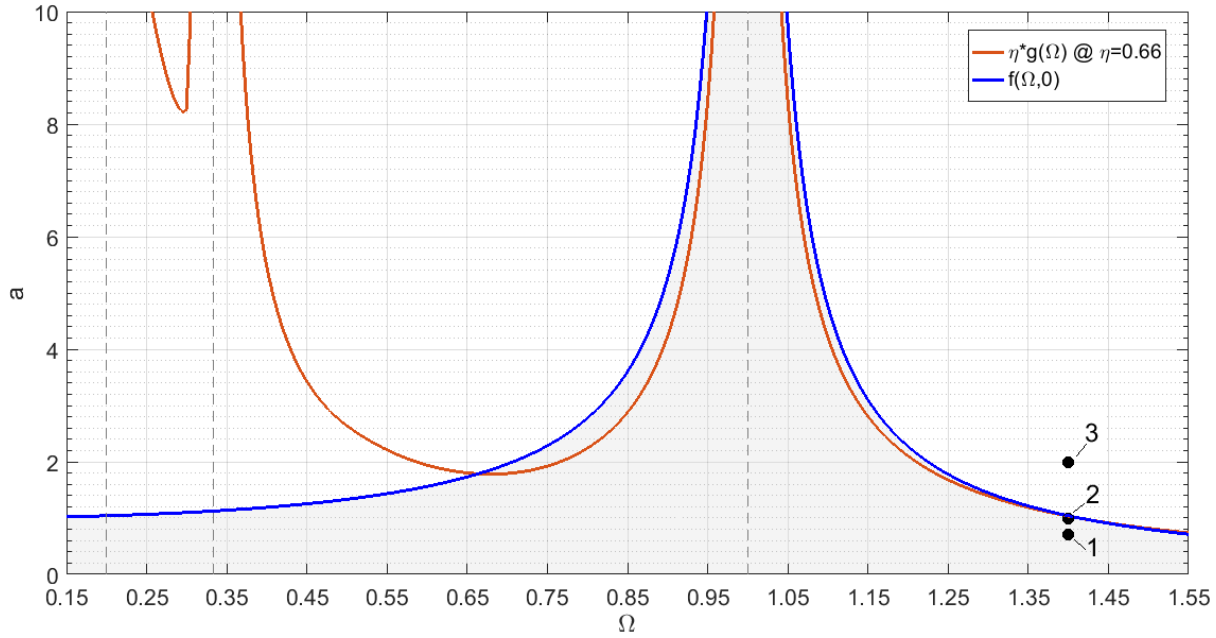

Figure 3: Reference map summarizing the limit cycles constraints

5 AN APPLICATION EXAMPLE

In the literature, several works propose numerical or semi-analytical solutions to equations of motion like those considered here [11,14,15]. The solution strategy we follow is of the semi-analytical type. It consists of piecewise solution of the equations of motion by identifying, *a priori*, the transition time (if any) from a slip to a stick phase, or vice versa

The following section illustrates the results obtained by applying the developed method to a particular system, whose parameters (e.g., mass, elastic constant, and friction actions) have been chosen so as to be representative of a small-sized building fitted with a seismic protection system. Different values of a and Ω, as well as different initial conditions, have been considered.

5.1 Simulation results

Many simulations have been performed, starting with different initial conditions, and for different values of the system parameters a and Ω. Three typical results are illustrated in the following (see Figures 4-6). The simulations have been performed by assuming a system mass of m = 6000 kg, elastic constant k = 30 kN/m, and values of the static and kinematic friction forces F_s = 240 kN and F_k = 168 kN, respectively.

The first example, in Figure 4, illustrates the results of a simulation in which the system (corresponding to point 1 in Figure 3), after an initial sliding phase, tends towards a sticking limit cycle. In the second example in Figure 5, the system (point 3 in Figure 3) is sliding right from the beginning and, after a certain period of time, tends towards a sliding limit cycle. Finally, the third example, in Figure 6, illustrates a case in which the system (point 2 in Figure 3) is sliding in an irregular fashion in the first part of the simulation and then, after a certain moment in time, tends towards a limit cycle characterized by alternating phases of sliding and sticking.

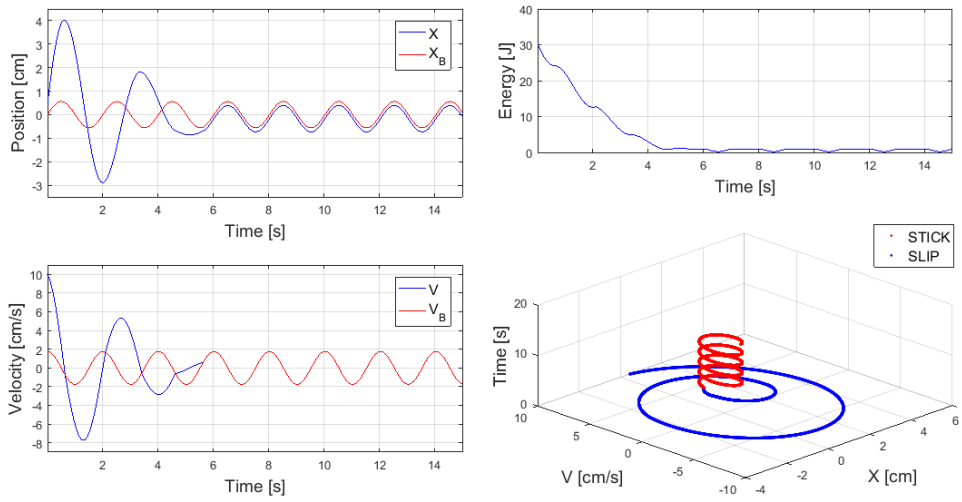

Figure 4: Sticking limit cycle (a =0.7, Ω=1.4) - positions and velocities (left), energy and trajectory (right)

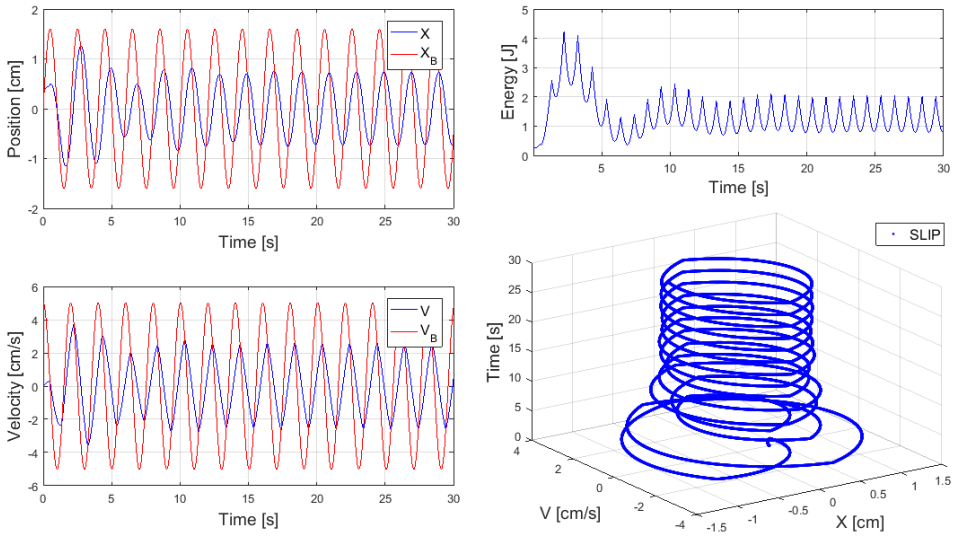

Figure 5: Sliding limit cycle (a =2.0, Ω=1.4) - positions and velocities (left), energy and trajectory (right)

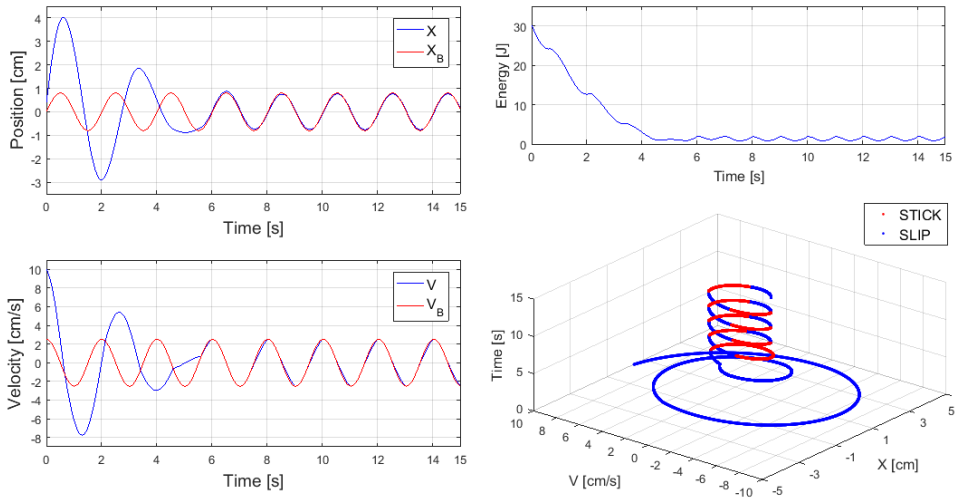

Figure 6: Stick-Slip limit cycle (a =1.0, Ω=1.4) - positions and velocities (left), energy and trajectory (right)

6 CONCLUSIONS

The present paper has addressed the dynamic response of a rigid block connected elastically to a support while in frictional contact with a rough support which is moving according to a sinusoidal law. Such a basic model has been chosen as a benchmark case to investigate the main features of dynamic systems undergoing stick-slip motion, such as seismic protection systems, wiper blades and brakes.

The contact force between the block and the support has been described by Coulomb's law, which has been suitably modified to account for the short time usually needed to restore static contact conditions after a sliding phase.

The nonlinear equation of motion for the block has been solved piecewise analytically in both the sticking and sliding phases, and the instants at which the system passes from one phase to another have been evaluated precisely. The study highlighted the effects on the system dynamics of three dimensionless parameters: the ratio Ω between the oscillation frequency of the moving support and the system's natural frequency; the ratio η between the kinematic and static friction coefficient; and the ratio a between the oscillation amplitude of the moving support and a reference length. In particular, the conditions for existence of some limit cycles have been discussed. According to the results obtained, it is possible to foresee some features of the long-term response of a system for which parameters Ω, a and η are known. The regions in the Ω, a plane corresponding to systems that may undergo continuous sticking or particular periodic sliding have been determined.

The proposed approach seems to provide a better understanding of the main features of the dynamic response of systems ruled by friction. The results obtained should prove to be useful for developing design criteria aimed at avoiding undesired jerking motion between such systems' components, with the final objective of optimizing their performance.

Abstract

The paper deals with dynamic analysis of reinforced shear wall under seismic loading. The shear walls of Kashiwazaki-Kariwa nuclear power plant structures reported no significant structural damage during 2007 Chuetsu earthquake despite of the fact, that the response spectra exceeded the design spectra of bearing structures. That was the reason for research of applied shear wall. The IRIS research project on industrial safety assessment and management included the cyclic testing of full-scale reinforced concrete walls. The results of the laboratory tests were used to analyze the nonlinear behavior of reinforced concrete wall under seismic excitation. The hysteresis (force-displacement relation) has been used for numerical SDOF model design. The calibrated model was used for earthquake simulations. Data of a set of strong motion records with different amplitudes, acceleration/velocity ratios and frequency content was selected to model excitation. The frequency analysis of the response signal was carried out with wavelet transformation. The frequency content at a certain time during the earthquake excitation was obtained. The responses of inelastic structure for different excitations were compared and analyzed in frequency domain.

Keywords: Shear Wall, FE Model, Structural Dynamics, Earthquake Engineering.

1 INTRODUCTION

Even though most of the surprises that earthquakes bring us are negative, examples on the positive note do exist. The 2007 Chūetsu offshore earthquake had an epicenter just 19km from the location of the Kashiwazaki-Kariwa nuclear power plant built in the 1980's. The earthquake shook the plant beyond design basis. The response spectra of the Chūetsu earthquake surpassed the design spectra for the investigated structures. The earthquake-proofing no significant structural damage was reported [1]. The power plant was shut down due to technological damage only. This was the incentive to delve deeper into the dynamic behavior of shear walls which are the structural elements that provide the necessary integrity to nuclear structures. It was also the reason to include base research in the form of shear wall testing in the IRIS research project on industrial safety assessment and management [2].

2 EXPERIMENTAL TESTING

The novel experimental testing was carried out (reported in Bekö et al. [3]). During cyclic testing (Fig. 1) of full-scale reinforced concrete low-rise shear wall specimen the pure shear was simulated. The obtained data was analyzed and well-defined hysteresis curve (Fig.2) was obtained.

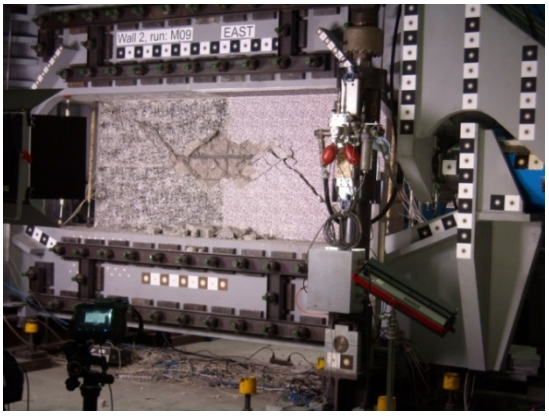

Figure 1: Reinforced concrete shear wall test.

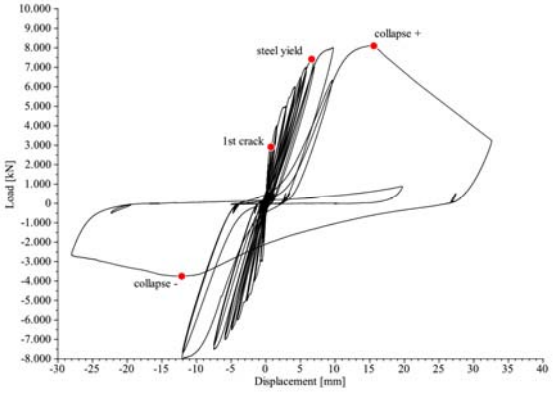

Figure 2: Test hysteresis (force vs displacement).

3 MODELING

A nonlinear mathematical model was created which is capable of simulating the hysteresis of the tested shear walls. The analytical model is a single DOF model of the Takeda family. Litton's [4] simplification of the Takeda model [5] was used as a base for the development of a dedicated model with stiffness degradation and pinching. The model is piecewise linear hysteresis model with a quadrilateral backbone curve and unsymmetrical positive and negative quadrants. Two separate sets of governing parameters were adopted for the positive and negative quadrants each with four variables $\alpha, \beta, \gamma, \delta$. The governing equations of the model are defined as follows (for definition of the symbols see Fig. 3)

- unloading stiffness $k_u = k_0 \left(\frac{u_{max}}{u_y}\right)^{-\alpha}$ (1)

- reloading point $Y = [u^+, f^+]$; $u^+ = \frac{u_{max}}{u_y} - \beta \frac{u_{max} - u_y}{u_y}$, $f^+ = f_y + k_t\left(u^+ - u_y\right)$ (2)

- pinching stiffness $k_s = \frac{f_{max}}{u_{max}-u_q}\left(\frac{u_{min}}{u_y}\right)^{-\gamma}$ (3)

- pinching point $P = [u_P, f_P]$; $u_P = \frac{-k_s u_q + k_u u_{0c}}{k_u - k_s}\delta$, $f_P = k_s(u_P - u_q)$ (4)

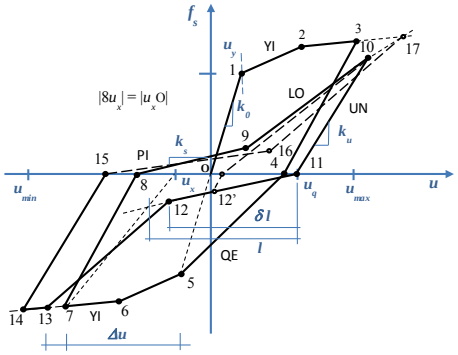

Figure 3: Takeda-Litton`s model

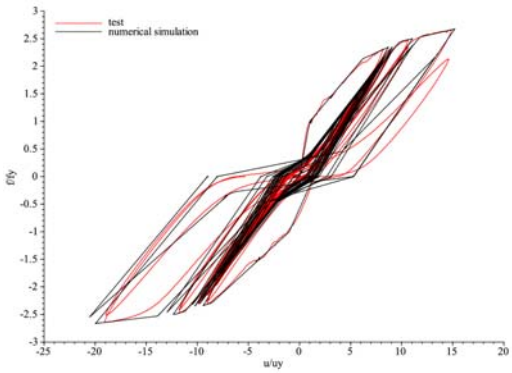

Figure 4: Test (red) and simulation (black) hysteresis

The verification of the model is shown in Fig. 4. The numerical investigations were hinged on an analytic model developed on the basis of laboratory tests. The model was used to analyze the nonlinear behavior of a single RC shear wall under seismic excitation. Various aspects of this behavior were studied using this model.

4 TIME-FREQUENCY ANALYSIS

The calibrated model was used for earthquake simulations of an imaginary shear wall that is analogous to the test. Nonlinear response spectra were derived for a selected set of earthquakes. The earthquake selection was based on the following considerations. It was required to have a selection of strong motions with different A/V (maximum acceleration to maximum velocity) ratios. At the same time we wanted to have different frequency content, varying duration and overall amplitudes of the ground motions. This has led to a set of well-studied earthquakes summarized in in Table 1.

Earthquake	Date	Mw	Site	E.Dist	A (g)	V(m/s)	A/V
Central Honshu Japan	Feb. 26 1971	5.5	Yoneyama Bridge	27	0.151	0.060	2.52

Table 1: Selected earthquake records.

To shed light into the workings of the inelastic structure its seismic response is compared to that of an elastic model. For analyzing the structural behavior over time a specific type of wavelet analysis was employed. Fundamentally, the wavelet analysis is defined as a correlation method, wherein one can define the wavelet transform trough a correlation coefficient

$$a(t) = \int_{-\infty}^{\infty} s(\tau) w^*(\tau - t) d\tau \tag{5}$$

where $w^*(t)$ is the complex conjugate to $w(t)$. If the signal $s(t)$ correlates with the wavelet $w(t)$ well the coefficient a(t) will be large; otherwise it will be small. The only requirement on the wavelet is that it be localized at a specific point of time. The harmonic wavelet developed by Newland [6] is one that is compact in the frequency domain. It has a simple structure of the form

$$W_{m,n} = \begin{cases} \dfrac{1}{(n-m)2\pi} & \text{for} \quad m2\pi \leq \omega \leq n2\pi \\ 0 & \text{elsewhere} \end{cases} \tag{6}$$

where *m* and *n* are real but not necessarily integer. As one can see easily the value of the wavelet function is nonzero and constant only in a frequency band specified by *m, n.* The result of the procedure above is a time series corresponding to each frequency band. This time representation of a selected band is a representation of information and energy within this band. The wavelet is applied to the data in the Fourier domain which then is inversely transformed to the time domain. The harmonic wavelet transform was applied to the response of the models.

The goal of this assessment was to understand how the nonlinearity of the wall influenced its response and possibly affects its bearing capacity in an event of an earthquake. To do this, structures of different eigenfrequencies were taken for each earthquake record in such a way that the response of the model to the specific strong motion in terms of displacements is close to the defining limits of the model. That is to say, the model with the chosen natural frequency under the corresponding ground motion yields a displacement response that nears the maximum displacement values reached in the tests. This takes the model well into the nonlinear range without exceeding physically feasible boundaries. Our application of the harmonic wavelet transform produces time-frequency plots which, for the responses to the six ground motions, are given below. The figures clearly show case how the frequency response of the nonlinear structure changes over time as well as with respected to its linear counterpart. Once the structure is taken beyond its elastic limit the frequency of vibration changes significantly. The frequency drop can be sudden as in the case of El Centro or Montenegro earthquakes or more gradual like for the Honshu and Mexico earthquakes.

Harmonic wavelet transforms of the displacement responses of the elastic (left) and inelastic (right) models including time history plots of displacements for six earthquakes: Honshu, San Fernando, El Centro, Montenegro, Bam, Mexico are presented in Fig. 5-16.

5 NONLINEAR VS CODE BASED RESPONSE SPECTRA

To investigate possible design margins from yet another perspective we have chosen to look at nonlinear responses more specifically. The goal was to examine if the code based response spectra can be exceeded by elastic response spectra for cases when the nonlinear model still performs within the physical limits of the specimen for it was calibrated to. For the normative response spectra the ones defined in Eurocode 8 were selected. In light of this, to increase the number of European earthquakes in the set, for the scope of this assessment the accelerogram of the Friuli earthquake was added to the ones specified in Table e. Three distinct hypothetical cases were analyzed with initial periods $T_{01} = 0.083s$, $T_{02} = 0.11s$ and $T_{03} = 0.225s$. These periods are in relation to the initial stiffness, i.e. before cracking, of the inelastic model. All models were taken through the same procedure. For each earthquake a scaling factor was found that pushes the inelastic model to its "elastic" limit. The elastic limit of the model was selected as the point which marks the start of the yielding of the reinforcement in the physical system. This was the point of 5.4mm and 6943kN. It is noted that the point of elasticity was taken such, as it is the most correct choice for practical purposes.

Earthquake	Model 1 $T_{01} = 0.083s$	Model 2 $T_{02} = 0.11s$	Model 3 $T_{03} = 0.225s$	Model 0 $T_0 = 0.027s$
Honshu 1971	3.44	3.17	1.33	57.5
San Fernando 1971	0.71	0.38	0.09	7.9
El Centro 1940	2.00	1.12	0.28	23.0
Montenegro 1979	3.12	1.61	0.43	47.5
Bam 2003	0.63	0.34	0.19	9.1
Mexico 1985	7.11	4.05	0.64	76.0
Friuli 1976	2.31	1.14	0.29	21.5

Table 2: Example Scaling factors for earthquake accelerograms that take the model to its elastic limit.

Elastic response spectra derived from scaled accelerograms were compared to design response spectra from EC8 for model 1, model 2 and model 3 in Fig. 17-19.

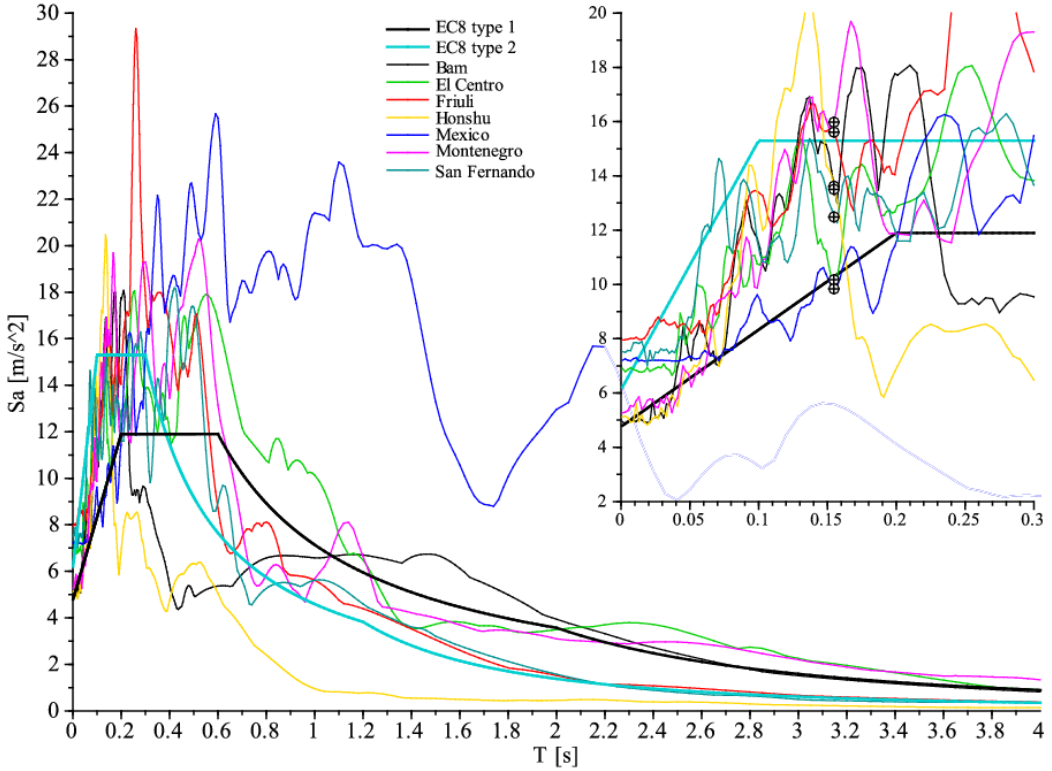

Figure 17: Elastic response spectra derived from scaled accelerograms compared to design response spectra from EC8 for model 1.

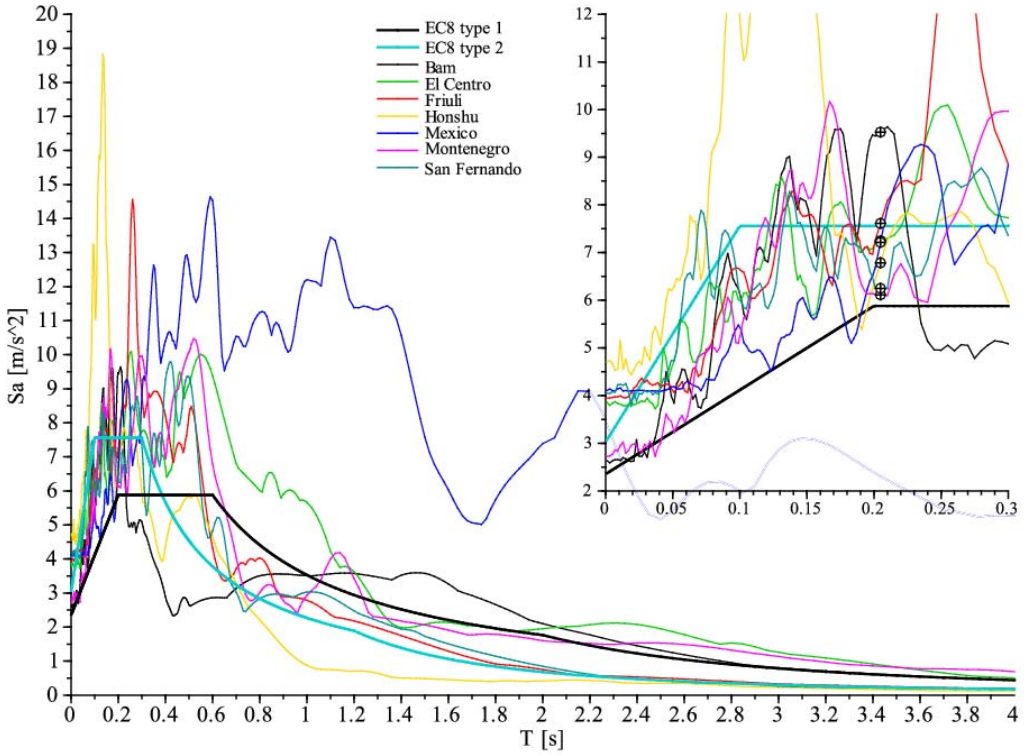

Figure 18: Elastic response spectra derived from scaled accelerograms compared to design response spectra from EC8 for model 2.

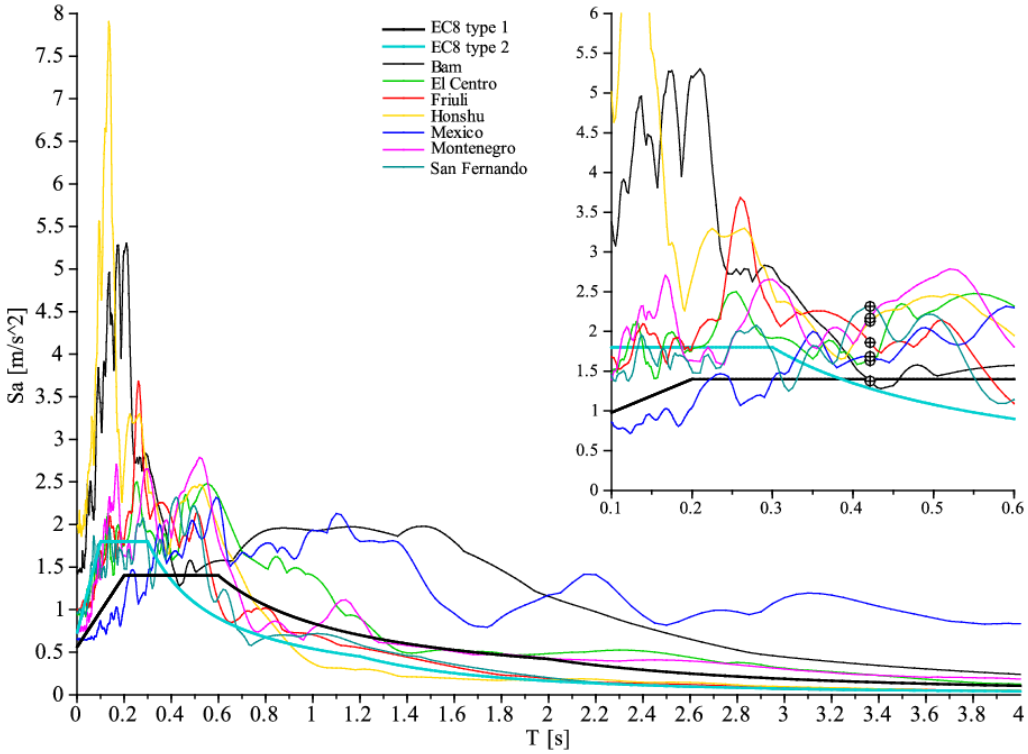

Figure 19: Elastic response spectra derived from scaled accelerograms compared to design response spectra from EC8 for model 3.

To define the imagined design capacity of the wall the value of 8.0MN, derived from testing, was assumed. To simulate design of the wall to this resistance the design response spectra needed to be scaled in such a way that at the design period they yield a design seismic force of 8.0 MN. This was simply achieved by an appropriate choice of base ground acceleration a_g for the type 1 response spectrum from EN 1998. Type 2 response spectrum was also plotted for reference. Viewing the results it is very evident that the model earthquake response spectra do reach above the design spectra. In some cases, especially for low periods, the overshoot is significant. Still when considering the differences at the design period (marked with dots in the subplots) many of the model response spectra lie above the design spectrum. In these cases it is not considered substantial, possibly with some exceptions. The interpretation of the results is that the linear response spectrum computed for a scaled excitation, which takes the nonlinear model to its elastic limit, yields forces that are higher than those defined by the code based design spectrum. Thus a reinforce concrete structure, namely a shear wall, to the extent it is represented by the mathematical model, can bear within its linear limits, dynamic forces higher than designed for based on a selected code, EN 1998 in this case.

6 CONCLUSIONS

- Based in the test data a mathematical hysteretic model was developed based on Litton's modification of the original Takeda model. This is a single degree of freedom nonlinear material model with the feature of pinching included. The model is tuned by two sets of four steering parameters for the two opposite quadrants. Upon the observation that the model would require different steering parameters for small and large displacement a functional relation was introduced for them. With such a refined model a good agreement with test data was reached.

- The behavior of a massive shear wall, represented by the mathematical model was analyzed for different selected earthquake records. The harmonic wavelet transform was applied to unravel the frequency response of the modelled structure over the time of excitation. The frequency shift could be evidently shown with the point of transition to inelastic yielding visible. For this analysis models of different natural frequencies were chosen for each earthquake record, so that they are driven by the excitation close to the maximum displacement value of the test specimen the model was based on. This was needed to study the inelastic behavior during an earthquake.
- The presented investigations were triggered by the need to explain seemingly unexpected phenomena observed in the wake of some earthquakes in nuclear power plants. And although nuclear facilities are designed to very strict criteria and substantial margins, there are indications of intrinsic margins beyond the intended ones due to disparities between the physics involved and the simplifications in the design procedures. It comes as no surprise that the accepted design procedures applicable in cases of massive shear walls were shown to be conservative.

Abstract

The paper investigates the modelling and calculation of the flutter instability condition due to the wind – structure interaction in the case of suspended bridges. In particular, the paper is focused on FEM (Finite Element Model) analyses on three dimensional models that compute the flutter instability. Geometric non-linear flutter instability analyses were carried out using a research and design software program (TENSO), which enables non-linear dynamic analysis of wind-structure interaction. All the bridge structure is modelled. In particular, the bridge deck model was simplified by a beam model located in the deck section's center of gravity and two massless rigid links to simulate the connection of the deck to the hangers and cables. The cables are represented by rectilinear cables element. The critical flutter speed was estimated using quasi-static approximation of the unsteady wind loads calculated by aerodynamic coefficients (i.e. lift, drag and moment coefficients) estimated by aerodynamic forces (i.e. lift, drag and moment) directly measured by wind tunnel tests. The executed analyses are by dynamic step-by-step integration of the nonlinear three-dimensional structure with geometric nonlinearities. The global stiffness matrix is updated at each load step by assembly of the stiffness sub-matrices of the elements, updated to account for the strain found at the previous time step, taking into account the geometric nonlinearity of the structure.

Firstly, the calculation provides for the static equilibrium of the structure under dead, gravity and construction loads by nonlinear static analysis. It was computed simultaneously using two methods: step-by-step incremental method and a "subsequent interaction" method with variable stiffness matrix (secant method). The secant method is a finite-difference approximation of the Newton-Raphson's modified method for systems of nonlinear algebraic equations. The solution under gravity loads is subsequently used as the initial step of the dynamic wind load analysis. The Newmark-Beta method with Rayleigh damping is used for numerical integration of the dynamic equations. Wind loads on the bridge deck are time dependent and they are simulated by applying the aerodynamic coefficients as a function of the time-dependent angle of attack at a given mean wind speed U. Displacements and rotations of the bridge deck at progressively increasing values of U, are estimated. The velocity at incipient flutter is fixed when the reference deck vibration amplitude exceeds ±5°. Details of the analyses results and calculation are given for an example of suspended foot bridges. Vertical displacements (δ) and rotations of the deck about the longitudinal bridge axis (αx) in normalized format (i.e. upward deck displacements are positive and counterclockwise rotations are positive) are discussed.

Keywords: Non-Linear analyses, Suspended bridge, flutter instability.

1 INTRODUCTION

The main suspended bridge structural model is a system made of a deck hanging by cables that are supported by pillars (i.e. bridge's towers).

Differently from traditional concrete bridges ([1]), suspended bridges are cables structures with a geometrical non-linear behavior and they are sensitive to the wind action ([2]). In addition, they have a small ratio between self-weight and length-span and this increases they vulnerability to dynamical action as for example the wind action. In particular, extreme peaks of wind force affect the structure reliability [3] and they have to be investigated in wind tunnel ([4], [5][6][7][8][9]). Alternatively, the wind-structure interaction can be analyzed by computational fluid dynamics simulations (CFD) and fluid and structure simulations (FSI). These approaches are common in the field of building construction and structural engineering and they are mostly used to investigate multihazard effects, as for example in the field of the sound propagation ([11], [12]), earthquake and tsunami effects or pedestrian-induced lateral vibrations ([13], [14], [15], [16]). However, the big Reynolds number (i.e. as in the case of civil big structures) makes it difficult to apply.

A suspended bridge design needs of two different experimental campaigns: aerodynamic and aeroealstic experiments ([17]).

Aerodynamic tests mostly aim to estimate the wind action around the bridge deck. The deck shape and its aerodynamics has a crucial role for bridge stability ([18], [19]). Generally, deck shape is regular and its aerodynamics is not discussed by codes ([20], [21], [22]). As for most shapes does not discussed by codes ([23]-[[27]), experimental tests in wind tunnel are necessary in order to estimate the pressure coefficients and the aerodynamic forces coefficients. The pressure coefficients are used to estimate the local pressure given by wind on the deck; the aerodynamic coefficients are used to calculate the flutter critical speed (i.e. quasi-static method) and to size the anchorages structures dimensions ([28][28]).

Aeroelastic tests aim to measure the wind-structure interaction dynamically. In particular, the goal is to calculate the flutter derivatives of the bridge section model. The flutter derivatives are used to estimate the flutter critical speed ([29]-[34]). In addition, aeroelastic tests permit to calculate the aerodynamic damping of the bridge.

Aerodynamic tests results give time histories of pressure coefficients or aerodynamic coefficients (i.e. Lift, Drag and Moment). Both results depend on the wind angle of attack. They are not wind-speed depending. Contrarily, aeroelastic tests results give speed-depending flutter derivatives.

Similarly to other cables structural systems, as for example cables nets ([35]-[38]) the experimental results in term of wind action are applied on Finite Element Method (i.e. FEM) models in the form of forces time histories. Time histories are applied on the structure nodes. In this phase, the different modeling approach followed for numerical model (i.e. FEM model) and experimental model (i.e. aerodynamic and aeroelastic tests model) represent one of the most severe problems in the wind-structure interaction study. For bridges, this is particularly relevant because the experimental model is commonly very simplified. It is often the case that numerical model is computed by a smaller grid mesh than experimental model. In this case, numerical methods to expand the experimental results are often used.

This paper discusses the wind-bridge interaction using aerodynamic tests results in term of aerodynamic coefficients though three dimension FEM non-linear analyses [39]. One of the three pedestrian suspended bridges ([40], [41]) discussed in [42] and [43] is used as case of study and experimental data and structural parameters are used for non-linear geometrically analyses. Analyses are pushed as far as the flutter instability and the flutter critical speed was estimated.

2 THEORETICAL FUNDAMENTALS OF WIND-STRUCTURE INTERACTION MODELLING

The critical flutter speed was estimated using two different approaches. The first is a two-mode (2-DOF) generalized numerical model of the deck motion in the frequency domain and flutter derivatives were considered to more correctly examine bridge aeroelasticity. The second consists in nonlinear dynamic analysis by three-dimensional finite element models and quasi-static approximation of the unsteady wind loads (i.e. lift, drag and moment derived from the wind tunnel tests) were employed.

The first approach is applying if aeroelastic tests results (i.e. flutter derivatives) are available. The dynamic response of a long-span bridge due to wind excitation can be modeled through the multi-mode approach in the frequency domain ([42]). The dynamic component of the wind loading, causing deck vibration, can be represented by superposition of turbulence-induced (aerodynamic) forces and motion-induced (aeroelastic) forces. Self-excited forces, acting on a unit-length section of the deck are defined as lift (L_h), drag (D_p) and moment (M_α). These forces are commonly based on a first-order linear expansion of the h vertical displacement and α torsional rotation of the generic deck cross section, ([33]). This model is strictly valid for simple-harmonic vibration of the deck and it is usually acceptable for small-amplitude random vibration. The aeroelastic lift and moment forces of the generic cross section, per unit deck span (or longitudinal model length), were determined as reported in Eqs. (1) and (2).

$$L_h = \frac{1}{2}\rho U^2 B\left[KH_1^*(K)\frac{\dot{h}}{U} + KH_2^*(K)\frac{B\dot{\alpha}}{U} + K^2H_3^*(K)\alpha + K^2H_4^*\frac{h}{U}\right] \tag{1}$$

$$M_\alpha = \frac{1}{2}\rho U^2 B^2\left[KA_1^*(K)\frac{\dot{h}}{U} + KA_2^*(K)\frac{B\dot{\alpha}}{U} + K^2A_3^*(K)\alpha + K^2A_4^*\frac{h}{U}\right] \tag{2}$$

In Eqs(1) and (2), ρ is the air density, U the mean wind speed perpendicular to the bridge (or model) longitudinal axis, B is the deck width; the "over-dot" symbol denotes derivation with respect to time t. The quantities H_i^* and A_i^* (with i=1,…,4) are the "flutter derivatives" (Scanlan and Tomko, 1971). These functions are experimentally found in wind tunnel by testing a section model of the full-scale girder at a reduced scale. The flutter derivatives depend on the reduced frequency $K=\omega B/U$ or, equivalently, reduced velocity $U_r=U/(nB)=2\pi/K$, with ω being the angular vibration frequency of the deck in rad/s and $n=\omega/(2\pi)$ the frequency in Hz.

The dynamic equilibrium equations of the 2-DOF system which is tested in the wind tunnel, reproduce the vertical (h) and torsional (α) aeroelastic vibration of a representative finite-length section of the full-scale bridge deck. The lift force L_h and overturning moment M_α per unit length of the deck are measured over the span length ℓ of the experimental model.

The vibration of the apparatus tested in wind tunnel, is given by Eqs(3) and (4) ([33], [34]).

$$M\left(\ddot{h} + \ddot{\alpha}\frac{S}{M} + 2\zeta_h\omega_h\dot{h} + \omega_h^2 h\right) = L_h\ell \tag{3}$$

$$I_\alpha\left(\ddot{\alpha} + \ddot{h}\frac{S}{I_\alpha} + 2\zeta_\alpha\omega_\alpha\dot{\alpha} + \omega_\alpha^2\alpha\right) = M_\alpha\ell \tag{4}$$

In Eqs. (3) and (4) M is the total mass of the model over the length ℓ, which also accounts for the mass of the moving components of the experimental rig; I_α is the total mass moment of

inertia; S is the static mass unbalance about the elastic axis, equal to the product of mass M and the distance (with appropriate sign) between the elastic center (center of stiffness) and the center of mass; ℓ is the longitudinal length of the model; ω_h and ω_α are the angular frequencies of vibration corresponding to the two DOFs; ζ_h and ζ_α are the corresponding structural damping ratios. The damping ratios coefficients replicate unavoidable dissipation mechanisms in the wind tunnel setup, which cannot be eliminated. The careful selection of the model's frequencies is also an important issue in the design of the experimental apparatus to ensure the successful measurement of the flutter derivatives.

According this theory, the solution to the flutter problem is based on the iterative procedure described by [34] simulating a 2DOF dynamical system with mass, inertia, damping ratios and flutter derivatives corresponding to the actual setup. The free-vibration method ([33]) is used for the extraction of the flutter derivatives, [44]

The second approach, discussed in detail in section 4, consists in Nonlinear dynamic flutter analysis, that are carried out using the aerodynamic coefficients in accordance with the reference force system.

3 EXPERIMENTAL MEASUREMENTS

Experimental tests results given by [42] are discussed here in order to explain the entire process of flutter analyses. Aerodynamic tests were carried out to estimate the deck loads of a pedestrian bridge with closed-box bridge deck (structural properties are described later in a subsequent section). It is important to note that, in this study, the deck guardrail was neglected because it was assumed that it was made of cables and, therefore, would not affect the aerodynamics and the aeroelastic response.

Aerodynamic tests were carried out using rigid wind tunnel models with the same dimensions. The tests were designed to minimize any potential discrepancies induced by geometric scaling differences. The models were made of wood. The geometry of the experimental models is illustrated in Fig. 1.

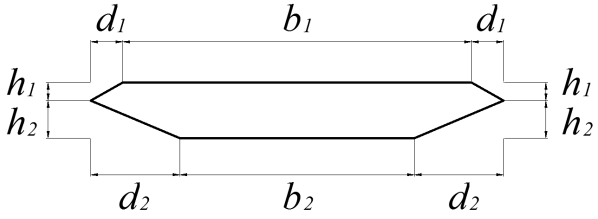

Figure 1 Section deck size.

Dimensions in Fig. 1 respectively are: $\boldsymbol{h_1}$ is equal to 530 mm at prototype scale and 13 mm at model scale; $\boldsymbol{h_2}$ is equal to 1110 mm at prototype scale and 27 mm at model scale**;** $\boldsymbol{d_1}$ is equal to 860 mm at prototype scale and 21 mm at model scale; $\boldsymbol{b_1}$ is equal to 1025 at prototype scale and 25 mm at model scale; $\boldsymbol{d_2}$ is equal to 2620 at prototype scale and 64 mm at model scale; $\boldsymbol{b_2}$ is equal to 6770 at prototype scale and 165 mm at model scale ([4], [42]).

Figure 2 experimental tests.

Measurements were carried out in the wind tunnel of the Marche Polytechnic University (Ancona, Italy). The wind tunnel is a closed-circuit facility. The cross-sectional dimensions of the main test chamber are about 1.8 m by 1.8 m. The main test section has three main test subsections: the first one is used for aerodynamic tests requiring uniform velocity distribution and low turbulence level. The second one is used to test aerodynamic interference between slender bodies. The last one is the environmental section where atmospheric boundary layer flows can be reproduced for general studies on buildings and structures. The wind tunnel is equipped with a motor/fan having a constant rotational speed (975 rpm) and 16 blades with adjustable pitch. The mean wind speeds range between 6 m/s and 40 m/s. Preliminary flow measurements, using a Constant Temperature Hot Wire Anemometer, showed a deviation less than 2.5% from the reference value of the mean flow speed and longitudinal turbulence intensity less than 0.3% across more than 90% of the test cross section. A compact heat exchanger was used to control temperature fluctuations within the range of ±1 [°C]. Fig. 2 presents a picture of a typical setup of the chamber with the experimental model. Measurements were carried out at a flow speeds equal to 14.8 m/s.

The purpose of these tests was to measure the Drag (D), Lift (L) and Torsional Moment (M) of the deck per unit span for the three geometries. The average values of drag, lift and torsional moment coefficients per unit span, respectively C_D, C_L and C_M, were evaluated according to Eq. 5 below. Fig.3 shows an example of the Lift aerodynamic force coefficient trend as function of the angle of attack ([42]).

In Eq. 5 U is equal to 14.5 m/s, ρ is equal to 1.18 kg/m^3 and, referring to Table 1, B is the reference width equal to $2d_1+b_1$= 298 mm. The model was placed vertically, as visible from Fig. 3, and the reference system for the calculation of the aerodynamic forces is given in Fig. 3. Twenty-one values of attack angle (α) were considered in the interval between -10° and +10°. Positive angles are “nose up” in relation to the approaching flow.

$$C_D = \frac{D}{\frac{1}{2}\rho U^2 B} \quad , \qquad C_L = \frac{L}{\frac{1}{2}\rho U^2 B}, \qquad C_M = \frac{M}{\frac{1}{2}\rho U^2 B^2} \tag{5}$$

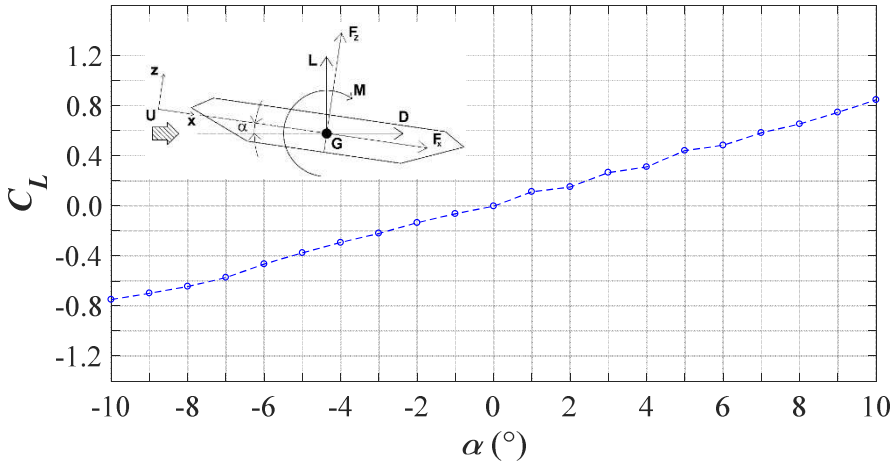

Figure 3 Example of Lift coefficient trend.

4 WIND-STRUCTURE INTERACTION CALCULATION

Nonlinear dynamic flutter analysis discussed here was carried out using the aerodynamic coefficients and were performed using the TENSO nonlinear geometrical analysis program, which can execute dynamic step-by-step integration of the nonlinear three-dimensional structure with geometric nonlinearities. Tenso is not a commercial software.

The software used includes modules for simulating cable and beam finite element models and for the study of wind-structure interaction phenomena with generation of wind speed time histories and simulation of various aeroelastic loads. The main cables are discretized as rectilinear cable segments.

The global stiffness matrix is updated at each load step by assembly of the stiffness submatrices of the elements, updated to account for the strain found at the previous time step. In this way the software considers the geometric nonlinearity of the structure. This software first solves for the static equilibrium of the structure under dead, gravity and construction loads (prior to the application of the wind loads) by nonlinear static analysis; two methods are simultaneously used: step-by-step incremental method and a "subsequent interaction" method with variable stiffness matrix (secant method). In TENSO, secant method is used as a check method that permits to stop the analysis with a unbalanced solution. Nonlinear problem can be transformed in a succession of linear problems. Each calculation step stores loads and strains history evaluated during the previous step. For each analysis step, a small enough part of load (ΔP) necessary to ensure that is possible to use the elasticity method is applied. A non-appropriate chosen range can cause an inexact solution. In order to solve it, this software uses a vector version of the Newton-Raphson modified method about nonlinear equation systems with the variable stiffness matrix. The Newton-Raphson procedure [42] guarantees convergence if and only if the solution at any iteration is close to the exact solution. Therefore, even without a path-dependent nonlinearity, the incremental approach (i.e., for subsequent load steps) is sometimes required in order to obtain a solution corresponding to the final load level. If the displacements

are large, the product between the stiffness matrix, evaluated on the basis of the solution of the previous step, and the displacements vector, give the internal force vector, not equilibrate with the external forces vector according to Eq.(6). In Eq.(6) K is the stiffness matrix, δ is the displacements vector, $\widetilde{P}$ is the external forces vector.

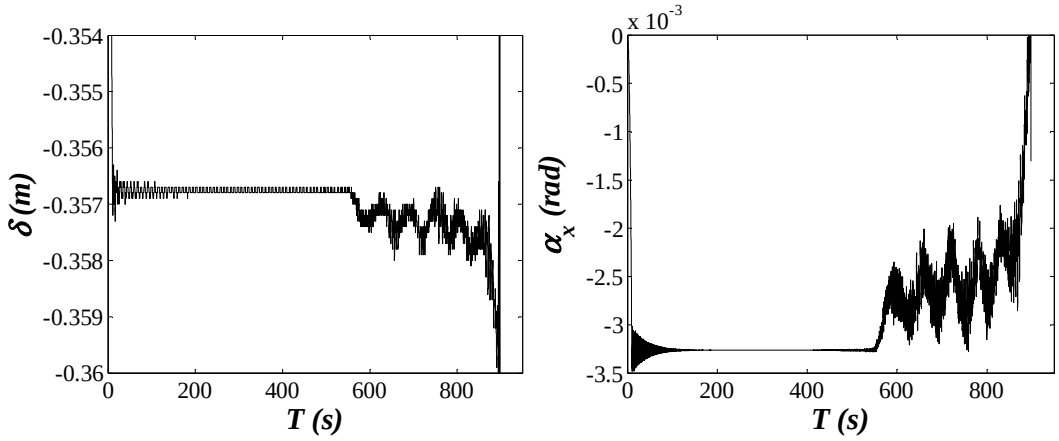

Figure 4 Flutter instability given by FEM analyses:

The difference between these two forces vectors (i.e. internal and external) represents the imbalance force vector, according to Eq. (7). R is the residual vector and P is the internal forces vector. Subsequently, R is applied as an external load modifying the displacement vector with a residual value of displacements $\Delta\delta$, according to Eq.(8).

$$[K]_{k+1}\{\delta\}_{k+1} = \{\tilde{P}\}_{k+1} \tag{6}$$

$$[R]_{k+1} = [\{P\} - \{\tilde{P}\}_{k+1}] \neq 0 \tag{7}$$

$$\{\Delta\delta\}_{k+1} = [K]_{k+1}^{-1}\{R\}_{k+1} \tag{8}$$

Wind loads on the bridge deck are time dependent; they are simulated by applying the aerodynamic coefficients (CD, CL and CM) as a function of the time-dependent angle of attack and by setting the appropriate values of dynamic wind pressure at a given mean wind speed U (at deck level). The program evaluates displacements and rotations of the bridge deck at progressively increasing values of U, and records the velocity at incipient flutter when the reference deck vibration amplitude exceeds ±5° [42]. Fig. 4 illustrates an example of time histories exhibiting flutter instability in terms of vertical deck displacement (δ) and rotation (α), for the middle-span section (i.e. upward displacements are positive and counter clockwise rotation are positive).

The critical flutter speed estimated was equal to 79.8 m/s. This value corresponds to global the instability illustrated in Fig.4.

5 CONCLUSIONS

This paper discusses the wind-structure interaction modeling for suspended bridges. The geometrical non-linear analyses operation using wind tunnel experiments was commented and the flutter instability analyses calculation was described on a case of study. The procedure to apply

wind tunnel experiments results on FEM models of suspended bridges was commented by explaining the functioning. The paper aims to inspire readers to deepen the wind-structure interaction analyses on cables structural systems.

Keywords: Peridynamics, Crack Branching, Concrete Damage, PMMA Interface Failure

Abstract. *The present work demonstrates the use of peridynamic equations to capture dynamic crack patterns observed during experimental tests performed in concrete and polymethylmethacrylate (PMMA) materials. In the first part of the work, two concrete specimen configuration, namely a compact tension and a L-specimen, are modeled at different dynamic loading rates. In the second part the effect of having a weaker interface in between a PMMA plate is simulated and compared, with the case of not having an interface at all. In both, it is observed that simulation provides good agreement with experimental results.*

1 INTRODUCTION

Peridynamics (PD) is a reformulation of classical elasticity where stress and strain partial derivatives are substituted by force and displacement integral equations. The fact of not having to differentiate displacement to get strains (as in classical mechanics where a continuous displacement field is assumed, therefore allowing for strains to be derived from the displacement as long as there are no discontinuities) allows PD to be naturally suited to model discontinuities.

Silling [11] in 1999 introduced peridynamics for the first time. This initial version, nowadays termed "Bond Based Peridynamics" (BB-PD), combined with a simple damage model [14], based on a critical bond stretch parameter, has successfully been used in high impact dynamic applications to predict complex crack patterns and fragmentation observed in quasi-brittle materials. Even today BB-PD still accounts for over 90% of all work developed in the PD field [13]. However, the original BB-PD suffers from the limitation of only being able to model materials with a Poisson ratio $\nu = 1/4$ for 3D, 2D plane strain, and $\nu = 1/3$ for 2D plane stress cases [4].

To overcome this limitation, Silling in 2007 [12] introduced the "State Based Peridynamics" (SB-PD) with two variants: ordinary (OSB-PD) and non-ordinary (NOSB-PD), the difference between the two being the force vector direction with respect to the bond deformation vector, which in the OSB-PD are parallel and in NOSB-PD are not.

SB-PD offers the advantage of modeling different Poisson ratios. In fact BB-PD may be viewed as a subset of OSB-PD [3], and through NOSB-PD it even allows to incorporate classical mechanics materials into PD formulation [18]. For the latter case, many works have tried to incorporate classical damage models too. Some works have apparently succeded, but it is still an open question when it comes to distributing the damage from the global particles to the individual bonds and then re-calculating an approximation of the deformation gradient.

On the other hand, the critical stretch damage model has shown to naturally capture cracks by first breaking individual bonds that eventually propagate into damage and therefore originate cracks.

The following work analyses three examples using the critical stretch damage model within an OSB-PD formulation. On the first part a brief introduction will be given to the OSB-PD material employed and of the critical stretch damage model. Afterwards it wil be shown how a 2D plane stress formulation may adequately capture the main crack patterns observed in two different concrete specimen configuration experiments. Following, the same method will be employed to capture crack branching at a weak interface in a PMMA plate subject to an impact stress wave.

1.1 State Based Peridynamic Theory

The SB-PD equation of motion is expressed as eq. (1):

$$\rho(\mathbf{x})\ddot{\mathbf{u}}(\mathbf{x},t) = \int_{\mathcal{H}_\mathbf{x}} \underline{\mathbf{T}}\big[\mathbf{x},t\big]\big\langle \mathbf{q}-\mathbf{x}\big\rangle - \underline{\mathbf{T}}\big[\mathbf{q},t\big]\big\langle \mathbf{x}-\mathbf{q}\big\rangle dV_\mathbf{q} + \mathbf{b}(\mathbf{x}) \tag{1}$$

where $\big\langle\cdot\big\rangle$ notation indicates the bond in which the force state $\underline{\mathbf{T}}$ is acting on. Following figure (1) $\mathcal{H}_\mathbf{x}$ is defined as a spherical neighbourhood of radius δ centered in $\mathbf{x}$, such that particles $\mathbf{q}$ inside it will have an influence over $\mathbf{x}$ through a bond force. δ is also refered as the particle's horizon and in our simulations it will assume a constant value. The quantities ρ, $\ddot{\mathbf{u}}$, dV and $\mathbf{b}$ represent the particle's density, acceleration, volume and body force correspondigly.

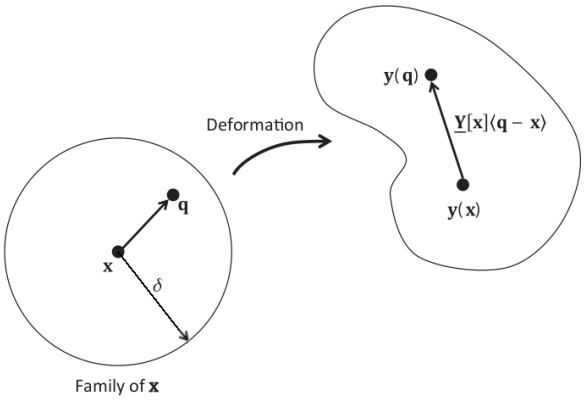

Figure 1: Deformation Map. (Adapted from [13])

In eq. (1), $\underline{\mathbf{T}}$ contains a constitutive model $\hat{\underline{\mathbf{T}}}(\underline{\mathbf{Y}})$ which depends on a deformation state $\underline{\mathbf{Y}}$. By employing a Fréchet derivative of a PD strain energy density $\hat{W}$, with respect to the deformation state, the expression in eq. (2) arises:

$$\underline{\mathbf{T}} = \hat{\underline{\mathbf{T}}}(\underline{\mathbf{Y}}) = \hat{W}_{\underline{\mathbf{Y}}} = \underline{t}\frac{\underline{\mathbf{Y}}}{\sqrt{\underline{\mathbf{Y}} \cdot \underline{\mathbf{Y}}}} = \underline{t}\underline{\mathbf{M}} \tag{2}$$

From eq. (2), $\underline{t}$ is a bond force and $\underline{\mathbf{M}}$ is a unit vector with direction of the deformed bond $\underline{\mathbf{Y}}\langle\xi\rangle = \mathbf{y}(\mathbf{q}) - \mathbf{y}(\mathbf{x})$. For completion, the bond initial configuration $\underline{\mathbf{X}}\langle\xi\rangle = \mathbf{q} - \mathbf{x}$, together with the deformed bond define the bond extension as (3).

$$\underline{e} = \underline{y} - \underline{x}, \qquad \underline{y} = |\underline{\mathbf{Y}}|, \qquad \underline{x} = |\underline{\mathbf{X}}| \tag{3}$$

By employing $\hat{W}$ from [12] for the 3D case, and from [3] for the 2D plane stress/strain conditions, and equating under the same deformations both strain energy densities: PD and classical mechanics $\hat{W}_{PD} = \hat{W}_{CCM}$, the bond force in (2) may be expressed as following:

$$\underline{t} = \begin{cases} \dfrac{3K\theta}{m}\underline{wx} + \dfrac{15\mu}{m}\underline{we^d} & \text{3D,} \\ \dfrac{4K\mu}{3K+4\mu}\dfrac{\theta}{m}\underline{wx} + \dfrac{8\mu}{m}\underline{we^d} & \text{pl. stress,} \\ \dfrac{4(3K-\mu)}{9}\dfrac{\theta}{m}\underline{wx} + \dfrac{8\mu}{m}\underline{we^d} & \text{pl. strain} \end{cases} \tag{4}$$

Quantities K and μ are the bulk and shear modulus correspondingly, $\underline{w}$ is an influence function which in our simulations takes the constant value 1, m, θ, and $\underline{e^d}$ are the weighted volume, dilatation and deviatoric bond extension defined as follows:

$$m = \int_{\mathcal{H}_{\mathbf{x}}} (\underline{wx}) \cdot \underline{x}\, dV_{\mathbf{q}} \tag{5}$$
$$\theta = \frac{3}{m} \int_{\mathcal{H}_{\mathbf{x}}} (\underline{\omega x}) \cdot \underline{e}\, dV_{\mathbf{q}}$$
$$\underline{e^d} = \underline{e} - \frac{\theta \underline{x}}{3}$$

1.2 Damage in Peridynamics

The simplest way to introduce damage in PD is through bond breaking as described in [14]. Following previous notation, the bond stretch is computed as $s = e/\underline{x}$.

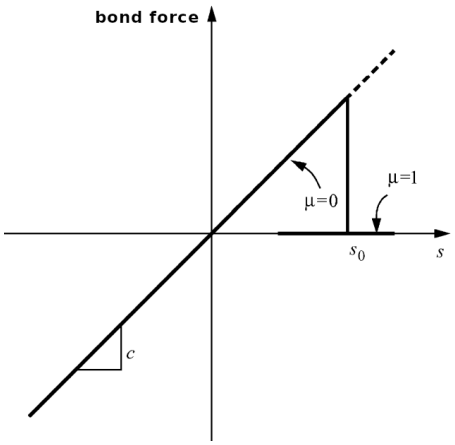

Figure 2: Critical Stretch Damage Model (Adapted from [14])

When s gets bigger than a critical bond stretch s_0 (figure 2), the bond becomes damaged:

$$\mu(\xi) = \begin{cases} 1 & \text{if} \quad s > s_0 \\ 0 & \text{otherwise,} \end{cases} \tag{6}$$

and the particle's damage is evaluated as the rate of broken bonds divided by the particle's total bond number:

$$d(\mathbf{x}) = \frac{\int_{\mathcal{H}_{\mathbf{x}}} \mu(\xi) dV q}{\int_{\mathcal{H}_{\mathbf{x}}} dV q} \tag{7}$$

s_0 is calibrated with the material's fracture energy release rate G_F. Following the procedure in [13] and after setting $\nu = 1/4$ for 3D and plane strain and $\nu = 1/3$ for plane stress conditions, the critical stretch expressions in (8) for the critical stretch are obtained:

$$s_0 = \begin{cases} \sqrt{\dfrac{5G_F}{6E\delta}} & \text{3D,} \\ \sqrt{\dfrac{8\pi G_F}{9E\delta}} & \text{pl. stress,} \\ \sqrt{\dfrac{5\pi G_F}{6E\delta}} & \text{pl. strain} \end{cases} \tag{8}$$

2 COMPACT TENSION TEST

In this example the experiments performed in [7] are simulated for a concrete specimen subjected to different dynamic loading rates. The specimen geometry and its initial hexagonal (for 3D) configuration are displayed in figure (3) on the left and right hand side correspondingly. It should be noted that PD deals with particles, not elements. However for simplicity is convenient to start by defining a pseudo-mesh, in this case of hexagons. For each hexagon a particle is assigned to the hexagon's centroid containing the total volume of the hexagon. For this simulation a non-uniform distribution of particles resulted, having an average distance between each particle of $\Delta x \approx 1\,mm$.

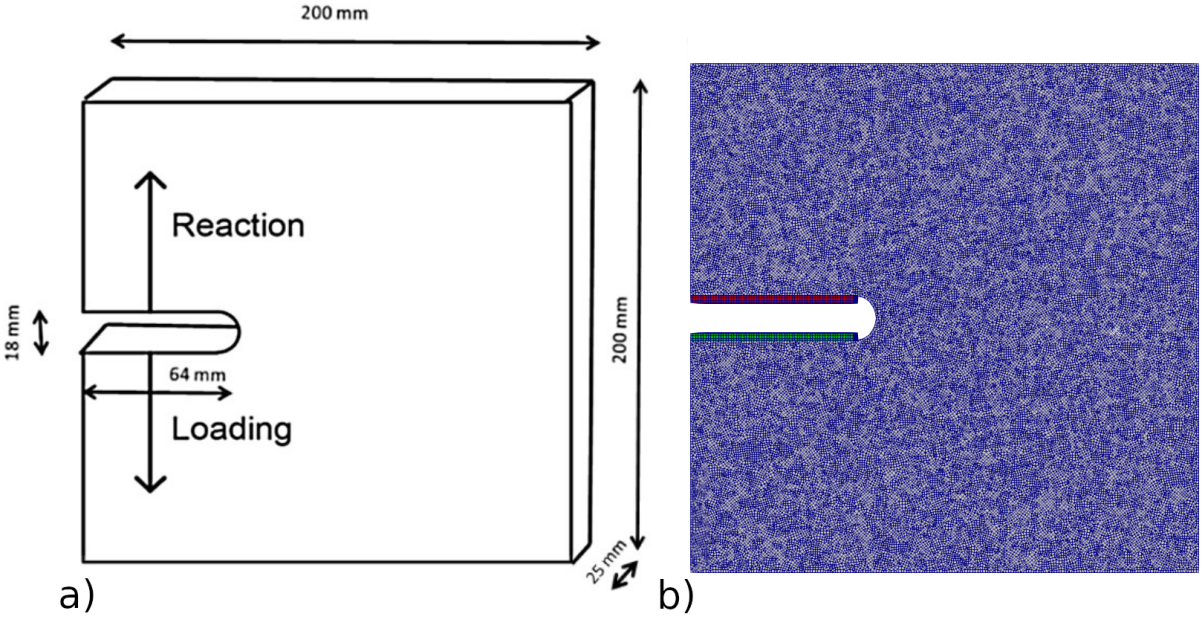

Figure 3: Compact Tension Specimen. a) Geometry (Reprinted from [2]), b) Initial Hexagonal Discretization

In red and green colors may also be observed two additional material blocks added to the geometry corresponding to the reaction (fixed position) and loading boundary conditions (BC). These two extra material blocks have δ width added size and are required because in PD (as in any other non-local theory), the existence of a "traditional" BC does not emerge as in the local theory [11].

The initial mesh was generated with GMSH and converted into EXODUS II format [15] using a local MATLAB script plus the MAT2EXO tool from SEACAS library. For performing PD calculations, the open source program PERIDIGM [8],[5] was employed, and modified to include 2D support and accordingly, the plane stress/strain material model mentioned before.

All results are output in another EXODUS II file that may be visualized using PARAVIEW. For the 3D case the file contains only particles with their respective computed properties. As for 2D, the mesh generator and Delaunay triangulator TRIANGLE [10] was implemmented to the PERIDIGM code to link particles to triangular elements. This helps to better visualize surface results and employ other PARAVIEW's available tools.

A velocity-Verlet time integration scheme was employed. Such scheme computes current velocities and displacements based on previous time step accelerations. All variables are stored explicitly and a small enough constant integration time step is selected. Such parameter is chosen to be 0.7 times the maximum stable time step Δt_{crit} determined as:

$$\Delta t_{crit} = \begin{cases} \sqrt{\dfrac{2\rho}{\sum_q dV_q C_q}} & \text{3D,} \\ \dfrac{h}{c} & \text{2D} \end{cases} \tag{9}$$

The expression in (9) for 3D was intrinsically developed in [14]. The summation implies an iteration over all neighbourhood $\mathbf{q}$ of material particle $\mathbf{x}$. dV is the particle's volume and C is the effective micromodulus constant computed as $C = 18k/\underline{x}\pi\delta^4$. The parameters ρ and k (material density and bulk modulus, respectively) and $\underline{x}$ (the undeformed bond length) were previously defined in eq. (3).

The expression for 2D follows the classical Courant Friedrichs-Lewy (CFL) approach, where h is the minimum undeformed bond length in all domain particles and c is the material wave speed computed as $c = \sqrt{k/\rho}$.

Table (1) lists the material and discretization parameters used in the simulations.

Parameter	Value
Elastic Modulus E	$36.00\,GPa$
Poisson's Ratio ν	0.18
Material Density ρ	$2400\,kg/m^3$
Block Horizon δ	$3.002\,mm$
Fracture Energy G_F	$65.00\,J/m^2$
Critical Stretch s_0	0.00130 / 0.00078 *@3D / pl.stress*
Time Step dt	$1.7495 \times 10^{-7}\,s$ / $1.3076 \times 10^{-7}\,s$ *@3D / pl.stress*
Number of Particles	$1,273,125$ / $50,925$ *@3D / pl.stress*

Table 1: Compact Tension Material and Discretization Parameters

Figure (4) shows the obtained damage results for the specimen, subject to four different increasing velocity loading rates: $v = 0.3,\ 1.4,\ 3.3$ and $4.0\,m/s$. For comparison, results obtained from [2] using a a two-scale FEM damage model were also included. For the PD case, plane stress and 3D simulations results compare quite well. One single main crack is observed when the velocity is lower than $3.3m/s$, but multiple crack branching starts to develop as the velocity increases. Regarding the maximum computed force, the plane stress material seems to overestimate it more than the 3D. However, except for the a) ($v = 0.3\,m/s$) case, simulations are observed to be close to the registered value. In general good agreement is observed between results in [2], the current PD simulation and the experimental ones.

3 L-SPECIMEN TEST

In this section the concrete L-Specimen in [6] is analyzed with the current approach. The simulated results compare quite well with the experimental ones. Figure (5) displays on the left side the geometry dimensions and simulation setup, whereas on the right the initial hexagonal mesh is displayed.

The loading point is modeled using an external block (in red) of size ($30 \times \delta\, mm$), whereas the blocked part is fixed in all directions on the same block. Table (2) displays the material and discretization parameters employed. Same as in the previous case, a non-uniform distribution of particles with an average particle distance $\Delta x \approx 2.33\,mm$ is employed.

Parameter	Value
Elastic Modulus E	$32.20\,GPa$
Poisson's Ratio ν	0.18
Material Density ρ	$2210\,kg/m^3$
Block Horizon δ	$7.002\,mm$
Fracture Energy G_F	$58.00\,J/m^2$
Critical Stretch s_0	$0.0004630\,/\,0.00084$ *@3D / pl.stress*
Time Step dt	$4.1492 \times 10^{-7}\,s\,/\,2.8120 \times 10^{-7}\,s$ *@3D / pl.stress*
Number of Particles	$939,834\,/\,44,757$ *@3D / pl.stress*

Table 2: L-Specimen Material and Discretization Parameters

The specimen is dynamically loaded with increasing velocity rates. Both crack patterns and registered forces for each rate are illustrated in figures (6, 7). When available, simulations performed by [2] are also included for comparison.

From PD results, it is observed that as velocity increases, the crack becomes more aligned with the applied loading direction. This behaviour was also observed during the experimental tests.

Regarding material models, both plane stress and 3D seem to provide close results between each other, either in crack pattern or maximum registered force.

One single main crack is observed for small loading rates, where as multiple branching is developed when the rate is increased, particularly for the last case, in which a crack developed near the loading area and another started next to the fixed boundary condition. Close agreement was also observed with simulation results obtained in [2], with a difference in the fracture energy, for which a lower value ($G_F = 40J/m^2$) than the one used in [6] is employed.

4 WEAK INTERFACE IN A PMMA PLATE

The case analyzed in this section intends to simulate the experiments performed in [16], whereby a PMMA plate glued in the middle, thus having a weaker interface than the monolithic case, kinks and branches an upcoming crack in two smaller symmetric daughter cracks.

Figure (8) ([17]) illustrates the original experiment, where a long AL 7075-T6 aluminum Hopkinson pressure bar of dimensions ($L = 1830\,mm$, $\phi = 25.4\,mm$), whose "wedge" shape end is in direct contact with the PMMA plate. A striker of the same material as the bar, and dimensions ($L = 305\,mm$, $\phi = 25.4\,mm$) hits it and induces a stress wave with time duration ($t_s \approx 120\mu s$). The wave travels through the bar and exerts a contact force on the "free" supported specimen. In the experiment free boundary conditions are achieved by applying a putty layer on top and bottom of the plate. Therefore in the simulations no other boundary conditions but the applied contact force were considered.

The plate dimensions are illustrated in figure (9). The monolithic case represents a single PMMA block material, where as the bilayered case is composed of two blocks of the same material and a layer of adhesive "Weldon 16" of thickness $0.025\,mm$ and $0.100\,mm$ representing the "strong" and "weak" interface correspondingly. However, in the following approach the interface thickness is not directly input, but rather modeled by weakening the bonds that cross from one region to the other. The way to perform this was by reducing the critical stretch parameter [1] and again, this was added to PERIDIGM.

Although it is possible to use PERIDIGM to completely simulate in 3D the whole experiment, this task would require a quite high computational time. Therefore the approached followed here was to split the simulation into two stages. On the first part, ABAQUS (FEM) was employed to fully model in 3D, the stress wave propagation through the long bar up to the contact with the specimen (no fracture was considered at this point), thus this stage being purely elastic. On the second part the computed contact force was input into PERIDIGM, using the 2D plane stress model to capture fracture (fracture stage). Following, the mentioned procedure in presented in sequential order.

4.1 Elastic Stage

Table (3) presents material and discretization parameters employed for the analysis, whereas fig. (10) illustrates the corresponding mesh. The simulation was carried out using a contact "surface to surface" condition type with a fully explicit time discretization. The total computed time was $1000\,\mu s$ with a time step $dt = 2.7042 \times 10^{-8}\,s$.

According to [9] the bar's propagated stress wave may be obtained as eq. (10), in which $v = 15\,m/s$ is the striker velocity and ρ, E are the bar's density and elastic modulus respectively. The pulse time length τ is twice the wave's transit time on the striker bar: eq. (11), where $L_s = 0.305\,m$ is the striker length and $c \approx 5051.33\,m/s$ is the wave's speed on aluminum medium. Combined, the generated input pulse specified into ABAQUS is represented in eq. (12).

$$\sigma = \frac{v\sqrt{\rho E}}{2} \approx 106.5\,MPa \tag{10}$$

Parameter	Value	
	AL 7075-76 Bar	PMMA Plate
Elastic Modulus E	$71.70\,GPa$	$5.00\,GPa$
Poisson's Ratio ν	0.33	0.34
Material Density ρ	$2810\,kg/m^3$	$1010\,kg/m^3$
Element length dx	$1.50\,mm$	$0.80\,mm$
Number of Elements	$1,289,945$	$599,104$

Table 3: Bilayer Plate: Elastic Stage performed in ABAQUS. Material and Discretization Parameters

$$\tau = 2\frac{L_s}{c} \approx 120.76\,\mu s \tag{11}$$

$$\sigma = \begin{cases} 106.5\,MPa & \text{if} \quad t < 120.76\,\mu s \\ 0 & \text{otherwise} \end{cases} \tag{12}$$

From ABAQUS, a graph of Time vs Contact Force - Area in fig. (11), indicates that contact may be considered constant along the wedge surface area of the specimen, where as the force may be approximated using a polynomial function. Such approximation (based on time) is obtained with the polifit function from MATLAB for a high polynomial degree, and imported into PERIDIGM as a body force. The result is illustrated in fig. (12), where the displacement on a single same point, from both ABAQUS and PERIDIGM (this latter one in 2D) are measured and compared. PD solution is offset by $\approx 280\mu s$ which is the time in takes for the stress wave to travel through the long bar and reach the specimen. Both displacements seem to agree well enough for the corresponding applied body force.

4.2 Fracture Stage

This section will present the obtained results during fracture of the PMMA bilayer plate. Such computations were performed based on the previous calculated contact force when imported into PERIDIGM and assuming a PD-plane stress condition. Table (4) displays the material and discretization parameters employed, and figure (13) illustrates the initial PD-plane stress quadrangular mesh, later converted into particles. On it, two extra blocks of size $(17.15 \times 2\delta\,mm)$ for the boundary conditions were added. On the mesh they appear overlapped, but in the simulation were specified not to interact. Remaining blocks behave as usual with the exception of the damage properties on the interface when the case applies. The total computed time was $230\,\mu s$ with a time step $dt = 3.1398 \times 10^{-11}\,s$.

The objective is to model the following three scenarios: a single monolithic type, where no interface is present; a weaker; and a stronger interface type. The adopted procedure was the following:

- Start modeling the monolithic type. Since no interface is required an initial critical stretch, just enough to avoid branching and ensure a monothonic mode I advancing crack was selected. Such parameter was found to be $s_0 = 0.0235$.

Parameter	Value
Elastic Modulus E	$5.00\,GPa$
Poisson's Ratio ν	0.34
Material Density ρ	$1010\,kg/m^3$
Block Horizon δ	$1.07\,mm$
Number of Particles	$394,432$

Table 4: Bilayer Plate: Fracture Stage Material and Discretization Parameters

- Model the weak and strong interface cases by choosing smaller critical stretchs correspondingly. The range ($s_0 = \{0.0116 - 0.0164\}$) was selected for such purpose and the corresponding results are illustrated in fig.(14).

From the results it is observed that small enough s_0 values on the interface perturb an upcoming mode I type crack. When s_0 is smaller than a specific range ($s_0 = \{0.0126 - 0.0156\}$), the crack propagates into two symmetric daugther cracks that remain trapped inside the interface, whereas if s_0 is bigger that the mentioned range, the crack propagates monotonically throughout the whole specimen without feeling the interface effect. Only inside the range, the crack got trapped and could also escape by branching in two inclined angled cracks. This same behaviour was observed in [16].

The two extremes s_0 of the mentioned range were identified correspondingly as "weak" and "strong" interfaces with $\approx 53\%$ and $\approx 66\%$ of virgin PMMA material. Surprisingly, similar percentage ratios were also obtained in [16] when characterizing the PMMA interface material crack initiation toughness.

A comparison of experimental and PD results is presented in figs. (15,16). From the results, both strong and weak interfaces present very similar crack bifurcation angles ($28°$). The principal difference was observed in the propagated crack length inside the interface, which for the strong scenario, was shorter ($\approx 1\,mm$) than the weak one ($\approx 3.5\,mm$). This behaviour was also observed during experiments, however numerical results seem to underestimate it. Regarding the monolithic case, a monothonic advancing crack front was attained as expected.

5 CONCLUSIONS

This work demonstrated the use of PD equations combined with a bond breaking damage rule (critical stretch) for simulating damage in concrete and PMMA specimen materials subject to high dynamic loading rates. Observed results display excellent crack path agreement between numerical and experimental tests.

For the compact tension and the L-Specimen, full 3D simulations were also carried out and compared with plane stress material model. The results matched very well both in damage and maximum registered force, suggesting the use of the plane stress model (when applicable), as a good alternative to speed up computational results.

By assigning lower critical stretch thresholds on specified regions inside a domain, PD was able to capture expected perturbations imposed when having a weaker interface over an advancing crack front. Other possible approaches may have included reducing the elastic modulus,

fully simulate in 3D the experiment and having contact evaluated using a PD model. Nevertheless, the assumed simplifications still managed to provide a good insight into the simulation of damage in PMMA.

Keywords: Wave Finite Element, Transition zones, Railway, Dynamics, Moving loads

Abstract. *The dynamics of a railway track on transition zones is the subject of numerous analytical and numerical researches. This article presents a new development of the wave finite element method for such a structure in order to reduce the calculation time. We consider a transition zone which is between two half infinite periodic tracks (which could be of different types, e.g. a zone between ballasted and non-ballasted tracks) and train loads are represented by concentrated moving loads. We applied WFE for each half periodic track to obtain the relationship that links the responses of the boundary zone of each periodic part with the help of the wave analysis. Then, this relationship is combined with the dynamic equation of the zone to get the global dynamic equation of the whole railway track. This technique permits to reduce the degrees of freedom (DoF) of the track to those of the transition zone. Numerical studies show the influence of the geometrical and mechanical parameters of the transition zone on the mechanical response of the track with a transition zone compared to a uniform track.*

1 Introduction

Mechanical behaviour of railway tracks have been studied for a long time. The most common model considers the track as an infinitely long beam resting on equally spaced identical supports. The dynamics of the track under some known loads can be solved analytically by modelling each support by a mass-springs-dampers system and the rail by an Euler beam [1–4] or a Timoshenko beam [5]. Metrikine and Popp [6] also modelled the support and the ballast - for ballasted tracks - as continuous media. All these studies used the Floquet's theorem which takes into account the spatial periodicity of the structure. In the case of transition zones, the structure is not periodic so the Floquet's theorem can't be used.

The high speed transition zone between a ballast to ballastless track situated in Chauconin (France) had been damaged by train traffic. These damages include hanging sleepers. Consequently, the train speed in this zone has been reduced from $320\,\mathrm{km}\cdot\mathrm{h}^{-1}$ to $230\,\mathrm{km}\cdot\mathrm{h}^{-1}$. This transition zone is the subject of both experimental and numerical studies [7, 8]. Fortunato *et al*. [9] also pointed out hanging sleepers which are due to the deformation of the lowest vertical stiffness part in transition zones. Wang [10] gave a review of studies dealing with transition zones in the railway domain. The problems encountered points out a need to better understand transition zones dynamics.

A default or a damage also breaks the track periodicity even if this default is very localised. Hoang *et al*. [11] studied the mechanical behaviour of such a track considering a constant moving load on a periodically supported beam. Considering a "sufficiently large" computation domain, Hoang *et al*. gave a digital method to compute this dynamic behaviour. Kouroussis *et al*. [12] proposed a two steps method for a numerical computation of the rail-support-train system response and applied it to some common defaults.

Dividing the structure into substructures and considering the equilibrium relationship in a substructure, Germonpré *et al*. [13] studied the free wave modes in a substructure and then computed the whole structure dynamics. By separating left going and right going modes, Germonpré *et al*. [14] applied this method to a transition zone including a train-track-soil coupling. Arlaud [15] developed a similar method excepted that it fixed the wave-number instead of fixing the frequency. Then, a mode reduction was performed in order to increase the calculation efficiency.

Like the method developed by Germonpré *et al*. [13], the wave finite element (WFE) method is a computational method for periodic structures and waveguides. In the WFE method, for each frequency, the equilibrium relationship in one pattern of the structure is transformed into a recurrence relationship. Free wave modes of the recurrence operator calculation is described in [16]. Hoang *et al*. improved this method by adding the possibility to take into account a load which may be applied to any pattern of the structure [17] and used it for computation of railway tracks dynamics [18].

In this article, a transition zone is defined as a zone between two semi-infinite periodic structures which can be different or not. This can represent either a zone passing from ballast to ballastless track or a damaged zone between two healthy identical zones. After this introduction, the classical WFE method is presented. The third part of this article presents new developments enabling the computation of transition zones mechanical behaviour. The forth part gives two examples of results of this method on the mechanical behaviour: effects of a damaged zone in an infinite periodic healthy track and effects of a variation in the support spacing. Then, the conclusions of this work are given in the last part.

2 WFE Method: Homogeneous Periodic Structure

In this part an homogeneous periodic structure is considered. It is assumed that all the loads applied to the structure are known. The dynamic equation of one pattern (a substructure) at a given angular frequency ω is given by the equation (1), where $\mathbf{q}$ is the vector containing the degrees of freedom of one substructure and $\mathbf{F}$ the vector containing the external loads applied on this substructure.

$$\mathbf{D}_{tot}\mathbf{q} = \mathbf{F} \tag{1}$$

The dynamic stiffness matrix (DSM) $\mathbf{D}_{tot}$ can be calculated using the finite element method with $\mathbf{D}_{tot} = \mathbf{K} + j\omega\mathbf{C} - \omega^2\mathbf{M}$ where $\mathbf{K}$ is the static stiffness matrix, $\mathbf{M}$ the mass matrix and $\mathbf{C}$ the damping matrix. Then, (1) can be rewritten separating the nodes of the left and right boundaries, and the inner nodes of the substructure respectively denoted with the subscripts $_{L,R}$ and $_I$. Hence, the relationship (2) is obtained.

$$\begin{bmatrix} \tilde{\mathbf{D}}_{II} & \tilde{\mathbf{D}}_{IL} & \tilde{\mathbf{D}}_{IR} \\ \tilde{\mathbf{D}}_{LI} & \tilde{\mathbf{D}}_{LL} & \tilde{\mathbf{D}}_{LR} \\ \tilde{\mathbf{D}}_{RI} & \tilde{\mathbf{D}}_{RL} & \tilde{\mathbf{D}}_{RR} \end{bmatrix} \begin{bmatrix} \mathbf{q}_I \\ \mathbf{q}_L \\ \mathbf{q}_R \end{bmatrix} = \begin{bmatrix} \mathbf{F}_I \\ \mathbf{F}_L \\ \mathbf{F}_R \end{bmatrix} \tag{2}$$

As shown in [18], this relation leads to the recurrence equation (3) where the superscript $^{(n)}$ denotes for the n^{th} substructure.

$$\mathbf{u}^{(n+1)} = \mathbf{S}\mathbf{u}^{(n)} + \mathbf{b}^{(n)} \tag{3}$$

where

$$\mathbf{u}^{(n)} = \begin{bmatrix} \mathbf{q}_L^{(n)} \\ -\mathbf{F}_L^{(n)} \end{bmatrix}, \quad \mathbf{b}^{(n)} = \begin{bmatrix} \mathbf{D}_{qI}\mathbf{F}_I^{(n)} \\ \mathbf{D}_{fI}\mathbf{F}_I^{(n)} - \mathbf{F}_{\partial R}^{(n)} \end{bmatrix}$$

$\mathbf{F}_{\partial R}^{(n)}$ is the external load applied at the right boundary of the n^{th} substructure and $\mathbf{S}, \mathbf{D}_{qI}$ and $\mathbf{D}_{fI}$ definitions are given in [18].

That leads to the equation system (4):

$$\begin{cases} \mathbf{u}^{(n)} = \mathbf{S}^n\mathbf{u}^{(0)} + \displaystyle\sum_{k=1}^{n} \mathbf{S}^{n-k}\mathbf{b}^{(k-1)} \\ \mathbf{u}^{(-n)} = \mathbf{S}^{-n}\mathbf{u}^{(0)} - \displaystyle\sum_{k=1}^{n} \mathbf{S}^{-n+k-1}\mathbf{b}^{(-k)} \end{cases} \tag{4}$$

To compute the power of the $\mathbf{S}$ matrix, the eigenvalues and eigenvectors $\{\mu_j, \phi_j\}_j$ of the $\mathbf{S}$ matrix are computed by a $\mathbf{S} + \mathbf{S}^{-1}$ transformation. The eigenvalues come in pair $\left(\mu_j, \mu_j^\star\right)$ with $\|\mu_j\| \leqslant 1$ and $\mu_j^\star = \frac{1}{\mu_j}$ [16]. The corresponding eigenvectors are noted $\left(\phi_j, \phi_j^\star\right)$. Let the eigenbasis $\{\mathbf{\Phi}\, \mathbf{\Phi}^\star\}$ be defined as: $\mathbf{\Phi} = [\phi_1 \dots \phi_n]$ and $\mathbf{\Phi}^\star = [\phi_1^\star \dots \phi_n^\star]$. Where the subscript "$_q$" (respectively "$_F$") denotes for the components of this basis corresponding to the degrees of freedom (DoF)[1] (resp. the loads), leading to (5).

$$\mathbf{\Phi} = \begin{bmatrix} \mathbf{\Phi}_q \\ \mathbf{\Phi}_F \end{bmatrix} \quad \mathbf{\Phi}^\star = \begin{bmatrix} \mathbf{\Phi}_q^\star \\ \mathbf{\Phi}_F^\star \end{bmatrix} \tag{5}$$

[1] Usually displacements/rotations

In (6), $\mathbf{u}^{(n)}$ and $\mathbf{b}^{(n)}$ are written in this wave basis:

$$\begin{aligned}\mathbf{u}^{(n)} &= \mathbf{\Phi}\mathbf{Q}^{(n)} - \mathbf{\Phi}^{\star}\mathbf{Q}^{\star(n)} \\ \mathbf{b}^{(n)} &= \mathbf{\Phi}\mathbf{Q}_E^{(n)} - \mathbf{\Phi}^{\star}\mathbf{Q}_E^{\star(n)}\end{aligned} \tag{6}$$

Hoang *et al.* proved [18]:

$$\begin{aligned}\mathbf{Q}_E^{(k)} &= \left[\left(\boldsymbol{\mu}\mathbf{\Phi}_q^{\star T}\mathbf{D}_{LI} + \mathbf{\Phi}_q^{\star T}\mathbf{D}_{RI}\right)\mathbf{F}_I^{(k)} - \mathbf{\Phi}_q^{\star T}\mathbf{F}_{\partial R}^{(k)}\right] \\ \mathbf{Q}_E^{\star(k)} &= \left[\left(\boldsymbol{\mu}^{\star}\mathbf{\Phi}_q^{T}\mathbf{D}_{LI} + \mathbf{\Phi}_q^{T}\mathbf{D}_{RI}\right)\mathbf{F}_I^{(k)} - \mathbf{\Phi}_q^{T}\mathbf{F}_{\partial R}^{(k)}\right]\end{aligned} \tag{7}$$

3 Transition Zone between Two Semi-infinite Zones

In this part, a transition zone between two infinite periodic zones (see figure 1) is considered. For railways the transition zone can for instance be a zone between a ballasted track and a concrete slab track. These two types of track have different stiffness. Therefore, $\mathbf{S}$ can be different in each zone and some formulas from the previous part are no longer valid.

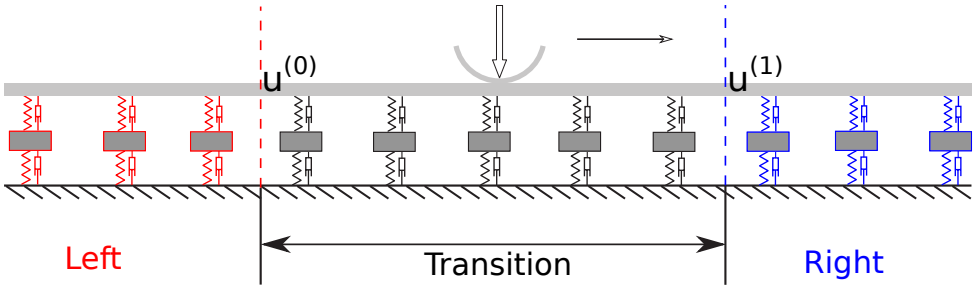

Figure 1: Transition zone between two semi-infinite periodic railway tracks.

In the transition zone the equilibrium relationship is:

$$\mathbb{D}_{H,trans}\begin{bmatrix}\mathbf{q}_I \\ \mathbf{q}_L \\ \mathbf{q}_R\end{bmatrix} = \begin{bmatrix}\mathbf{F}_I \\ \mathbf{F}_L \\ \mathbf{F}_R\end{bmatrix} \tag{8}$$

Where $\mathbb{D}_{H,trans}$ is the dynamic stiffness matrix (DSM) of the transition zone.

The equilibrium relationships for one pattern in the left and right zones were written in the same way replacing $\mathbb{D}_{H,trans}$ by the DSM of the corresponding zone. So, applying the same method as in the previous part, propagation equations (9) were obtained (instead of (3)) - with "$_R$" subscript denoting for the right zone and "$_L$" subscript the left zone.

$$\begin{cases}\forall n \geqslant 1,\ \mathbf{u}_R^{(n+1)} = \mathbf{S}_R\mathbf{u}^{(n)} + \mathbf{b}^{(n)} \\ \forall n \leqslant 0,\ \mathbf{u}_L^{(n-1)} = \mathbf{S}_L^{-1}\mathbf{u}^{(n)} - \mathbf{S}_L^{-1}\mathbf{b}^{(n-1)}\end{cases} \tag{9}$$

With $\mathbf{u}^{(0)}$ corresponding to the left boundary of the transition zone, and $\mathbf{u}^{(1)}$ to the left boundary of the right zone (see figure 1).

3.1 Decomposition in the Right Zone and in the Left Zone

Thus, for the right zone the recurrence relationship is:

$$\forall n \geqslant 1,\ \mathbf{u}^{(n)} = \mathbf{S}_R^{n-1}\mathbf{u}^{(1)} + \sum_{k=2}^{n} \mathbf{S}_R^{n-k}\mathbf{b}^{(k-1)} \tag{10}$$

Let $\mathbf{u}_R = \mathbf{u}^{(1)}$. As in the first part, $\mathbf{u}_R$ was rewritten in the eigenbasis $\{\mathbf{Q}_R, \mathbf{Q}_R^\star\}$ of $\mathbf{S}_R$ associated with the eigenvalues $\{\boldsymbol{\mu}_R, \boldsymbol{\mu}_R^\star\}$ where $\|\mu_{R,j}\| \leqslant 1$ and $\|\mu_{R,j}^\star\| \geqslant 1$. That led to the wave decomposition (11) for $\mathbf{u}_R$ and (12) for $\mathbf{u}^{(n)}$ and $\mathbf{b}^{(n)}$:

$$\mathbf{u}_R = \boldsymbol{\Phi}_R\mathbf{Q}_R - \boldsymbol{\Phi}_R^\star\mathbf{Q}_R^\star \tag{11}$$

$$\forall n \geqslant 1, \begin{cases} \mathbf{u}^{(n)} = \boldsymbol{\Phi}_R\mathbf{Q}^{(n)} - \boldsymbol{\Phi}_R^\star\mathbf{Q}^{\star(n)} \\ \mathbf{b}^{(n)} = \boldsymbol{\Phi}_R\mathbf{Q}_E^{(n)} - \boldsymbol{\Phi}_R^\star\mathbf{Q}_E^{\star(n)} \end{cases} \tag{12}$$

Using (10) with (11) and (12) led to:

$$\begin{aligned} \mathbf{u}^{(n)} &= \boldsymbol{\Phi}_R\mathbf{Q}^{(n)} - \boldsymbol{\Phi}_R^\star\mathbf{Q}^{\star(n)} \\ &= \boldsymbol{\Phi}_R\boldsymbol{\mu}_R^{n-1}\left(\mathbf{Q}_R + \sum_{k=2}^{n}\boldsymbol{\mu}_R^{\star k-1}\mathbf{Q}_E^{(k-1)}\right) - \boldsymbol{\Phi}_R^\star\boldsymbol{\mu}_R^{\star n-1}\left(\mathbf{Q}_R^\star + \sum_{k=2}^{n}\boldsymbol{\mu}_R^{k-1}\mathbf{Q}_E^{(k-1)}\right) \end{aligned} \tag{13}$$

$\|\boldsymbol{\mu}_R^\star\| > 1$, so taking the limit $n \to +\infty$ led to $\mathbf{Q}_R^\star = -\sum_{k=2}^{+\infty}\boldsymbol{\mu}_R^{k-1}\mathbf{Q}_E^{(k-1)}$ because DoF and loads can't be infinite. (13) then became (14).

$$\begin{cases} \mathbf{q}_R = \boldsymbol{\Phi}_{R,q}\mathbf{Q}_R + \boldsymbol{\Phi}_{R,q}^\star\displaystyle\sum_{k=1}^{\infty}\boldsymbol{\mu}_R^k\mathbf{Q}_E^{\star(k)} \\ \mathbf{F}_R - \mathbf{F}_{\partial R} = \boldsymbol{\Phi}_{R,F}\mathbf{Q}_R + \boldsymbol{\Phi}_{R,F}^\star\displaystyle\sum_{k=1}^{\infty}\boldsymbol{\mu}_R^k\mathbf{Q}_E^{\star(k)} \end{cases} \tag{14}$$

With the same reasoning on the left part of the structure, the relationship (15) was proved.

$$\begin{cases} \mathbf{q}_L = \boldsymbol{\Phi}_{L,q}\displaystyle\sum_{k=1}^{\infty}\boldsymbol{\mu}_L^{k-1}\mathbf{Q}_E^{(-k)} - \boldsymbol{\Phi}_{L,q}^\star\mathbf{Q}_L^\star \\ -\mathbf{F}_L = \boldsymbol{\Phi}_{L,F}\displaystyle\sum_{k=1}^{\infty}\boldsymbol{\mu}_L^{k-1}\mathbf{Q}_E^{(-k)} - \boldsymbol{\Phi}_{L,F}^\star\mathbf{Q}_L^\star \end{cases} \tag{15}$$

Finally, by substituting (14) and (15) into (8), (16) was obtained:

$$\begin{aligned} &\mathbb{D}_{H,trans}\begin{bmatrix} \mathbf{q}_I \\ -\boldsymbol{\Phi}_{L,q}^\star\mathbf{Q}_L^\star \\ \boldsymbol{\Phi}_{R,q}\mathbf{Q}_R \end{bmatrix} + \mathbb{D}_{H,trans}\begin{bmatrix} \mathbf{0} \\ \boldsymbol{\Phi}_{L,q}\sum_{k=1}^{\infty}\boldsymbol{\mu}_L^{k-1}\mathbf{Q}_E^{(-k)} \\ \boldsymbol{\Phi}_{R,q}^\star\sum_{k=1}^{\infty}\boldsymbol{\mu}_R^k\mathbf{Q}_E^{\star(k)} \end{bmatrix} = \\ &\qquad\begin{bmatrix} \mathbf{0} \\ \boldsymbol{\Phi}_{L,F}^\star\mathbf{Q}_L^\star \\ \boldsymbol{\Phi}_{R,F}\mathbf{Q}_R \end{bmatrix} + \begin{bmatrix} \mathbf{F}_I \\ -\boldsymbol{\Phi}_{L,F}\sum_{k=1}^{\infty}\boldsymbol{\mu}_L^{k-1}\mathbf{Q}_E^{(-k)} \\ \mathbf{F}_{\partial R} + \boldsymbol{\Phi}_{R,F}^\star\sum_{k=1}^{\infty}\boldsymbol{\mu}_R^k\mathbf{Q}_E^{\star(k)} \end{bmatrix} \end{aligned} \tag{16}$$

Which was rewritten as follows:

$$\left(\mathbb{D}_{H,trans}\mathbb{C}_q - \mathbb{C}_F\right)\tilde{\mathbf{q}} = \tilde{\mathbf{F}} \tag{17}$$

where

$$\begin{aligned}
\tilde{\mathbf{q}} &= \begin{bmatrix}\mathbf{q}_I \\ \mathbf{Q}_L^\star \\ \mathbf{Q}_R\end{bmatrix},\ \mathbb{C}_q = \begin{bmatrix}\mathbf{I} & \mathbf{0} & \mathbf{0} \\ \mathbf{0} & -\mathbf{\Phi}_{L,q}^\star & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \mathbf{\Phi}_{R,q}\end{bmatrix},\ \mathbb{C}_F = \begin{bmatrix}\mathbf{0} & \mathbf{0} & \mathbf{0} \\ \mathbf{0} & \mathbf{\Phi}_{L,F}^\star & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \mathbf{\Phi}_{R,F}\end{bmatrix} \\
\tilde{\mathbf{F}} &= \begin{bmatrix}\mathbf{F}_I \\ -\mathbf{\Phi}_{L,F}\sum_{k=1}^{\infty}\boldsymbol{\mu}_L^{k-1}\mathbf{Q}_E^{(-k)} \\ \mathbf{F}_{\partial R} + \mathbf{\Phi}_{R,F}^\star\sum_{k=1}^{\infty}\boldsymbol{\mu}_R^{k}\mathbf{Q}_E^{\star(k)}\end{bmatrix} - \mathbb{D}_H\begin{bmatrix}\mathbf{0} \\ \mathbf{\Phi}_{L,q}\sum_{k=1}^{\infty}\boldsymbol{\mu}_L^{k-1}\mathbf{Q}_E^{(-k)} \\ \mathbf{\Phi}_{R,q}^\star\sum_{k=1}^{\infty}\boldsymbol{\mu}_R^{k}\mathbf{Q}_E^{\star(k)}\end{bmatrix}
\end{aligned} \tag{18}$$

In the case of a constant moving load[2], $\mathbf{Q}_E^{\star(k)}$ and $\mathbf{Q}_E^{(-k)}$ follow:

$$\forall k \geqslant 1, \begin{cases}\mathbf{Q}_E^{\star(k)} = e^{-i(k-1)\frac{\omega L}{v}}\mathbf{Q}_E^{\star(1)} \\ \mathbf{Q}_E^{(-k)} = e^{i(k-1)\frac{\omega L}{v}}\mathbf{Q}_E^{(-1)}\end{cases} \tag{19}$$

That led to (20):

$$\begin{cases}\displaystyle\sum_{k=1}^{\infty}\boldsymbol{\mu}_L^{k-1}\mathbf{Q}_E^{(-k)} = \frac{1}{1-\boldsymbol{\mu}_L e^{i\frac{\omega L}{v}}}\mathbf{Q}_E^{(-1)} \\ \displaystyle\sum_{k=1}^{\infty}\boldsymbol{\mu}_R^{k}\mathbf{Q}_E^{\star(k)} = \frac{\boldsymbol{\mu}_R}{1-\boldsymbol{\mu}_R e^{-i\frac{\omega L}{v}}}\mathbf{Q}_E^{\star(1)}\end{cases} \tag{20}$$

With $\mathbf{Q}_E^{\star(k)}$ and $\mathbf{Q}_E^{(k)}$ given by (7).

Then, $\tilde{\mathbf{q}}$ can be computed by inverting the linear equation (17). This computation gives the DoF of each node in the transition zone ($\mathbf{q}_I$) and at its boundaries ($\mathbf{q}_L$ and $\mathbf{q}_R$ calculated with (15) and (14)). The DoF in the other zones can be calculated using the classical WFE method (*ie.* using (10) for the right zone and a similar formula for the left zone).

4 Examples

In this part, the track considered is a ballastless track in which each support contains two elastic floors: one under rail rubber pad and one under sleeper rubber pad. The support was modelled as a mass (the sleeper) between two damper-spring systems (the pads). B21 elements from ABAQUS were used to get the beam DSM and the supports dynamic stiffness were added to the corresponding terms to obtain the DSM of each substructure. The beam cell length was $1\,\mathrm{cm}$. In the results presented here, the spatial period choosen for the computation was of the same length $L = 3\,\mathrm{m}$ for each zone (five sleepers per period). The right, left and transition zones are represented in the figure 1. To simplify results understanding, only a single load moving at a constant speed was applied. Table 1 gives the rail and supports mechanical characteristics and the load characteristics.

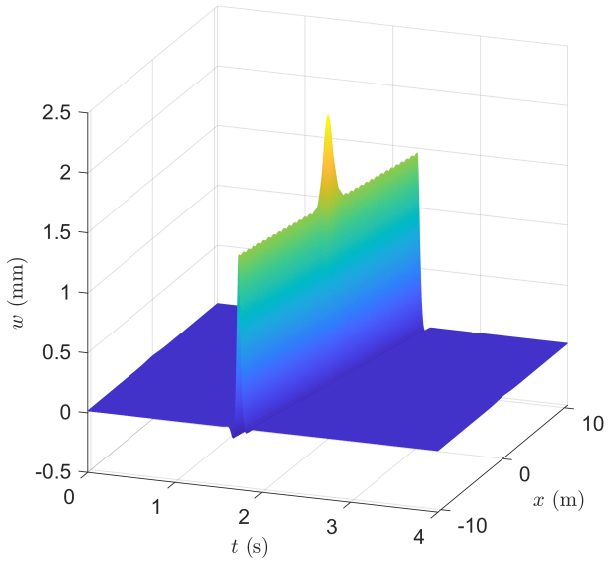
4.1 Periodically Supported Beam with a Broken Support

We considered a periodically supported beam resting on identical supports which means that the right and left zones were identical. To model a broken support, we assumed that this support had no influence on the structure stiffness. This is equivalent to a lack of one support. This broken support was located in the middle of the transition zone ($x = 0\,\mathrm{m}$).

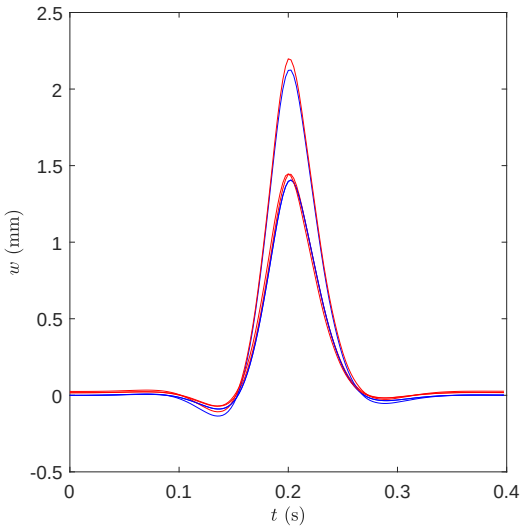
[2](19) remains true if the load is repeated with a spatial period equal to the length of one substructure.

Content	Notation	Value	Unit
Rail linear mass	ρS	60	$\mathrm{kg \cdot m^{-1}}$
Load speed	v	38	$\mathrm{m \cdot s^{-1}}$
Load applied	Q	100	kN
Rail stiffness	EI	6.38	$\mathrm{MN \cdot m^{2}}$
Sleeper mass	m	100	kg
Sleeper spacing	l	0.6	m
Under rail pad stiffness	k_1	192	$\mathrm{MN \cdot m^{-1}}$
Under rail pad damping coefficient	η_1	1.97	$\mathrm{MN \cdot s \cdot m^{-1}}$
Under sleeper pad stiffness	k_2	26.4	$\mathrm{MN \cdot m^{-1}}$
Under sleeper pad damping coefficient	η_2	0.17	$\mathrm{MN \cdot s \cdot m^{-1}}$

Table 1: Parameters of the load and railway track considered.



(a) Rail deflection against time and position.



(b) Rail deflection against time for three different sleepers. WFE results (red curves) and results obtained with the method of [11] (blue curves).

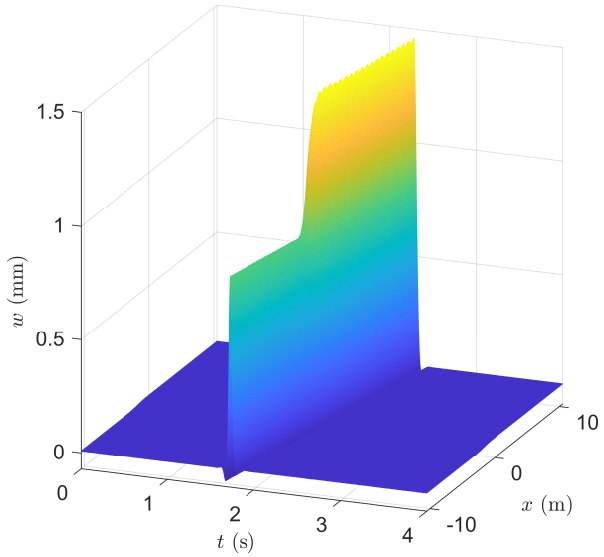
Figure 2: Rail deflection for a track with a broken support.

Figure 2 shows the track deflection due to the load for this type of track. On the left side (figure 2a) the deflection is plotted against time and position. As the WFE method works in the frequency domain, an inverse Fourier transform was necessary to obtain temporal values. At each position, the maximum of the deflection corresponds to the time when the load is over this position. Consequently, the line of the maxima represents the load trajectory. As expected, the deflection is maximum for the broken support. On the right part of this figure (figure 2b), the deflection obtained by the WFE method (red curves) is compared with the one obtained with [11] method (blue curves, 21 supports modelled, 80 iterations). In this graph the deflection is plotted against time for three supports: the broken one ($x = 0\,\mathrm{m}$) and two suports at $x = \pm 6\,\mathrm{m}$. These results show a good agreement which validated the WFE method for computing track deflection in damaged zones.

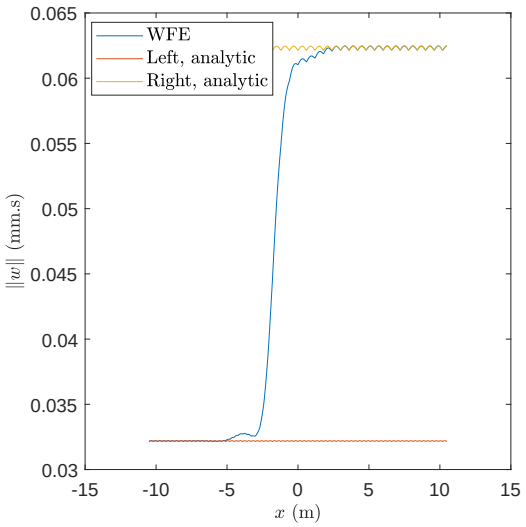
4.2 Variation of the Support Spacing

In this example, the influence of a variation in the support spacing on the track behaviour was evaluated. In the left zone, the distance between two consecutive sleepers was $l_L = 0{,}3\,\mathrm{m}$ whereas in right and transition zones, this distance was $l_R = l_T = 0{,}6\,\mathrm{m}$. All the other parameters remained identical to the values given in the table 1.

The computed deflection of this track is given in figure 3. Once again, in the left part of the figure (figure 3a), the deflection is plotted against time and position. There were two times more support in the left zone, thus, as expected, this zone seems approximately two times stiffer. The right part of the figure (figure 3a) gives the deflection at the frequency $5\,\mathrm{Hz}$. The results are compared with analytical results obtained with an equivalent periodically supported Timoshenko beams with supports spacing equal to the one of the left or right zones (formula from [5]). Analytical formulas and WFE results are in close agreement for points sufficiently far from the transition. Whereas the transition is steep, the rail needs several meters to pass from one mechanical behaviour to the other one. This transition does not show overcharged support.



(a) Rail deflection against time and position.



(b) Rail deflection in the frequency domain (at $5\,\mathrm{Hz}$) against position. WFE results compared with analytical results obtained for an infinite track.

Figure 3: Rail deflection for a variation in the support spacing.

5 Conclusion

The Wave Finite Element method is very efficient to compute infinite periodic structures mechanical behaviour under charges compared to classical finite element methods (see [18]). This article presented new developments to apply this method to transition zones between two semi-infinite periodic structures. Railway examples of application were presented and show a strong agreement with other semi-analytical methods or analytical laws. This method can also provide information on the damping of waves which can propagate over a given structure.

Keywords: Elastic wave propagation, axisymmetric, dynamic stiffness matrix.

Abstract. *In the context of range-independent solid media, we propose a well-conditioned dynamic stiffness matrix for an elastic layer sitting over an elastic half-space. This formulation overcomes the well-known problem of numerical ill-conditioning when solving the system of equations for deep-layered strata. The methodology involves the exact solutions of transformed ordinary differential equations in the wavenumber domain, namely a projection method based on the transformed equations with respect to the depth coordinate. By re-arranging the transformed equations, the solutions remain numerically well-conditioned for all layer depths. The inverse transforms are achieved with a numerical quadrature method and the results presented include actual displacement fields in the near-field of the load in plane-strain and three-dimensional axisymmetric cases. Verification against finite element method (FEM) calculations demonstrates the performance and complexity of the two approaches.*

1 INTRODUCTION

A three-dimensional axisymmetric model is considered which demonstrates the effect of a harmonic finite rigid disk-load over various layered strata. The results derived by Fourier transformation are valid for any frequency and, more importantly, for any depth of the layer. In principle, following the well-known traditional methods, [1], we could use displacement-continuity and traction-equilibrium boundary conditions at the bottom and top of a layer with equations at the ground surface to generate equations for six subsequent unknowns of stress and displacement. However, this direct approach leads to formidable numerical problems. The reason for this work is that if traditional expressions for the characteristic wave functions, such as $\cosh$ or $\sinh$, are employed, these can have a dramatic effect on the numerical evaluation of solutions. Problems arise due to the cancellation or division of either very small or very large numbers. To overcome this, Karasalo [2] derived a well-conditioned propagator matrix for radially symmetric problems. Recent advances in propagator-matrix techniques have proved successful, [3] and [4]; but we derive a simple and robust technique. In this work, then, we construct a single stiffness matrix for the physical layer for plane-strain problems which conveniently avoids these difficulties. We therefore deduce a new global dynamic stiffness matrix for functions that do not cause numerical problems on a desktop PC.

Although not developed in this work, solutions to characteristic equations, such as dispersion equations, which establish wave propagation parameters, can now be determined more efficiently. Similar work in this area for dynamic problems where the load is stationary has been presented in [6] or for general moving-load problems in [7]. In this work we show how we are able to solve *large* (read: deep) problems, due to the reduced number of equations.

2 VIBRATION TRANSMISSION

The model considered is shown in Figure 1(a). A rigid disk load has a radius $b > 0$, with respect to the r-axis. It rests on homogeneous, isotropic, axisymmetric elastic layers, with material properties E (Young's modulus), ρ (density) and ν (Poisson's ratio). A harmonic vertical load acts uniformly over the disk. A submerged elastic layer (the concrete block) of finite depth, $H > 0$, of homogeneous and isotropic material then overlies a half-space of flexible material. The block is considered as a finite-width disk, radius $L > 0$, or as having infinite width, which is a similar problem to one studied in [8].

2.1 Geometry

The problem is solved semi-analytically by a numerical quadrature method suited for oscillatory integrands and, for verification and parametric analysis, by COMSOL 5.2 Solid Structures analysis. For the benefit of the reader, Fig. 1(b) includes an illustration of a typical mesh for the problem in the axisymmetric case. The model has $37,454$ degrees of freedom (d.o.f.), $4,064$ domain elements, and 611 boundary elements with cubic shape functions. In this example, the perfectly matched layer (PML) region surrounds the solution zone at $R = 75.0$ m, and receiver positions of interest are at $R_1 = 4.0$ m, $R_2 = 16.0$ m, and $R_3 = 32.0$ m.

2.2 Theoretical background

Much of the analysis necessary for the derivation of the dynamic stiffness matrix has been presented in references [9] and [10], so this will only be briefly summarized. For plane strain, the behaviour of the isotropic elastic material is described by Navier's elastodynamic equations,

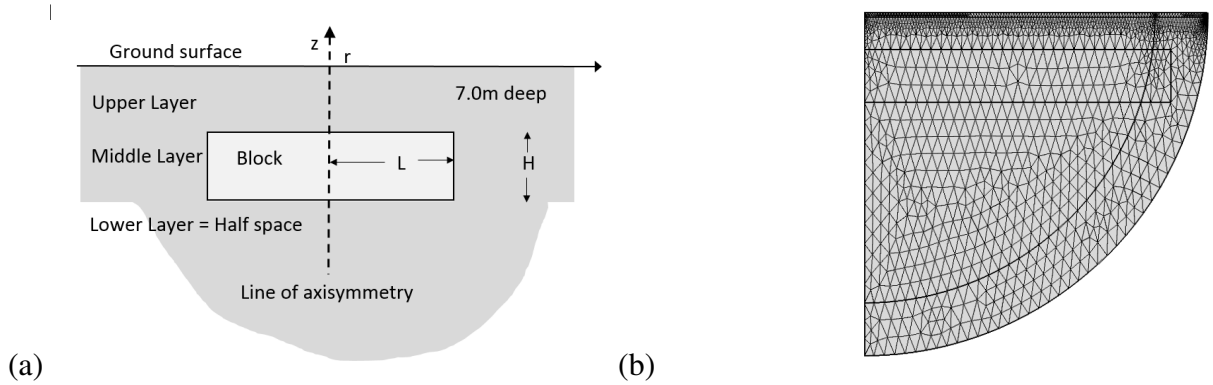

Figure 1: The schema for the two approaches: (a) For the semi–analytical domain, block has radius $L \to \infty$; (b) Axisymmetry model from COMSOL 5.2 showing the block of finite radius $L = 70$ m penetrating the PML region within the finite element mesh.

[9]. In the absence of body forces, these can be written as:

$$(\lambda+\mu)\frac{\partial e}{\partial z^2} \;+\; \mu\left(\frac{\partial^2 u}{\partial r^2}+\frac{1}{r}\frac{\partial u}{\partial r}-\frac{u}{r^2}+\frac{\partial^2 u}{\partial z^2}\right) \;=\; \rho\frac{\partial^2 u}{\partial t^2}, \tag{1}$$

$$(\lambda+\mu)\frac{\partial e}{\partial z} \;+\; \mu\left(\frac{\partial^2 w}{\partial r^2}+\frac{1}{r}\frac{\partial w}{\partial r}+\frac{\partial^2 w}{\partial z^2}\right) \;=\; \rho\frac{\partial^2 w}{\partial t^2}, \tag{2}$$

where u, w are the components of the displacement in the r and z directions and e is the volume strain, and λ, μ are complex Lamé constants assuming a constant loss-factor damping model. The quantities c_1 and c_2 are, respectively, the P and S wave speeds, given by:

$$c_1^2=\frac{\lambda+2\mu}{\rho}=\frac{E(1-\nu)}{\rho(1+\nu)(1-2\nu)}, \quad c_2^2=\frac{\mu}{\rho}=\frac{E}{2\rho(1+\nu)}. \tag{3}$$

and the boundary conditions for this problem are a uniform rigid disk-load of width b acting over the surface and at, for the example given here, at $z = H_1$, $z = (H_1 + H_2)$ continuity of displacement and equilibrium of traction between the mid-layer and the upper and lower media. Equations (2) may be solved by introducing potentials ϕ and H such that

$$u \;=\; \frac{1}{r}\frac{\partial \phi}{\partial r} \;-\; \frac{\partial H}{\partial z} \quad \text{and} \quad w \;=\; \frac{\partial \phi}{\partial z} \;+\; \frac{1}{r}\frac{\partial H}{\partial r}. \tag{4}$$

Also, assuming harmonic time-dependence $\mathrm{e}^{\mathrm{i}\omega t}$ and axial symmetry of the problem, this suggests seeking solutions in the form of Hankel integrals. For this purpose, the following Hankel transforms are introduced, assuming ζ is the transform variable:

$$\overline{U} \;=\; \int_0^\infty u\, r J_1(\zeta r)\, dr \quad \text{and} \quad \overline{W} \;=\; \int_0^\infty w\, r J_0(\zeta r)\, dr, \tag{5}$$

Taking the Hankel transform of the frequency version of equations (1) and (2) leads to a coupled set of ordinary differential equations.

$$\mu\frac{d^2\overline{U}}{\partial z^2}+\left[(\lambda+2\mu)\zeta^2-\rho\omega^2\right]\overline{U}-(\lambda+\mu)\zeta\frac{d\overline{W}}{\partial z} \;=\; 0, \tag{6}$$

$$(\lambda+2\mu)\frac{d^2\overline{W}}{\partial z^2}-\left[\mu\zeta^2-\rho\omega^2\right]\overline{W}-(\lambda+\mu)\zeta\frac{d\overline{U}}{\partial z} \;=\; P\, r J_0(\zeta r). \tag{7}$$

Soil	Upper–layer and half–space Soft soil–type	Embedded block Concrete
E (Pa)	2.69×10^8	204×10^8
ρ (kg m^{-3})	1550	2450

c_2 (m s^{-1})	263	1879
c_1 (m s^{-1})	459	3005

Table 1: Material properties

It is common practice to write solutions to the ensuing ordinary differential equations over a finite-length domain, $z \in [0, D]$ in terms of $\cosh$ and $\sinh$ functions. For computational purposes, this choice of characteristic functions is not convenient for problems involving spatial domains chosen to be extremely deep. Hence, we propose the general solutions may be written as a *scaled formulation*:

$$\begin{aligned} \overline{\phi} &= A_1\, \mathrm{e}^{-\alpha_1 z} + A_2\, \mathrm{e}^{\alpha_1 (z-D)}, \quad 0 \le z \le D \\ \overline{H} &= B_1\, \mathrm{e}^{-\alpha_2 z} + B_2\, \mathrm{e}^{\alpha_2 (z-D)}, \quad 0 \le z \le D. \end{aligned} \tag{8}$$

$$\alpha_1^2 = \zeta^2 - k_1^2 \quad \text{and} \quad \alpha_2^2 = \zeta^2 - k_2^2.$$

The reasons for choosing the scaled exponential characteristic functions over the hyperbolic functions is clear. Essentially, this choice ensures the characteristic functions do not grow unbounded with depth. Substituting the values $z = 0$ and $z = D$ into the equations (8) yields the first matrix equation

$$\{\overline{u}\} = [C]\,\{A\}\,. \tag{9}$$

where $\overline{u} = [\mathrm{i}\overline{w}_0,\ \overline{u}_0,\ \mathrm{i}\overline{w}_D,\ \overline{u}_D]^T$ and the 4×4 complex-valued matrix $[C]$ is given by

$$[C] = \begin{bmatrix} -\mathrm{i}\alpha_1 & \mathrm{i}\alpha_1 \mathrm{e}^{-\alpha_1 D} & -\zeta & -\zeta \mathrm{e}^{-\alpha_2 D} \\ \mathrm{i}\zeta & \mathrm{i}\zeta \mathrm{e}^{-\alpha_1 H} & \alpha_2 & -\alpha_2 \mathrm{e}^{-\alpha_2 D} \\ -\mathrm{i}\alpha_1 \mathrm{e}^{-\alpha_1 D} & \mathrm{i}\alpha_1 & -\zeta \mathrm{e}^{-\alpha_2 D} & -\zeta \\ \mathrm{i}\zeta \mathrm{e}^{-\alpha_1 D} & \mathrm{i}\zeta & \alpha_2 \mathrm{e}^{-\alpha_2 D} & -\alpha_2 \end{bmatrix}. \tag{10}$$

Now, further developing the system of equations, we get

$$\{\overline{\sigma}\} = [S]\,\{A\}\,, \tag{11}$$

$$[S] = \begin{bmatrix} -\mathrm{i}\alpha_1^2\beta + \mathrm{i}\lambda\zeta^2 & (-\mathrm{i}\alpha_1^2\beta + \mathrm{i}\lambda\zeta^2)\, g_1 & -2\mu\zeta\alpha_2 & 2\mu\zeta\alpha_2\zeta g_2 \\ 2\mathrm{i}\mu\zeta\alpha_1 & -2\mathrm{i}\mu\zeta\alpha_1\zeta g_1 & \mu\,(\alpha_2^2 + \zeta^2) & \mu\,(\alpha_2^2 + \zeta^2)\, g_2 \\ \mathrm{i}\,(\alpha_1^2\beta - \lambda\zeta^2)\, g_1 & \mathrm{i}\,(\alpha_1^2\beta - \lambda\zeta^2) & 2\mu\zeta\alpha_2 g_2 & -2\mu\zeta\alpha_2 \\ -2\mathrm{i}\mu\zeta\alpha_1 g_1 & 2\mathrm{i}\mu\zeta\alpha_1 & -\mu\,(\alpha_2^2 + \zeta^2)\, g_2 & -\mu\,(\alpha_2^2 + \zeta^2) \end{bmatrix} \tag{12}$$

with $\beta = \lambda + 2\mu$, $g_i = \mathrm{e}^{-\alpha_i D}, i = 1, 2$, and $\overline{\sigma} = [-\mathrm{i}\overline{\sigma}_0,\ -\overline{\tau}_0,\ \mathrm{i}\overline{\sigma}_D,\ \overline{\tau}_D]^T$. We now combine equations (9) and (11), to arrive at a single matrix expression which expresses the displacements and stresses at the surface and the interface in the wavenumber domain:

$$[T]\,\{\overline{u}\} = \{\overline{\sigma}\}\,. \tag{13}$$

where $[T] = [S][C]^{-1}$. The entries of the matrix $[T]$ are provided in the work of Peplow, [5]. Specifically, $[T]$ is the dynamic stiffness matrix for a single elastic layer, valid for any layer-depth $D > 0$. To include the half-space, we utilize the matrix equations presented in [10], which leads to a matrix system:

$$[P] = \frac{1}{DET}\begin{bmatrix} (\lambda+2\mu)\alpha_2 k_1^2 & 2\mu\zeta(\alpha_1\alpha_2-\zeta^2)+(\lambda+2\mu)\zeta k_1^2 \\ 2\mu\zeta(\alpha_1\alpha_2-\zeta^2)+\mu\zeta k_2^2 & \mu\alpha_1 k_2^2 \end{bmatrix}\begin{bmatrix} \mathrm{i}\overline{w}_D \\ \overline{u}_D \end{bmatrix} = \begin{bmatrix} \mathrm{i}\overline{\sigma}_D \\ \overline{\tau}_D \end{bmatrix} \quad (14)$$

where $DET = 1/(\alpha_1\alpha_2 - \zeta^2)$ and it is understood the soil parameters are related to the half-space below the upper layer.

Equations can now be combined to give a single matrix equation for an elastic layer over an elastic half-space, involving the *scaled* stiffness matrix for the elastic layer $[T_{ij}]$ and the matrix for the half-space $[P_{ij}]$. The general matrix form for any global domain becomes a 4×4 complex valued matrix:

$$[T]_G = \left[\begin{array}{cc:cc} T & T & T & T \\ T & T & T & T \\ \hdashline T & T & T\text{-}P & T\text{-}P \\ T & T & T\text{-}P & T\text{-}P \end{array}\right] \quad (15)$$

It is straightforward then to generalise this technique to n elastic layers over a half-space, where the size of the dynamic stiffness matrix will become a single complex-valued $2(n+1)\times2(n+1)$ matrix. On our case we have essentially two layers on a half-space ($n = 2$), which results in a 6×6 system.

3 NUMERICAL COMPUTATIONS

Generally, for non-dimensional wavenumbers $k_s h \geq 13$, where k_s is the shear wavenumber, the conventional approach "breaks down". That is, for depths greater than around two shear wavelengths, $h \geq 2\lambda_s$, a numerical bottleneck problem arises when solving the linear system of algebraic equations. Equally, for high frequencies, computations can become ill-conditioned. The choice of projected method permits a stable numerical evaluation for entries in the stiffness matrix for all soil types, frequencies and layer depths. This avoids numerical round-off errors.

It was found that numerical inversion of the Hankel transforms worked well with a cut-off at $R = 20\,\mathrm{m}^{-1}$ with $2,000$ sample points spaced logarithmically in the interval $\zeta \in [10^{-4}, R]$. Fast numerical Hankel methods, similar to Fast Fourier Transform (FFT), which are freely available, were not used in this work since our interest is in a few receiver positions.

4 RESULTS

Soil parameters used are presented in Table 1, that is two sets of soil characteristics which represent different conditions, soil and concrete. The response has been calculated for a disk-load with $b = 1.0$ m and subjected to a uniform unit load, $P = 1$ N. Calculation times for 100 frequency points on an i3-chip desktop took around 3.0 minutes in total. Integration was not particularly slow due to the modes associated to the deep bedrock stratum. Numerical integration is possible for all deep models and it is recommended to include an underlying half-space for computational and realistic modelling purposes, since bedrock models will include many modes.

Nonetheless the results presented are calculated using the Clenshaw–Curtis numerical quadrature method. The related ground parameters are shown in Table 1. The configuration is an elastic

circular block layer embedded 7.0 m deep within a half-space. To verify results of the simple model, we compare with a numerical scheme provided by COMSOL 5.2, see Fig. 1(b).

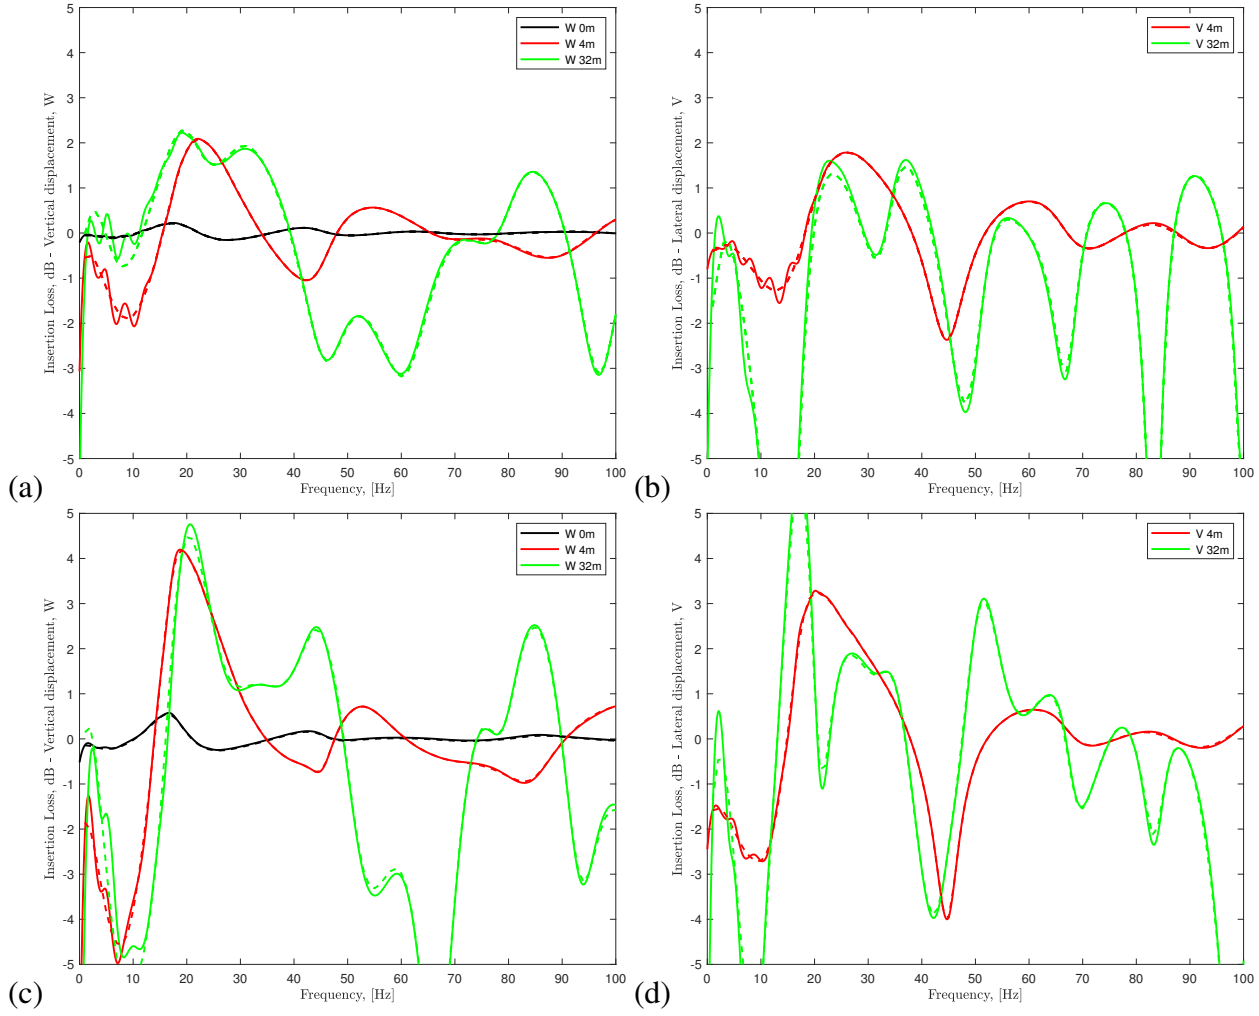

Figure 2: Verification of the method compared to a PML version in COMSOL 5.2 for: (a) and (b) 0.5 m deep embedded concrete block; and (b) and (c) a 2.0 m embedded block.

Our approach, as a possible measure for mitigating vibration, is based on the impeding behaviour of a soil layer over a bedrock. It occurs if the excitation frequency is below the lowest eigenfrequency of the layer. Since it is not convenient to develop real bedrock layers below buildings, where the length of the block in Fig. 1 tends to infinity, for example, we may use a stiff finite-length obstacle as an artificial bedrock instead. The results correspond to the possible positive effect for replacing bedrock by a feasible concrete block. For a bedrock layer at depth, $H = 7.0$ m, the first eigenfrequency related to shear waves is around 10 Hz. We only show two examples where the rigid bedrock is approximated by a concrete block, 0.5 m thick, with various lengths and evaluated at three receiver positions.

Figures 3(a) and (b) correspond to amplitude increase or decrease, against the half-space response, as the thin 0.5 m concrete block increases width from $L = 2.0$ m, to $L = 4.0$ m to $L = 12.0$ m with respect to the receiver position 4.0 m from the load-centre. For both vertical and longitudinal motion we observe a characteristic dip in insertion loss below the cut-on frequency with a slight insertion loss up to 2 dB performance in the interval 20 Hz to

40 Hz. A concrete block of length 12.0 m appears to approximate well as a substitute for an infinite layer. Figures 3(c) and (d) correspond to amplitude increase or decrease as the thin 0.5 m concrete block increases width from $L = 8.0$ m, $L = 16.0$ m to $L = 24.0$ m with respect to the receiver position 16.0 m from the load–centre. Here, the complex interactions below cut-on are evident, again a possible 2 dB insertion loss between 20 Hz and 40 Hz seems possible. Figures 3(e) and (f) correspond to amplitude increase or decrease as the thin 0.5 m concrete block increases width from $L = 24.0$ m, $L = 32.0$ m to $L = 40.0$ m with respect to the receiver position 32.0 m from the load-centre. As the receiver position increases its distance from the load, the concrete block, substituting a rigid layer foundation, also requires greater length Again the possible effectiveness as a mitigation device reduces to below 40 Hz.

5 CONCLUSIONS

An axisymmetric three-dimensional model has been developed for investigating the propagation of surface vibration over arbitrary-depth elastic layers. The model consists of an elastic, isotropic and homogeneous layer which overlies a half-space. A well-conditioned dynamic stiffness matrix has been developed for this model, which is derived by considering a different set of characteristic functions.

We have shown that by including a bedrock foundation buried under a surface load this can have a positive effect in reducing vibration across the surface of the ground, in certain frequency bands. However, below the *cut–on* frequency, in which travelling waves cannot propagate, the effectiveness is difficult to assess.

Rather than turning to large-scale finite element models we have shown that it is possible to draw conclusions for vibration reduction assessments from an alternative general semi-analytical model. In future work we shall extend the semi-analytical model illustrated in this work from the axisymmetric case to general three-dimensional models.

EFFICIENT PROPORTIONAL DAMPING MODEL FOR SIMULATING SEISMIC RESPONSE OF LARGE-SCALE STRUCTURES

Chin-Long Lee[1]

Keywords: Proportional Damping Model, Constant Modal Damping Ratio, Sparse Matrix, Large Number of Degrees of Freedom, Computational Efficiency.

Abstract. *An efficient proportional viscous damping model is proposed to simulate energy dissipation in a large-scale structure due to components not already accounted for by hysteretic material models. The proposed model overcomes the limitations of existing models, e.g. Rayleigh model, Caughey model, Wilson-Penzien model, and a generalized proportional model, that are either inflexible in matching a damping ratio curve in the structural frequency domain, or computationally expensive for response history analysis due to a fully populated damping matrix, or both. The proposed model allows a smooth function without large oscillation to match damping ratios across a wide range of frequencies. The damping matrix of this model can be implemented exactly as a sparse block matrix without using an approximate version, leading to very fast computation for response history analysis. The larger the number of degrees of freedom, the more computationally efficient is the proposed model compared to existing models that result in a fully populated damping matrix. Several case studies are reported to showcase the superior performance of the proposed model against existing models in terms of accuracy and computational efficiency.*

1 INTRODUCTION

In a typical seismic analysis of a large-scale structure, proportional viscous damping models are popularly used to simulate damping. They are particularly preferred to other non-proportional or non-viscous damping models in the consideration of computational cost and calibration against measured damping ratios.

Popular models usually considered include Rayleigh model [1], Caughey model [2; 3], and Wilson-Penzien model [4]. A generalized proportional model has recently been proposed [5] but is not as popular.

In the following, the advantages and disadvantages of these models will be reviewed, focusing on the accuracy in matching a user-defined damping ratio curve in the structural frequency domain, and the computational efficiency in computing displacement solutions from time step to time step in a response history analysis.

In terms of accuracy for matching a curve, the Rayleigh model, with only two terms, could only match modal damping ratios for two modes. For other modes, the damping ratios follow the curve controlled by these two modes. The Rayleigh model is, therefore, very inaccurate in matching a curve for a structure with more than two modes. The Caughey model allows the modal damping ratio to be matched at a lot more modes. Unfortunately, the curve often oscillates drastically, with some parts potentially fall into a negative region. The matrix for determining the coefficients also becomes ill-conditioned when more terms are considered. The coefficients would eventually become sensitive to round-off errors. The Wilson-Penzien model directly matches a damping ratio at each mode. However, it requires a costly computation of eigendecomposition to determine structural frequencies and mode shapes. To reduce this cost, only the frequencies and mode shapes for some lower modes are calculated. Consequently, most higher modes become undamped. A stiffness proportional term could be added to avoid undamped higher modes [6], but the corresponding damping ratios are forced to follow this linear curve. The generalized proportional damping model generates the damping ratio with general functions including square root, trigonometric, hyperbolic, or exponential functions. Compared to the previous models, it is much more flexible in matching an arbitrary damping ratio curve.

In terms of computational cost, it is important to note that the computational cost is directly related to the number of nonzero elements in the damping coefficient matrix $\mathbf{C}$. The sparser the $\mathbf{C}$ matrix, the lower the computational cost. The Rayleigh model forms the $\mathbf{C}$ matrix with a mass proportional term and a stiffness proportional term. Since it gives a $\mathbf{C}$ as sparse as the stiffness matrix, it is computationally very efficient. The Caughey model forms the $\mathbf{C}$ matrix with each term written as $\mathbf{M}\alpha_l(\mathbf{M}^{-1}\mathbf{K})^l$, where l is an integer, $\mathbf{M}$ the mass matrix, and $\mathbf{K}$ the stiffness matrix. Its $\mathbf{C}$ matrix is often dense and even fully populated. It also requires $\mathbf{M}$ to be invertible, which is, unfortunately, rare for large-scale structures based on lumped masses. The Wilson-Penzien model forms the $\mathbf{C}$ matrix by superposition of modal damping matrices. The resultant $\mathbf{C}$ matrix is generally fully populated for the degrees of freedom (DOFs) with mass inertias, even if only a few modes are included. The generalized proportional damping model forms the $\mathbf{C}$ matrix using general functions of $\mathbf{M}^{-1}\mathbf{K}$, $\mathbf{K}^{-1}\mathbf{M}$, $\mathbf{K}\mathbf{M}^{-1}$, or $\mathbf{M}\mathbf{K}^{-1}$. Its $\mathbf{C}$ matrix is likely fully populated. In addition, it is not always computationally friendly for computing functions of matrices, and the cost is likely in the same order of computing eigendecomposition. It also requires either $\mathbf{M}$ or $\mathbf{K}$ to be invertible, making it undesirable for lumped mass

systems commonly used for large-scale structures.

As discussed above, the existing models are not only very inflexible in matching damping ratios but also very costly for computing structural response due to a fully populated $\mathbf{C}$ matrix, or both.

In addressing the above limitations, the author has recently proposed a proportional viscous damping model [7]. This model has the following advantages over existing models:

- Damping ratios can be matched for any number of modes,
- The damping ratios at the zero and infinite frequencies are zero, avoiding spurious damping forces on DOFs without mass inertia [8] and unrealistic damping forces during rigid body motions, and
- The resultant damping ratio curve is smooth without large oscillation and is accurate for a constant damping ratio across a wide range of frequencies.

This model is further discussed in this paper in terms of computer implementation, which is not yet reported in the last paper [7]. The focus will be placed on the sparsity of the resultant damping $\mathbf{C}$ matrix and its computational efficiency for computing solutions, particularly for a large-scale structure with a large number of DOFs. Several examples will be used to showcase its advantages compared to other damping models. Due to space limitation, only key results will be presented in this paper to demonstrate the computational efficiency of the proposed model. Detailed discussions on the formulas and computer implementations of the proposed model have been submitted to a journal and will soon be made available to keen readers.

2 PROPOSED DAMPING MODEL IN FREQUENCY DOMAIN

The proposed model [7] generates a curve of modal damping ratio ζ in the domain of structural circular frequencies ω by a sum of multiple basis functions $N(\omega)$. Each basis function is a bump-like function given in Eq. (1) and plotted in Fig. 1.

$$N(\omega;\omega_p) = \frac{2\omega_p\omega}{\omega_p^2+\omega^2} \tag{1}$$

The parameter ω_p is the frequency at the peak of the function, serving as the parameter

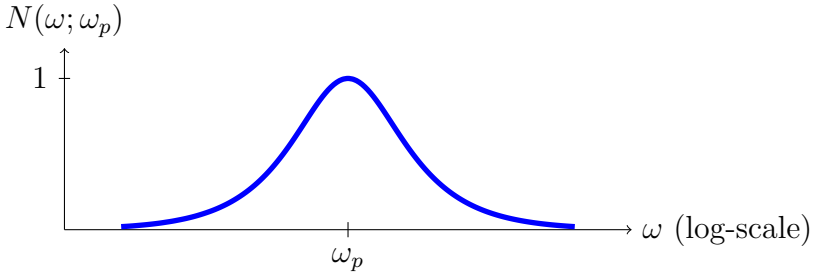

Fig. 1: Basis function of proposed damping model in frequency domain.

controlling the location of the peak.

The basis function is non-negative, has only one unit peak at frequency ω_p, is symmetric about the line where $\omega = \omega_p$ on the logarithmic scale, has a constant bandwidth independent of ω_p on the logarithmic scale, approaches asymptotically to zero at the two

extreme limits of frequencies, i.e. $\omega = 0$ and $\omega = \infty$, is a zero function when $\omega_p = 0$ or $\omega_p = \infty$, is independent from functions with different ω_p, and is symmetric with respect to ω_p and ω, i.e. $N(\omega;\omega_p) = N(\omega_p;\omega)$.

With n_b number of basis functions an arbitrary modal damping ratio curve could be generated with the following equation.

$$\zeta(\omega) = \sum_{j=1}^{n_b} N(\omega;\omega_{p_j})\zeta_{p_j} \tag{2}$$

where ζ_{p_j} is the ζ-coordinate of the peak for the j^{th} basis function. For example, suppose a constant damping ratio of 5% is matched for frequencies between 0.1 Hz and 10 Hz, three basis functions could be used to generate this curve. The values of ω_p's and ζ_p's can be obtained by using a least squares curve fitting method. The resultant damping ratio curve is shown in Fig. 2. The figure shows that the damping ratio curve matches the constant

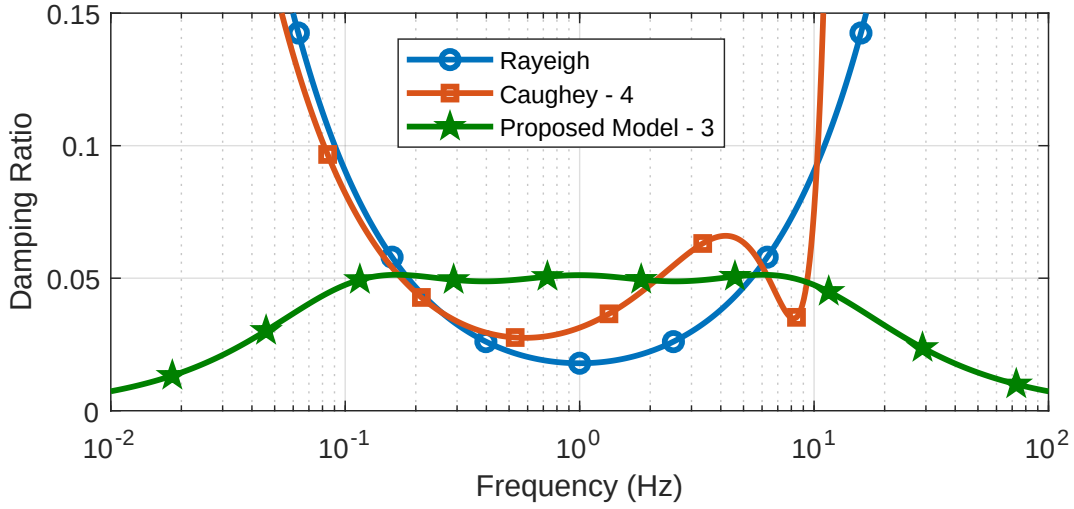

Fig. 2: Damping ratio curves generated using Rayleigh, Caughey and proposed damping models.

damping ratio within the frequency interval of [0.1 Hz, 10 Hz] with high accuracy. There is oscillation within the interval but the relative error is within 2 to 3%, and the error reaches 5% only at the ends of the interval. This error is considered negligible, as can be shown in an example later. If so desired, more basis functions could be added to further reduce the error. Outside the interval, the damping ratio decreases asymptotically to zero on the logarithmic scale. For comparison, the curves obtained using the Rayleigh and the Caughey models (4 terms) are also plotted for comparison. They were also obtained using a least squares curve fitting method. Their curves have much larger errors that are evidently unacceptable.

3 MATRIX FORM, SPARSITY AND COMPUTATIONAL EFFICIENCY

The proposed model has the damping coefficient matrix $\mathbf{C}$ shown in the following when one basis function is used.

$$\mathbf{C} = \mathbf{M_C} - \mathbf{M_C}\left(\mathbf{K_C} + \mathbf{M_C}\right)^{-1}\mathbf{M_C} \tag{3}$$

where $\mathbf{M_C}$ and $\mathbf{K_C}$ are defined as

$$\mathbf{M_C} = 4\zeta_p\omega_p\mathbf{M}, \quad \mathbf{K_C} = \frac{4\zeta_p}{\omega_p}\mathbf{K} \tag{4}$$

It is, nonetheless, fully populated. However, unlike other models, this form can be expanded into a larger block matrix $\mathbf{C_X}$ of size $2n \times 2n$, where n is the number of DOFs, shown in the following for one basis function

$$\mathbf{C_X} = \begin{bmatrix} \mathbf{M_C} & -\mathbf{M_C} \\ -\mathbf{M_C} & \mathbf{K_C} + \mathbf{M_C} \end{bmatrix} \tag{5}$$

This matrix $\mathbf{C_X}$, an expanded matrix form of $\mathbf{C}$, has the number of DOFs doubled. The first block row corresponds to the usual displacement DOFs, and the second block row corresponds to a new set of DOFs being introduced. When multiple basis functions are used, the matrix will be expanded further with more block rows. Although the size of $\mathbf{C_X}$ is larger than $\mathbf{C}$, it is much sparser, as explained below using an example to compare $\mathbf{C}$ and $\mathbf{C_X}$.

Consider a two-dimensional simply-supported beam. Suppose it is discretized into 101 beam elements with 100 free transverse DOFs and 100 free rotational DOFs. The axial DOFs are ignored. The mass of the beam is lumped at the nodes and the mass inertias are only considered for transverse DOFs. As a result, $\mathbf{M}$ is diagonal and $\mathbf{K}$ is banded. Note, although a simple structure is used in this comparison, the ensuing conclusions will be the same should this structure be much more complex like multi-span bridges or multi-story multi-bay buildings.

Fig. 3 shows the sparsity patterns of the two matrices $\mathbf{C}$ and $\mathbf{C_X}$ for this chimney using a MatLab™ function `spy` that shows a dot at the corresponding row and column indices for each nonzero in the matrices. In this example, four basis functions are used to form the damping matrices, covering the frequency interval of [0.1 Hz, 10 Hz]. The size of $\mathbf{C_X}$ is 1000×1000 because each basis function requires a new set of 200 DOFs to be introduced.

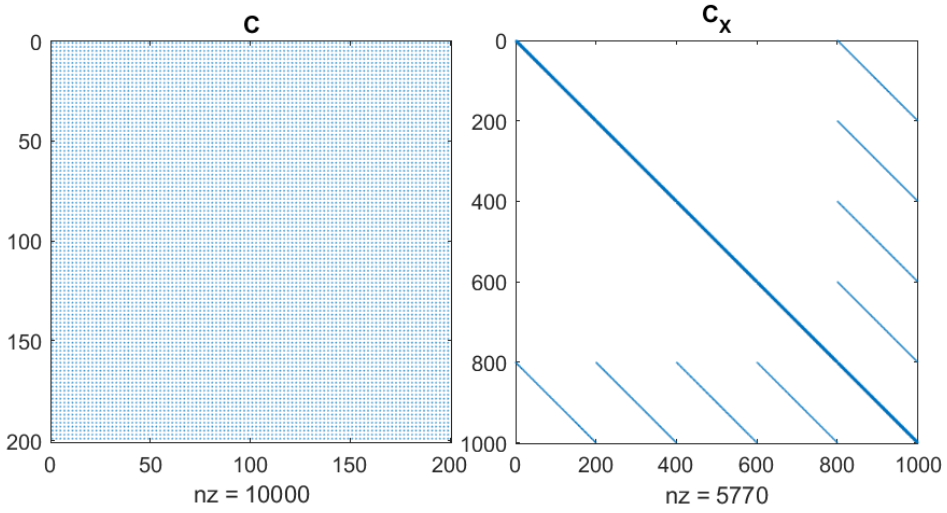

Fig. 3: Comparison of sparsity patterns of $\mathbf{C}$ (left) and $\mathbf{C_X}$ (right).

This example shows that, although $\mathbf{C_X}$ is much larger in size than $\mathbf{C}$, it is much sparser. In fact, the ratio, denoted as r, between the numbers of nonzeros in $\mathbf{C_X}$ and of nonzeros in $\mathbf{C}$ is inversely proportional to the number of DOFs n.

$$r \overset{\text{def}}{=} \frac{nnz(\mathbf{C_X})}{nnz(\mathbf{C})} = O(1/n) \tag{6}$$

In other words, the larger the number of DOFs, the fewer are the nonzeros in $\mathbf{C_X}$ compared to a fully populated $\mathbf{C}$ of other damping models. This ratio of comparison also applies to the time required to compute the displacement solutions using the effective tangent stiffness based on $\mathbf{C_X}$ and $\mathbf{C}$. Fig. 4 shows the ratio r for number of nonzeros and the elapsed time required estimated using MatLab functions `tic` and `toc`, with increasing number of DOFs. The solution process is based on MatLab's backslash (\) operation, i.e. `mldivide`, which has been optimised for each matrix type. The computer used was a personal desktop computer. Note, the solutions using $\mathbf{C_X}$ and $\mathbf{C}$ are practically identical with negligible differences due to round-off errors.

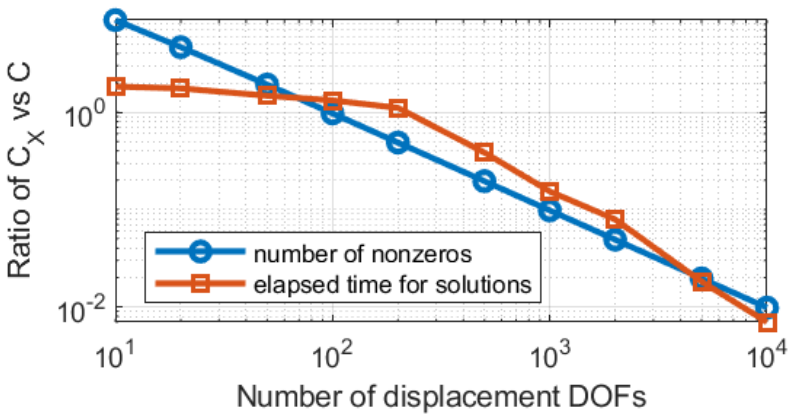

Fig. 4: Ratio of $\mathbf{C_X}$ vs $\mathbf{C}$ for number of nonzeros and elapsed time for computing solutions.

Fig. 4 shows that the ratio r for the number of nonzeros and the elapsed time for computing solutions in this example is indeed inversely proportional to the number of DOFs. The increase in efficiency is at least 100 times when n is larger than 10,000. This example clearly shows the remarkable performance of the proposed model with the expanded representation of the damping matrix, i.e. $\mathbf{C_X}$, in terms of memory storage and computational efficiency. Nevertheless, when n is small, it may be better to use the original matrix representation of damping matrix, i.e. $\mathbf{C}$.

4 EXAMPLE OF RESPONSE HISTORY ANALYSIS

In this example, the accuracy of the proposed model is compared against the Wilson-Penzien model in response history analysis. The structure considered is a two-dimensional 1-bay 5-story steel frame with fixed based. The story height is 2.5 m and the bay width is 3 m. All the beams are 610UB125kg/m and all the columns are 310UC158kg/m. They are modelled using concentrated plastic hinge element with N-M interactions incorporated. The yield strength of the materials is 300 MPa. Masses are lumped at nodes. Only horizontal mass inertias are considered. Vertical and rotational mass inertias are ignored. Each mass is 15300 kg. The five fundamental frequencies of the structure are 1.9 Hz, 6.0

Hz, 10.9 Hz, 15.3 Hz, and 18.6 Hz. The damping ratio is 5% for the first three modes. For the proposed model, two basis functions are used such that the relative error within the frequency interval covering the first three modes is about 2%. The damping ratios using the Wilson-Penzien model and the proposed model are shown in Fig. 5. The damping ratios at structural frequencies are highlighted with markers. The damping matrix remains

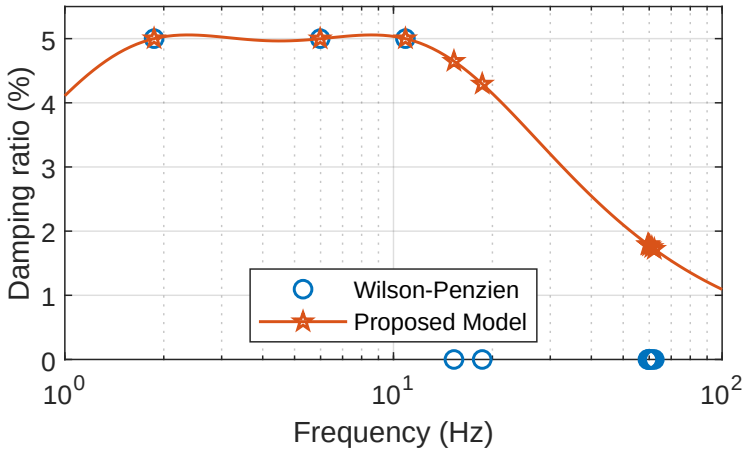

Fig. 5: Damping ratios using Wilson-Penzien and proposed damping models.

constant throughout the analysis, as suggested by Chopra [8]. The ground motion is the North-South component of the 1940 El Centro earthquake with its PGA scaled to 1 g.

The roof displacement time histories are shown in Fig. 6. The comparison shows that

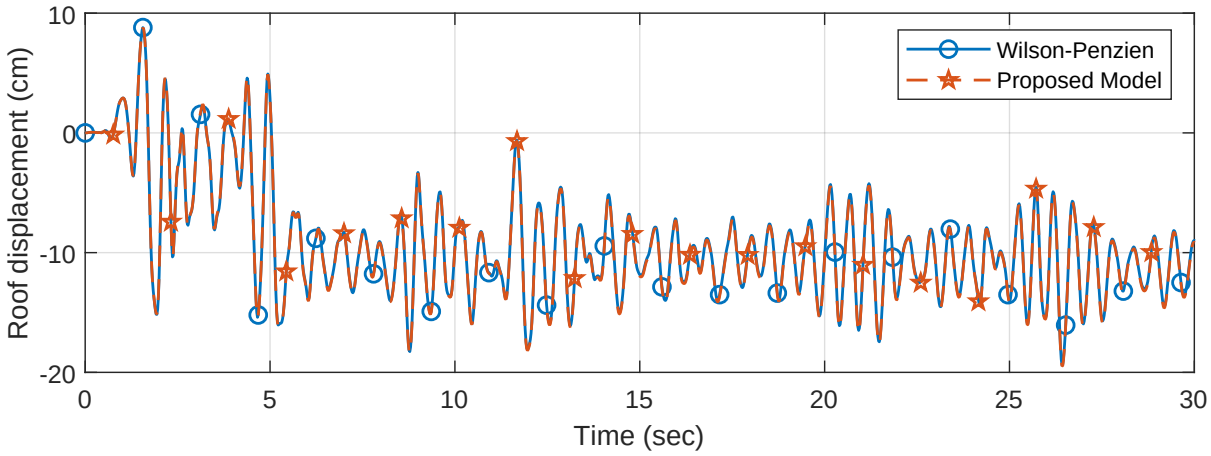

Fig. 6: Roof displacement time histories using Wilson-Penzien and proposed damping models.

both models give almost identical roof displacement time histories. It proves that the proposed model is as accurate as the Wilson-Penzien model for this structure where the lowest three modes dominate the roof displacement response.

5 CONCLUSIONS

A proportional viscous damping model has recently been proposed. It generates a damping ratio curve with multiple bump-like basis functions controlled by frequency and

damping ratio at the peak of each basis function. It is accurate for matching a constant damping ratio typically used in the earthquake engineering community for a response history analysis of large-scale structures.

In this paper, the matrix form of this model has been introduced, and its computer implementation has been discussed, with its computational efficiency emphasized. It has its damping matrix in a special form that can be expanded into a sparse block matrix. Although the expanded block matrix is much larger than the original damping matrix, it is much sparser. The computation of solution using this block matrix is, therefore, much faster compared to a fully populated damping matrix of existing models. The ratio of nonzeros between the block matrix and the original matrix is inversely proportional to the number of degrees of freedom. The larger the number of degrees of freedom, the faster the computation. The proposed model is, therefore, suitable for a structure with a large number of degrees of freedom. Some case studies have been reported to showcase the performance of the proposed model against existing models in terms of accuracy and computational efficiency.

6 ACKNOWLEDGEMENTS

The author thanks Prof. Athol Carr of the University of Canterbury, Christchurch, for many helpful discussions on the problems and challenges of existing damping models.

Keywords: drilling element, RC shear wall, nonlinear dynamic analysis

Abstract. *To simulate reinforced concrete shear walls under seismic loads, a new finite element called GCMQ (generalized conforming mixed quadrilateral) developed based on the three-field Hu-Washizu variational principle is adopted in this paper for the nonlinear time history analysis of a reinforced concrete shear wall multistory building. Unlike other well-known 1D wall elements, GCMQ is a 2D membrane element that exhibits very good performance in terms of coarse mesh accuracy. It takes into consideration the nonlinear distribution of both strain and stress across the wall width, which is difficult to achieve with 1D elements that often adopt 'plane sections remain plane' assumption. Two shear wall examples are analysed in this paper. With a smeared approach adopted for reinforcement and a proper material model for concrete, GCMQ can simulate accurate global response with a coarse mesh grid. For time efficient analysis, one element per storey could also be adopted. GCMQ provides a more versatile solution to wall simulation and could be a useful tool in future analysis and design of wall structures.*

1 INTRODUCTION

Unlike slender structural members such as beams and columns that could be idealised as 1D finite elements, modelling reinforced concrete shear walls is in general a difficult task due to the conflict between efficiency and accuracy of numerical analyses. Classic finite elements such as four-node isoparametric quadrilateral element (Q4) can, of course, be adopted to develop fine models for static analysis. However, such an approach is not practicable when it comes to nonlinear time history analysis due to the large amount of computational power required, particularly with very dense mesh grids. On the other hand, recently proposed 1D macroscopic elements, such as MVLEM [1] and its variants, including SFI-MVLEM [2], are typically formulated based on spring systems. Although they are relatively more efficient, those elements lack proper justifications in terms of representing the physical problem from continuum mechanics perspective. As a result, the error of analysis could be significantly large and convergence to theoretical solutions may not be guaranteed.

To ease the problem, as well as to achieve a better balance between analysis efficiency and accuracy, a mixed membrane element called GCMQ (generalized conforming mixed quadrilateral) is proposed recently [3]. This paper evaluates the performance of GCMQ in the context of nonlinear time history analysis. Two examples are presented to showcase both linear elastic and inelastic performance. The formulation of GCMQ is briefly discussed first, followed by a summary of material models used. The performance in simulating two cantilever walls is then investigated. The numerical results indicate that GCMQ is a good element for future nonlinear response history analysis of shear wall structures.

2 THE GCMQ ELEMENT

The GCMQ element is a mixed four-node quadrilateral with in-plane drilling degrees of freedom. It is formulated in a three field framework based on a modified Hu-Washizu variational theorem. The displacement field is split into two components by using additive decomposition. An illustration of such a procedure can be seen in Fig. 1. The distortion $\mathbf{u}_d$ is generated purely by the drilling degrees of freedom.

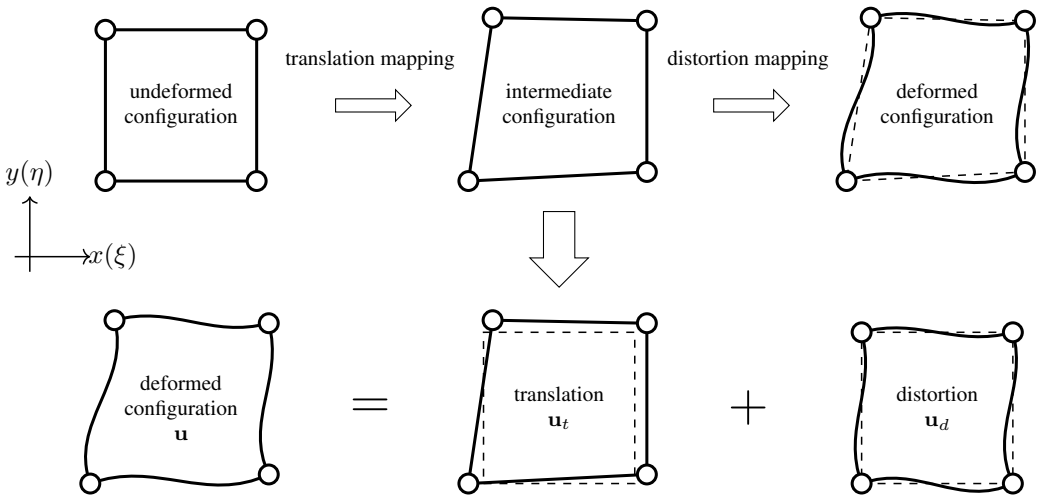

Figure 1: Deformation decomposition.

Another feature of GCMQ that is worth mentioning is the fully interpolated stress field which is complete up to second order. It also satisfies the stress equilibrium. Various stress patterns

could be described, some of which are shown in Fig. 2. Although such a stress field does not possess inter-element continuity, it is considered to be sufficient for elements without edge loadings.

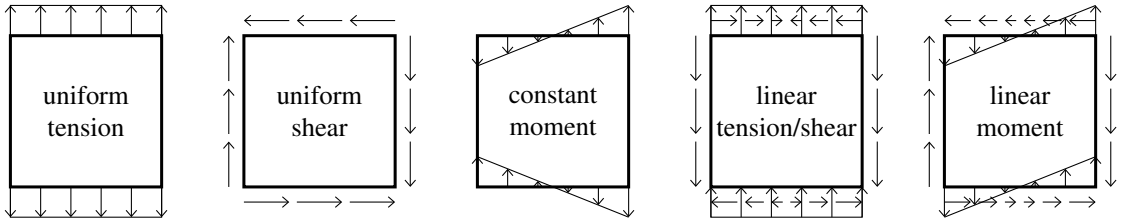

Figure 2: Stress patterns of selected terms.

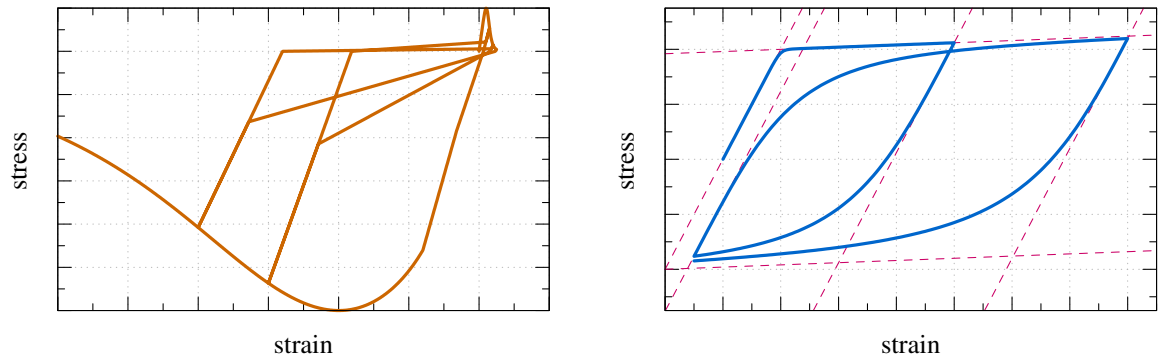
For numerical integration, compared to other elements, more choices are provided in GCMQ. Three different schemes are proposed. They are:

1. GCMQ-I: five-point scheme, four at element edge centres, one at element centre.
2. GCMQ-L: nine-point Lobatto scheme, eight on edges, one at element centre.
3. GCMQ-G: nine-point Gauss scheme, all nine points located inside element.

All three schemes are tested in this paper. For different types of analysis, different schemes may be recommended due to their different performance and efficiency. Details are presented in the following sections.

3 MATERIAL MODELS

For linear analyses, an isotropic elastic material model is used. For idealised inelastic analyses, a bilinear isotropic hardening model with the J2 yield criterion and associative plasticity is adopted for the ease of obtaining a converged solution. The corresponding material parameters are chosen to be close to that of concrete.



(a) concrete model (b) steel model

Figure 3: Schematic sketches of the material models used in analyses.

For a more realistic concrete model, a fix crack planar concrete model that incorporates a Rankine type square initial yield surface is used. The formulation resembles the one presented

by Crisfield and Wills [4]. Similar formulations can be seen elsewhere. For simplicity, no coupling effect between two crack directions are considered. For each direction, the uniaxial concrete model uses Tsai's equation [5] as the backbone and a simple linear hysteresis rule. An illustrative example is depicted in Fig. 3a. It shall be noted that the parameters are tweaked for a clearer plot and do not represent a real concrete behaviour. The shear response is assumed to be bilinear elastic with a shear retention factor to account for dowel action, aggregate locking, etc. Such a concrete model is simple and in most cases convergence can be achieved with little computational effect. Nevertheless, other more complex material models [6, 7] can also be used.

Reinforcement is implemented in a smeared approach. In this work, all reinforcements are assumed to be uniformly distributed and they do not necessarily represent the real rebar layout. An alternative could be the combination of both concentrated and smeared reinforcement. The Menegotto-Pinto steel model [8] is used to simulate the behaviour of reinforcement. A representative example is shown in Fig. 3b.

4 WALL EXAMPLES

Two different wall examples are presented for different purposes. A summary is shown in Table 1. For both examples, no vertical load is considered for simplicity and only horizontal point mass is applied. The Rayleigh damping model is used.

Table 1: Summary of wall examples.

	type	material	excitation	purpose
Example 1	cantilever	homogeneous	long impulse	performance baseline in both elastic and inelastic cases
Example 2	cantilever	reinforced concrete	El Centro (NS)	general performance with RC material

4.1 Example 1 — A cantilever beam

The first example is a simple cantilever wall with isotropic material models, which is illustrated in Fig. 4. A critical damping of $5\,\%$ is applied to the first two modes via Rayleigh

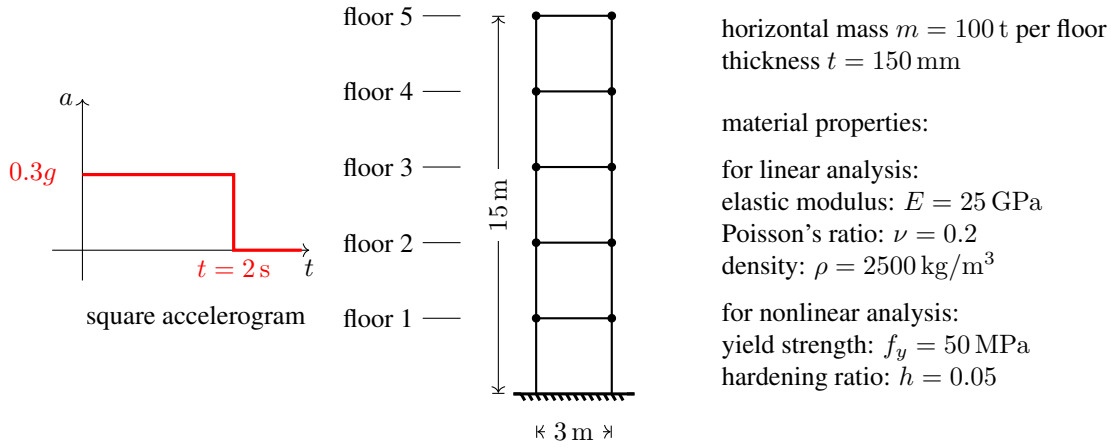


Figure 4: An idealised wall specimen

damping model. A long impulse with a constant acceleration of $0.3g$ is used as excitation with

the duration (2 s) twice the first period. The main purpose of such a choice is to suppress high frequency response as much as possible so that the comparison and analysis of results would become clearer.

4.1.1 Natural period

Before presenting natural frequencies/periods, various formulations of mass matrix $\mathbf{M}$ are first discussed. Several approaches are available:

1. Full rank consistent formulation derived from nodal displacement shape function,
2. Diagonalised (lumped) consistent mass matrix.The off diagonal terms are omitted while the main diagonal terms are scaled,
3. Rank deficient consistent mass matrix with drilling components omitted. This mass matrix is identical to the one of Q4, with additional zero rows and columns at drilling DoFs, and
4. Lumped version of the rank deficient consistent mass matrix.

The modal analysis is performed with the above four mass matrices. The first four frequencies are listed in Table 2. Numerical investigations show neither two lumped formulations nor two consistent matrices show significant difference. Hence only two categories are shown in the table. With a coarse mesh grid, GCMQ is able to predict the periods of lower modes with good accuracy, this could be validated by the result of a beam model. Compared to beam and Q4 elements, GCMQ is softer and produces smaller frequencies. Furthermore, consistent formulations give slightly higher frequencies than lumped versions. Also, since Gauss scheme has a higher integration accuracy, GCMQ-G predicts a more accurate fourth frequency than that of the other two schemes. In conclusion, all four mass formulations could be used in practical analysis. The lumped versions can be adopted for a smaller matrix storage.

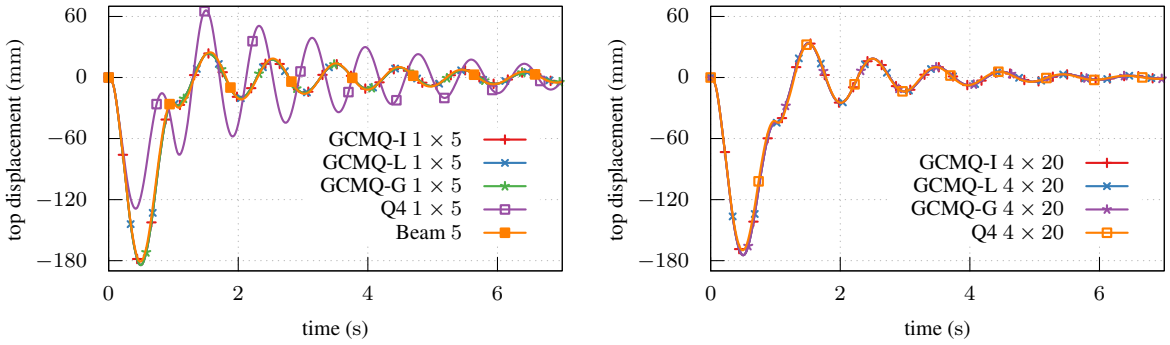
4.1.2 Dynamic analysis

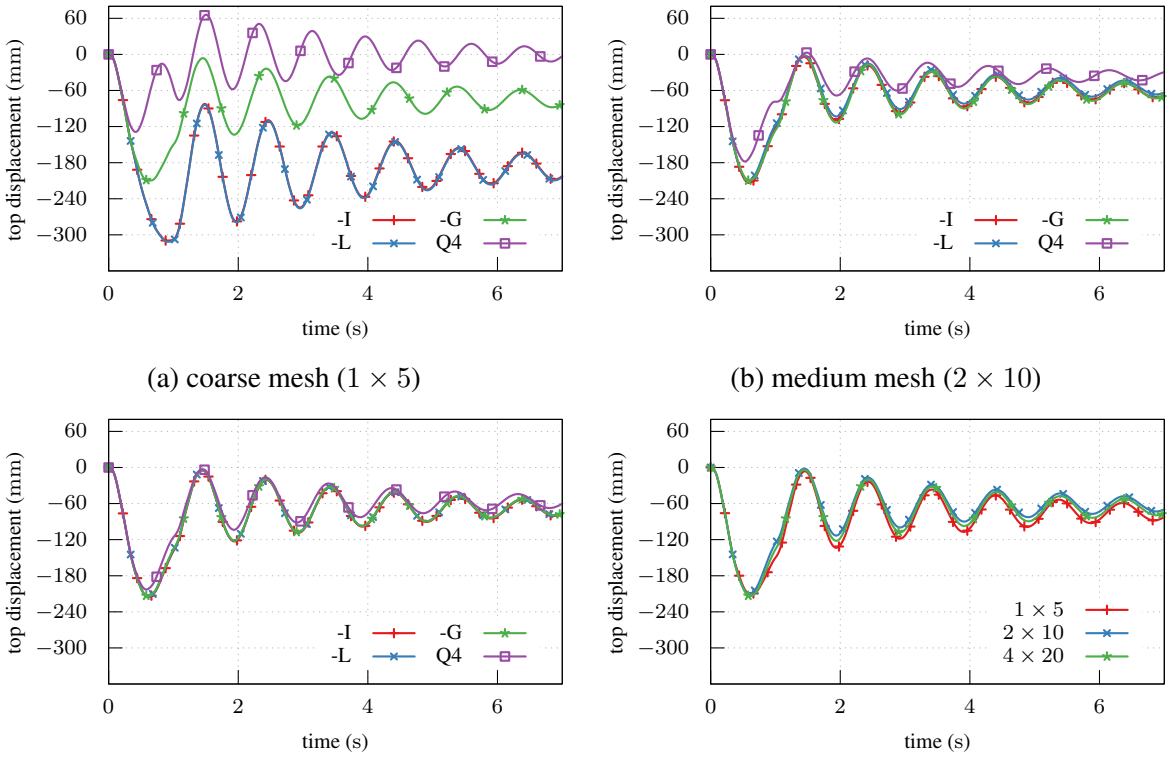
The consistent mass matrix is used in the following examples. Fig. 5 shows the linear displacement history of Example 1 using linear elastic material model. According to Fig. 5a,

GCMQ and beam models give very close response. However, with the same mesh grid, Q4 model is stiffer and results in quite a different response. It can be spotted that with mesh refinement, Q4 model can converge to the same solution to that of GCMQ and beam models. It could be concluded that GCMQ element could be used with very coarse mesh grids to predict accurate response.



(a) coarse mesh (b) mesh refinement

Figure 5: linear displacement history due to long impulse



(a) coarse mesh (1 × 5) (b) medium mesh (2 × 10)

(c) fine mesh (4 × 20) (d) mesh refinement of GCMQ-G

Figure 6: nonlinear displacement history due to long impulse

The nonlinear displacement history is shown in Fig. 6. In this particular example, the model using five Q4 elements (with four quadrature points well inside the element) cannot develop any plasticity. Hence, as can be seen in Fig. 6a, there is no residual displacement generated by Q4

model. In the meantime, the GCMQ elements produce distinctive response. Due to that most integration points are located on element edges, GCMQ-I and GCMQ-L exaggerate plasticity development. As a result, the peak and residual displacements are large than that of GCMQ-G. However, with a 2×10 or denser mesh grid, the difference between three versions is negligible. Another important fact can be observed from Fig. 6d, that is, for inelastic applications, GCMQ-G has a very low initial error bound and the difference between three mesh grids are exceptionally small. With 5 elements, GCMQ-G could predict more accurate result than using 80 Q4 elements. It indicates that GCMQ-G could be used in practical simulations with the most coarse mesh grid.

4.2 Example 2 — A RC shear wall

This wall model is taken from Taylor's work [9] and is depicted in Fig. 7. The first two natural periods computed are $2.49\,\mathrm{s}$ and $0.45\,\mathrm{s}$, which are close to the values ($2.46\,\mathrm{s}$ and $0.42\,\mathrm{s}$) reported in the original literature. Taylor [9] adopted $10\,\%$ damping on the first two modes. It shall be emphasised that such a value is considered too large for RC shear walls. However, given that the Rayleigh damping model has its own issues in inelastic analysis [10, 11], here the authors have no intention of matching the damping ratio with a more realistic value. Meanwhile, the gross reinforcement ratio can be computed as $8\,\%$ for the bottom four floors. This value appears unrealistically large for such a wall section and may violate modern design practice. But as an illustrative example, no correction would be made, so that comparison with the original literature is possible. Another issue may be clarified is the relatively low strength of both concrete and steel, $21\,\mathrm{MPa}$ and $280\,\mathrm{MPa}$ respectively. These values are typical of 1970s. Nowadays, higher performance material would be used. The total mass w of the system is $56\,\mathrm{MN}$. The model is analysed with ten GCMQ-G elements (one per storey).

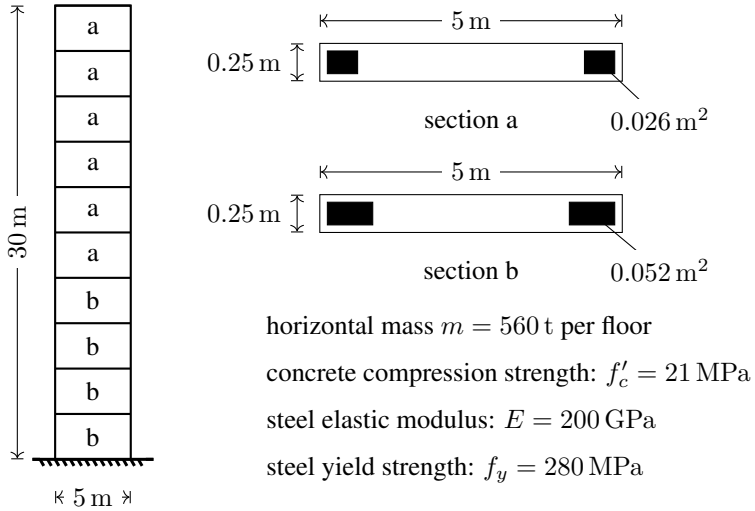


Figure 7: A reinforced concrete shear wall specimen

Fig. 8 shows the nonlinear displacement history for all floors. Clearly, it is dominated by the first vibration mode. The asymmetric behaviour of concrete leads to a one-sided displacement dominated history, which significantly differs from the linear response. The maximum displacement predicted is around $300\,\mathrm{mm}$, which is equivalent to $1\,\%$ drift. The residual drift is around $0.1\,\%$ due to the presence of a large amount of reinforcement.

The roof displacement against base shear/moment is plotted in Fig. 9. Although simple hysteresis rules are defined in concrete and steel material models, no explicit pattern can be found to relate material behaviour with global response of structure. This is because the roof displacement is mainly affected by the first vibration mode while the base shear has contributions from all modes of free vibration.

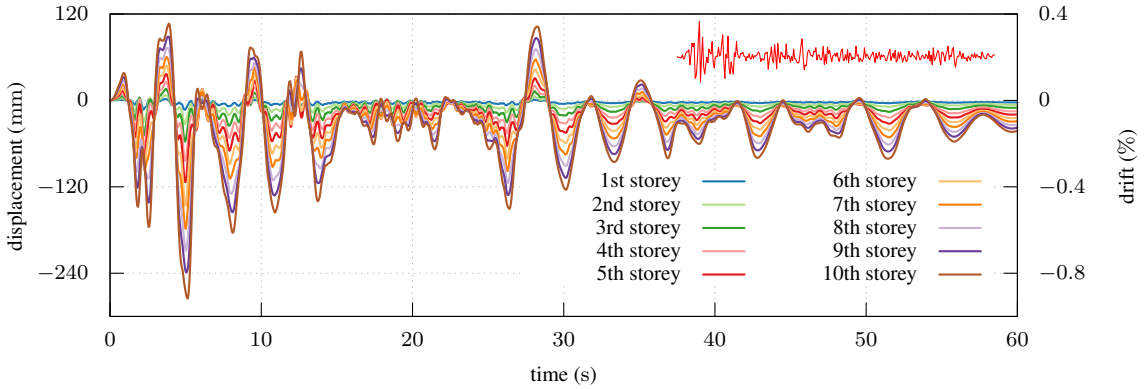

Figure 8: Nonlinear displacement history of Example 2.

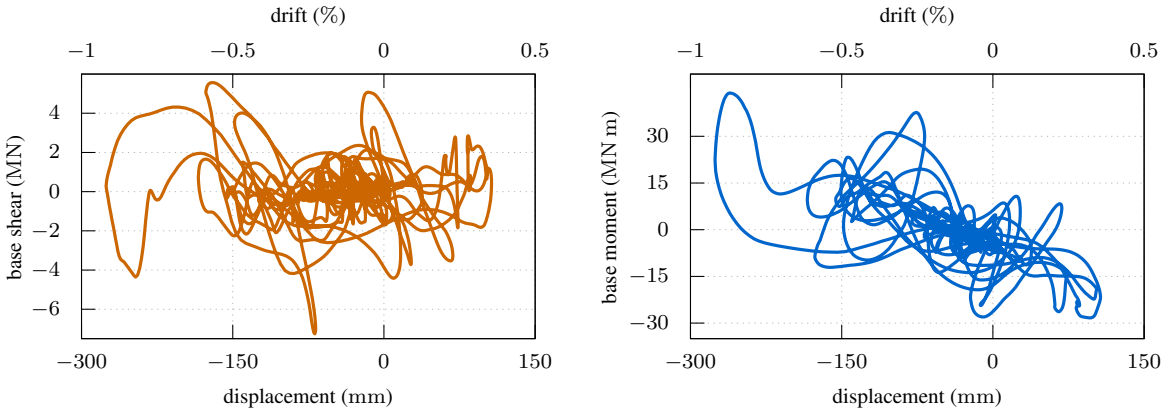
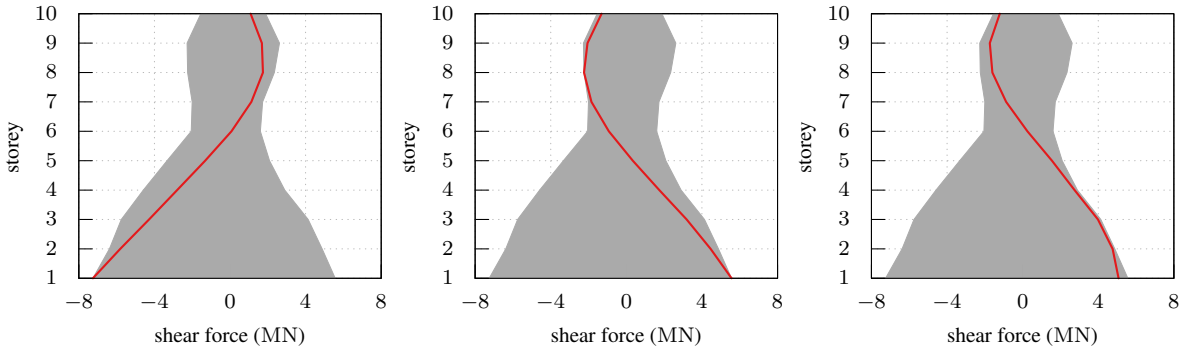


(a) base shear (b) base moment

Figure 9: Nonlinear hysteresis of Example 2.



(a) $t_1 = 2.173\,\mathrm{s}$ (b) $t_2 = 2.634\,\mathrm{s}$ (c) $t_3 = 12.285\,\mathrm{s}$

Figure 10: Distribution of shear forces with envelops of Example 2.

The distributions of storey shear forces at three distinct time points are plotted in Fig. 10 with their envelopes. Between sixth to seventh floor, shear force changes its sign, indicating that the maximum moment occurs here. Fig. 11 and Fig. 12 show the absolute acceleration and shear force history respectively for each storey. From the plots, it is clear to see the eighth storey experiences significantly smaller acceleration, indicating that the second mode is dominant in terms of acceleration.

5 CONCLUDING REMARKS

This paper presents evaluations of GCMQ in nonlinear dynamic analysis. As a guideline, the following recommendations are made for the use of GCMQ.

- For linear elastic analysis, all three versions of GCMQ converge to the same response with the most coarse mesh configuration (one element per storey). Since GCMQ-I could reduce the analysis time by about $30\,\%$, it is thus recommended.
- For inelastic analysis, GCMQ-G has a lower initial error bound, which results in an excellent response with the coarse mesh grid.
- For any mesh grids denser than one element per storey, the difference among all three versions of GCMQ is negligible. In such a case, to improve efficiency, GCMQ-I is recommended. Nevertheless, material objectivity shall be handled carefully to obtain mesh independent results.

The novel GCMQ element shows great potential in terms of coarse mesh accuracy. As it is formulated based on continuum mechanics theories, the convergence is guaranteed with mesh refinement. Compared to other wall elements, GCMQ is considered a better analysis tool for future simulations of wall structures. The GCMQ element has been implemented in `suanPan` [12], which is available online[1].

A DUAL FORMULATION OF CYCLIC SYMMETRY: APPLICATION IN FREE VIBRATION ANALYSIS

Keywords: Cyclic Symmetry, Dual Formulation, Free Vibration, Projected Arnoldi Algorithm, Preconditioner.

Abstract. *In this work, the cyclic symmetry boundary condition between sectors of a rotationally periodic structure are reformulated and the compatibility condition is imposed by means of Lagrange multipliers. In the augmented system, the constraint matrix carries the dependence on the nodal diameters (ND) whereas stiffness and mass matrices do not vary with ND. The Dual assembly formulation is exploited in the computation of eigenvectors and eigenvalues using a Preconditioned Projected Arnoldi Algorithm. The complex constraint matrix is used to build a projection operator, which imposes the compatibility constraint between the left and right side of the periodic geometry. Because the complex constraint matrix has orthogonal rows, the projector operator is easily assembled without the need of matrix inversion. The explicit factorization of the projected stiffness matrix is not required since Preconditioned Conjugated Gradient algorithm is used to solve the linear system during the inverse Arnoldi iteration step. Consequently, all ND share the same preconditioner reducing the global cost of eigenpairs computation, especially when multiple ND solutions are required. Five different preconditioners are tested to evaluate the numerical scalability of the linear solution: Identity, Projected Incomplete Chosleky, Projected Cholesky, Incomplete Cholesky and Cholesky. The Preconditioned Projected Arnoldi Algorithm is implemented in Python using the Scipy library which provides a wrapper for the Implicity Restarted Arnoldi method implemented in ARPACK. The projection and preconditioner steps are carried-out by Scipy sparse linear operator. The method is applied in 2D and 3D finite element models. The preconditioners studied can dramatically reduce the number of iterations when compared to CG without preconditioning. The full Cholesky preconditioner is on average 8 times faster than the identity precondicioner in the 2D, whereas it is approximately 16 faster in the 3D case. The factorizing is performed only once, and its computational cost can be divided among the different NDs, which makes the method especially advantageous for geometries with a large number of sectors.*

1 INTRODUCTION

Free vibration analysis plays an important role in understanding the dynamics of structures. It provides the natural frequencies which must be identified in order to avoid catastrophic failures due to resonances. Moreover, eigenmodes can be used to reduce the number of degrees of freedom by using Reduced Order Models (ROM) such as Craig-Bampton [1], Dual-Craig-Bampton [2], Rubin [3], among others. Despite its advantages, full eigenanalysis is very costly, which means that in many cases only the modes related to the lowest frequencies are relevant for practical problems. Therefore, Lanczos [4], and implicit restarted Arnoldi algorithms [5] are often used as eigensolvers due to their efficiency. The major cost of the algorithms mentioned lies in the inverse iteration, where the solution of a linear system is required.

When structures such as turbines, propellers, and gears are analysed, the property of rotational periodic symmetry is often utilized, reducing the computational cost of the linear system as well as the memory required to store the system matrices. Figure 1 shows a cyclic structure with the highlighted reference sector used for analyzing the whole geometry. In such cases, a Discrete Fourier Transform is applied in the equation of motion and in the compatibility condition between neighbors, which reformulates the problem in terms of harmonic indices. The speed-up is achieved by means of a harmonic decoupling among sectors when imposing the periodic condition by eliminating the constrained degrees of freedom, namely, primal assembly. In the work developed in[6], the cyclic symmetry is imposed by complex constraints relating the left to the right side. Considering a periodic structure composed of N sectors, which has θ as the sector angle, the classical cyclic boundary condition creates approximately $N/2$ different systems of equation to be solved independently. The number of variables is not changed by the harmonic transformation, because the transformed system has complex degrees of freedom. Therefore, the cyclic symmetry should not be understood as a reduction technique, since it is only a transformation operation. However, the decoupling provided by the harmonic decomposition results in the ability of solving independent problems for a given set of harmonic indices, also known as Nodal Diameter (ND). If cyclic symmetry is considered for ROM, not only a subset of modes must be selected but also a subset of nodal diameters. This is usually done by analyzing the possible excitations, using the Campbell diagram or SAFE diagram, see [7].

In this paper, the primal and dual assembly of cyclic constraints are presented using a substructuring framework and applied to the computation of the eigen-pairs of a cyclic structure. In the dual formulation, the cyclic constraints are described with a complex constraint matrix thereby rendering the system matrices, namely stiffness, and mass, unaffected. Due to the hybrid nature of the eigen-value problem in the dual formulation (displacements and Lagrange multipliers), the conventional eigen-solvers are not suitable. Therefore, a modified version of Projected Arnoldi algorithm is employed to efficiently solve the dual cyclic formulation. The novel approach introduces a preconditioning step in the inverse iteration of the Arnoldi process, which uses the reference sector without constraints. Five different preconditioners are tested to evaluate the numerical scalability of the linear solution, namely: Identity, Projected Incomplete Chosleky, Projected Cholesky, Incomplete Cholesky and Cholesky.

In the remaining sections the classical cyclic symmetry is formally introduced and the dual formulation is presented. The projected Arnoldi method is described, eigen-analysis is performed using the complex cyclic constraints and its projection operator. Three different Finite element test-cases are presented in order to show the application of the new formulation.

2 Classical Cyclic Symmetry Formulation

In this section, the classical theory behind cyclic symmetry boundary condition is summarized. Let us consider a geometry composed of N identical sectors, as shown in the Figure 1. If each sector has its own local coordinate system and no mistuning is considered, the equation of motion together with the compatibility constraint can be written as:

$$\begin{aligned} M\ddot{u}^s + Ku^s &= f^s + g^s \qquad s = 1, ..., N \\ Tu_l^s &= u_r^{s+1} \\ Tg_l^s &= -g_r^{s+1} \end{aligned} \tag{1}$$

where M and K are the mass and stiffness matrices respectively, f is the external force vector, g is the connecting forces among neighbors, and superscript s represents the index of a sector. The second expression in (1) represents the compatibility condition among sectors, where T is a rotation matrix, and the subscripts l and r represent the interface dofs of the left and right respectively.

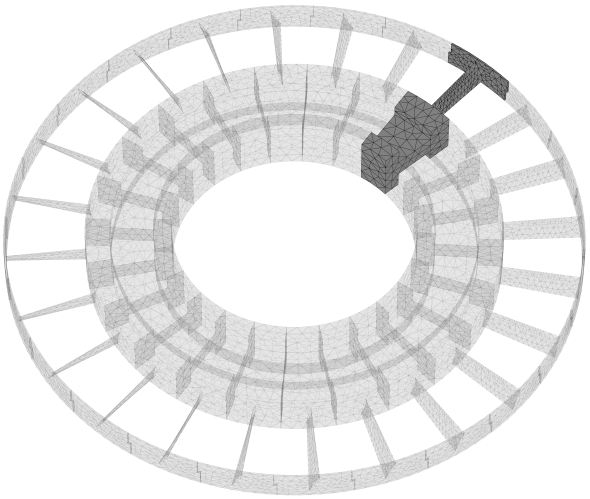

Figure 1: Cyclic Structure and the highlighted reference sector.

It is important to notice that given the choice of local coordinate system, the stiffness and mass matrices are the same for all sectors, however the transformation matrix T is required to define a proper compatibility condition. Applying a Discrete Fourier Transform in space $\{\mathcal{F} : u^s \rightarrow u^n \quad | \quad \sum_{s=1}^{N} u^s e^{-jn\theta s}\}$ in (1) and rewriting the displacement solution, interface force and external forces in terms of Fourier Series:

$$\begin{aligned} u^s &= \frac{1}{\bar{N}} \sum_{n=0}^{\bar{N}} u^n e^{jn\theta s} \\ g^s &= \frac{1}{\bar{N}} \sum_{n=0}^{\bar{N}} g^n e^{jn\theta s} \\ f^s &= \frac{1}{\bar{N}} \sum_{n=0}^{\bar{N}} f^n e^{jn\theta s} \end{aligned} \tag{2}$$

where $j = \sqrt{-1}$ is the imaginary unit, $\theta = \frac{2\pi}{N}$ is the sector angle, n is the nodal diameter index, and $\bar{N}$ is the largest nodal diameter index such that:

$$\begin{aligned} \bar{N} &= \frac{N}{2} - 1 \quad \text{if } N \text{ is even} \\ \bar{N} &= \frac{N-1}{2} \quad \text{if } N \text{ is odd} \end{aligned} \tag{3}$$

equation (1) becomes (4).

$$\begin{aligned} M\ddot{u}^n + Ku^n &= f^n + g^n \qquad n = 1, ..., \bar{N} \\ Tu_l^n &= u_r^{n+1} = u_r^n e^{jn\theta} \\ Tg_l^n &= -g_r^{n+1} = -g_r^n e^{jn\theta} \end{aligned} \tag{4}$$

If a permutation matrix is applied in the displacement degrees of freedom of a sector such that one defines a block vector $u = [u_r, u_l, u_i]$, where the indices r, l and i are the right, left and interior dofs respectively, equation (4) can be rewritten using block matrices:

$$\begin{bmatrix} M_{rr} & M_{rl} & M_{ri} \\ M_{lr} & M_{ll} & M_{li} \\ M_{ir} & M_{il} & M_{ii} \end{bmatrix} \begin{bmatrix} \ddot{u}_r^n \\ \ddot{u}_l^n \\ \ddot{u}_i^n \end{bmatrix} + \begin{bmatrix} K_{rr} & K_{rl} & K_{ri} \\ K_{lr} & K_{ll} & K_{li} \\ K_{ir} & K_{il} & K_{ii} \end{bmatrix} \begin{bmatrix} u_r^n \\ u_l^n \\ u_i^n \end{bmatrix} = \begin{bmatrix} f_r^n \\ f_l^n \\ f_i^n \end{bmatrix} + \begin{bmatrix} g_r^n \\ g_l^n \\ g_i^n \end{bmatrix} \tag{5}$$

Classically, the left degrees of freedom are removed by replacing the harmonic compatibility presented in equation (4) into equation (5):

$$\begin{bmatrix} M_{rr} + TM_{ll}T^T + e^{jn\theta}M_{rl}T^T + e^{-jn\theta}TM_{lr} & M_{ri} + e^{-jn\theta}TM_{li} \\ M_{ir} + e^{jn\theta}M_{il}T^T & M_{ii} \end{bmatrix} \begin{bmatrix} \ddot{u}_r^n \\ \ddot{u}_i^n \end{bmatrix} + \begin{bmatrix} K_{rr} + TK_{ll}T^T + e^{jn\theta}K_{rl}T^T + e^{-jn\theta}TK_{lr} & K_{ri} + e^{-jn\theta}TK_{li} \\ K_{ir} + e^{jn\theta}K_{il}T^T & K_{ii} \end{bmatrix} \begin{bmatrix} u_r^n \\ u_i^n \end{bmatrix} = \begin{bmatrix} f_r^n + e^{-jn\theta}Tf_l^n \\ f_i \end{bmatrix} \tag{6}$$

Equation (6) is the constrained equation of motion, which contains only the right and interior degrees of freedom. Using the property $TT^T = I$, the elimination process can be carried out by defining a complex matrix L_n which lies in the null space of the constraints.

$$L_n = \begin{bmatrix} I & 0 \\ e^{jn\theta}T^T & 0 \\ 0 & I \end{bmatrix} \tag{7}$$

Therefore, the primal assembly of cyclic symmetry can be written using a substructuring framework as presented in [8]:

$$M_n\ddot{u}_{\text{primal}}^n + K_n u_{\text{primal}}^n = L_n^H f^n \qquad n = 1, ..., \bar{N} \tag{8}$$

where $M_n \equiv (L_n^H M L_n)$ and $K_n \equiv (L_n^H K L_n)$, and the superscript H represents the adjoint matrix. It can be readily verified that (8) leads to the form (6).

For free vibration problems, one sets $f^n = 0$ and $u_{\text{primal}}^n = \phi_{\text{primal}}^n e^{\omega t}$, which leads to the generalized eigenvalue problem:

$$[K_n - \omega^2 M_n]\phi_{\text{primal}}^n = 0 \qquad n = 1, ..., \bar{N} \tag{9}$$

where the subscript n represents the dependency on the nodal diameter, ϕ^n_{primal} is a complex eigenvector, and K_n and M_n are Hermitian matrices. If the full set of eigenvector is required, all nodal diameter indices in (9) must be evaluated.

3 Dual Cyclic Symmetry Formulation

The classical treatment of cyclic symmetry formulation modifies the system operator, namely stiffness and mass matrices, by means of the primal assembly operator L_n as shown above. This results in a set of unique variables defined as u_{primal}. In this section, the dual formulation of (4) is presented. First, let us define two Boolean operators to extract 'left' and 'right' dofs as classical FETI methods [9].

$$\begin{aligned} u_l &= B_l u \\ u_r &= B_r u \end{aligned} \tag{10}$$

For the re-arranged displacement vector $u = [u_r, u_l, u_i]$ the Boolean operators are defined by $B_r = [I\ 0\ 0]$ and $B_l = [0\ I\ 0]$. Rewritting the compatibility constraint in (4) by using the Boolean definition in (10):

$$C_n u = [B_r - e^{-jn\theta} T B_l] u = 0 \tag{11}$$

where C_n is a linear complex cyclic constraint operator. It is easy to show that $L_n^H C_n^H = 0$. Therefore, a Lagrange multiplier must be introduced in the equation of motion in order to satisfy the compatibility constraint, such that:

$$\begin{aligned} M\ddot{u}^n + Ku^n &= f^n - C_n^H \lambda^n \qquad n = 1, ..., \bar{N} \\ C_n u^n &= 0 \end{aligned} \tag{12}$$

Or in matrix notation:

$$\begin{bmatrix} M & 0 \\ 0 & 0 \end{bmatrix} \begin{bmatrix} \ddot{u}^n \\ \lambda^n \end{bmatrix} + \begin{bmatrix} K & C_n^H \\ C_n & 0 \end{bmatrix} \begin{bmatrix} u^n \\ \lambda^n \end{bmatrix} = \begin{bmatrix} f^n \\ 0 \end{bmatrix} \qquad n = 1, ..., \bar{N} \tag{13}$$

where C_n^H is the adjoint matrix of the cyclic constraint operator.

The above expression is the dual assembly formulation for cyclic symmetry boundary condition. This equation contains not only displacement dofs but also Lagrange multipliers to enforced continuity among sectors. Clearly, this results in a system which contains more unknowns than the formulation in (8), however the stiffness and mass matrices do not depend on the nodal diameter n. Therefore, this property can be exploited using dual Schur complement solvers such as described in [10]. A similar technique for cyclic problems was already applied in the work developed in [11]. However, in [11] the Lagrange multipliers are connected to sectors as substructures, whereas in this work, λ^n is defined in the harmonic space. The novel approach can be seen as a decoupling of the interface displacement and forces generated among neighboring sectors. Besides that, the formulation gives the explicit harmonic gap, namely $C_n u^n$, which can be useful when the interface connection between sector is nonlinear.

3.1 Projected Arnoldi for Cyclic Symmetry Modal Analysis

The free vibration analysis of the system (13) results in the following hybrid generalized eigenvalue problem:

$$\begin{bmatrix} K & C_n^H \\ C_n & 0 \end{bmatrix} \begin{bmatrix} \phi'_u \\ \phi_\lambda \end{bmatrix} = \omega^2 \begin{bmatrix} M & 0 \\ 0 & 0 \end{bmatrix} \begin{bmatrix} \phi'_{u_1} \\ \phi_\lambda \end{bmatrix} \tag{14}$$

The dimension of the above problem is n_c+n_{dofs}, where n_c is the number of cyclic symmetry constraints, and n_{dofs} is the total number of dofs in the reference sector. The eigenpair solutions $(\omega_i, [\phi'_{u_i}, \phi_{\lambda_i}])$ have the form:

$$\left(\omega_1^u, \begin{bmatrix} \phi'_{u_1} \\ \phi_{\lambda_1} \end{bmatrix}\right), ..., \left(\omega_{n_{dofs}}^u, \begin{bmatrix} \phi'_{u_{n_{dofs}}} \\ \phi_{\lambda_{n_{dofs}}} \end{bmatrix}\right), \left(+\infty, \begin{bmatrix} 0 \\ \phi_{\lambda_{(n_{dofs}+1)}} \end{bmatrix}\right), ..., \left(+\infty, \begin{bmatrix} 0 \\ \phi_{\lambda_{(n_{dofs}+nc)}} \end{bmatrix}\right) \tag{15}$$

Note that, the eigenvector ϕ'_{u_i} lies in the null space of the complex cyclic symmetry constraint $C_n\phi'_{u_i} = 0$. In [12] some techniques are presented to solve the constrained eigenvalue problem presented in (14) , but it does not explore the structure of the problem to accelerate the inverse iteration of the eigen-solver. In order to solve the eigenvalue problem efficiently and profit from the independence of stiffness and mass matrices of the nodal diameter n, a constrained Krylov subspace is built based on the complex cyclic constraint operator, see [13]. The Krylov matrix for the generalized eigenvalue problem without constraints is defined as:

$$V_m = [b,\ Db,\ D^2b,\ ...\ ,\ D^{m-1}b] \tag{16}$$

where $D \equiv (K-\sigma M)^{-1}M$, which is the inverse shift operator such that $D : \mathbb{R}^n \to \mathbb{R}^n$, $b \in \mathbb{R}^n$. When a constraint $h(b) = 0$ such that $h : \mathbb{R}^n \to \mathbb{R}^{n_c}$ is defined, a Krylov basis vector b' must lie in the set of admissible vectors, mathematically $\Omega = \{b' \in \mathbb{R}^n \mid h(b') = 0\}$ as represented in Figure 2. Thus, the constrained Krylov matrix has the form:

$$V_m^c = [b',\ (Db')',\ (D^2b')',\ ...\ ,\ (D^{m-1}b')'] \tag{17}$$

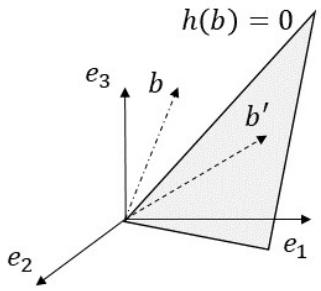

Figure 2: Vectors b and b' to build constrained Krylov subspace.

In the case of cyclic symmetry, one has a linear constraint, defined by $C_nu = 0$. One can write a projection operation P_n into the $Null(C_n)$ such that $P_n : b \to b'$, where the constraint $C_nb' = 0$ always holds. The projection matrix is explicitly written as:

$$P_n = I - C_n^H(C_nC_n^H)^{-1}C_n \tag{18}$$

where the subscript n refers to the nodal diameter dependency in the constraint matrix C_n. It is easy to show that $(C_n C_n^H)^{-1} = \frac{1}{2} I$, therefore the projection matrix can be written without matrix inversion as shown below:

$$P_n = \begin{bmatrix} I & 0 & 0 \\ 0 & I & 0 \\ 0 & 0 & I \end{bmatrix} - \frac{1}{2} \begin{bmatrix} I & -e^{-jn\theta} T & 0 \\ -e^{jn\theta} T^T & I & 0 \\ 0 & 0 & 0 \end{bmatrix} \tag{19}$$

The generalized constrained eigenvalue problem (14) can be rewritten as:

$$K\phi'_u + C_n^H \phi_\lambda = \omega^2 M \phi'_u \tag{20}$$

where ϕ'_u is a vector which respects the cyclic symmetry constraint. If one projects equation (20) in the feasible space using P_n^H and uses the relation $\phi'_u = P_n \phi_u$ one finally derives the projected eigenvalue problem:

$$P_n^H K P_n \phi_u = \omega^2 P_n^H M P_n \phi_u \tag{21}$$

where $\phi_u \in R^n$. Therefore a projected Arnoldi algorithm can be used to build the constrained orthonormal Krylov bases vectors. The projected Arnoldi method is exploited in [14] for updating eigenvalues in nonlinear dynamic problems. The procedure is summarized in Algorithm 1.

Algorithm 1 Projected Arnoldi Iteration

• **Parameters:** K, M, P_n and n_{int}.

1: **Initialization**
Compute $M_n^P = P_n^H M P_n$ and $K_n^P = P_n^H K P_n$
Start with an arbitrary vector ϕ_u^0 and $\beta_0 = 0$

2: **First step iteration**
Compute a projected unitary vector $v_n^1 = \frac{M_n^P \phi_u^0}{||\phi_u^0||_{M_n^P}}$
Solve the static-like problem $K_n^P \hat{\phi}_u^1 = v_n^1$
Compute $\alpha_1 = \hat{\phi}_u^{1T} v_n^1$
Compute a new orthogonal constrained Krylov vector ${\phi_u}^1 = \hat{\phi}_u^1 - \alpha^1 v_n^1$

3: **For** $j = 2, ..., n_{int}$
compute $\beta_j = ||\phi_u^{(j-1)}||_{M_n^P}$
if $\beta_j \neq 0$ then compute $v_n^j = M_n^P \phi_u^{(j-1)} / \beta_j$
Solve the static like problem $K_n^P \hat{\phi}_u^j = v_n^j$
Compute $\alpha_j = \hat{\phi}_u^{jT} v_n^j$
Compute a new constrained Krylov vector $\phi^{j+1} = \hat{\phi}_u^j - \alpha^j v_n^j - \beta_j v_n^{(j-1)}$

The bottleneck of Algorithm (1) is the solution of the singular linear system $K_n^P \hat{\phi}_u^j = v_n^j$. In this work, the linear system is solved by a Preconditioned Conjugate Gradient (PCG) algorithm. The preconditioner $\bar{K}_n^P$ is an estimation of the generalized pseudoinverse of $(K_n^P)^{-1}$. A set of preconditioners are constructed such that, they can be reutilized for all nodal diameters. In this paper, 5 different preconditioners are studied:

- Identity : I
- Incomplete Cholesky : $\hat{K}^{-1}$

- Complete Cholesky : K^{-1}
- Projected Incomplete Cholesky : $P_n\hat{K}^{-1}P_n$
- Projected Cholesky : $P_nK^{-1}P_n$

4 Application Examples

The Preconditioned Projected Arnoldi Algorithm is implemented in Python using the Scipy [15] sparse linear algebra library, which provides a wrapper for the Implicity Restarted Arnoldi (IRA) method implemented in ARPACK. The projection and preconditioner steps are carried-out by Scipy sparse linear operator. Three examples are considered to illustrate the algorithm proposed by this paper. In all cases, structural steel property is used ($E = 210GPa$, $\nu = 0.3$ and $= 7500Kg/m^3$). The PCG tolerance is set to 1.0^{-10} and maximum Arnoldi iterations n_{int} is set to 10 times the number of eigenpairs required. For all test-cases, the first 20 modes are computed for all possible nodal diameters.

The first example, named case A, consists of a 2D mesh, with plane stress triangle elements with 1m of thickness. The number of displacement dofs of the reference sector is 266, number of cyclic constraints is 14, and the whole geometry consists of 8 sectors. Table 1 shows for all nodal diameters the number of average iterations took by the PCG depending on the choice of the preconditioner. The average iterations is measured by the number of linear operator calls divided by the predefined number of modes to be computed by the IRA algorithm. Consequently, the average is measuring the overall performance of the eigensolver and not only the PCG performance. Figure 3 shows the first three modal families for nodal diameter 0,1 and 2.

Preconditioner	I	$\hat{K}^{-1}$	K^{-1}	$P_n\hat{K}^{-1}P_n$	$P_nK^{-1}P_n$
$n = 0$	165.64	42.77	18.95	42.26	18.42
$n = 1$	163.33	45.31	20	45.41	20.00
$n = 2$	162.48	46.30	20	46.13	19.97
$n = 3$	161.77	47.36	19.99	47.30	19.98

Table 2: Average PCG iterations per mode for case B.

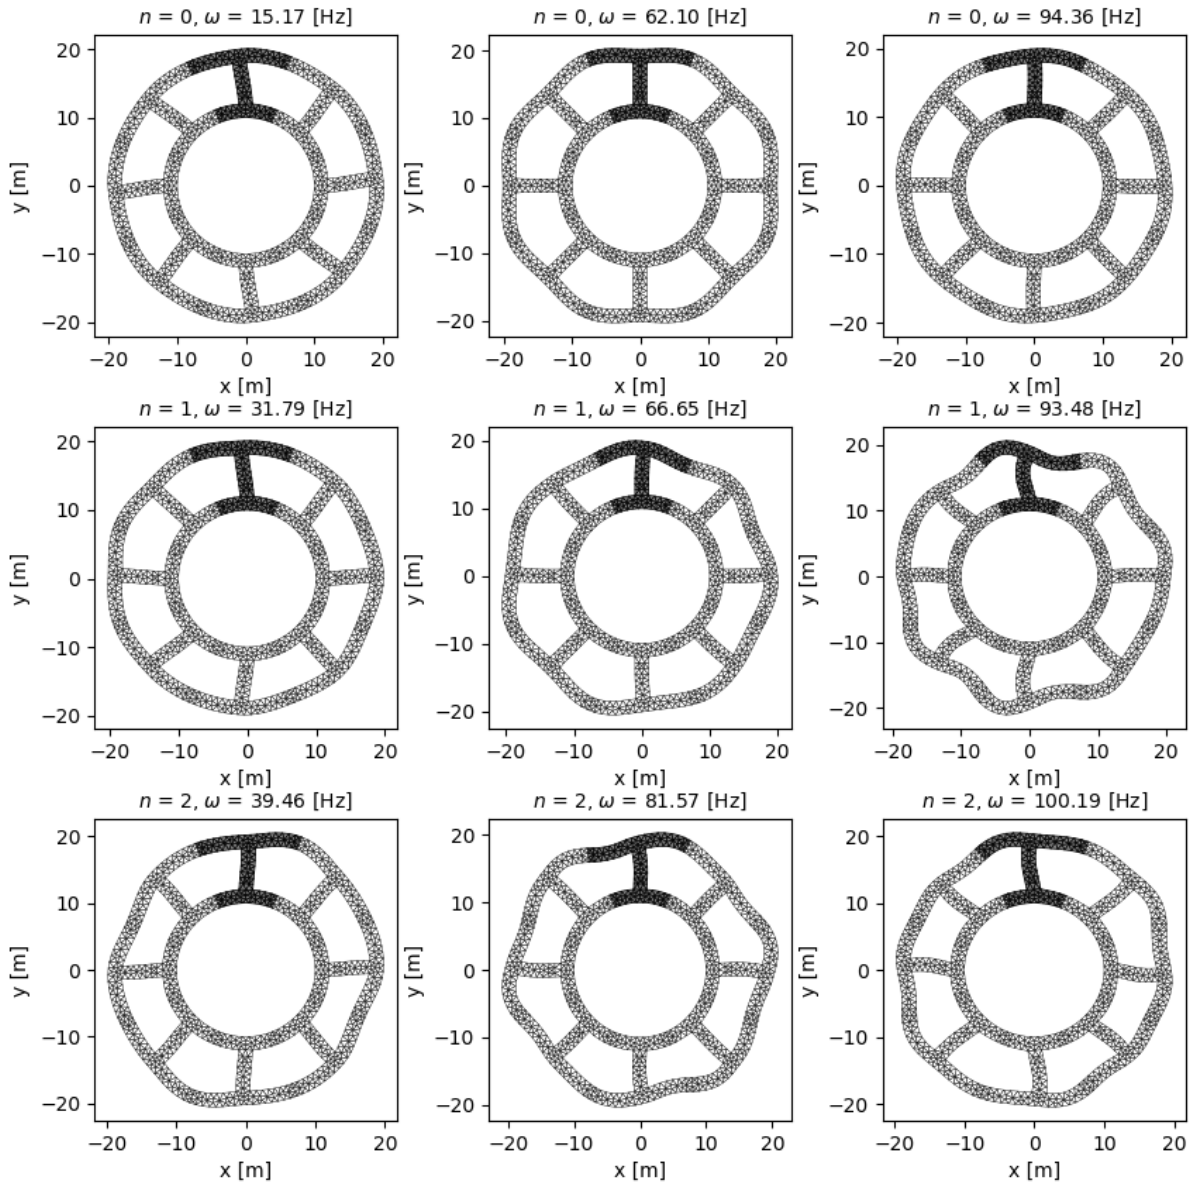

Figure 3: Mode shapes for case A.

The two remaining test cases, B and C, are both 3D Finite Element Models with 1596 and 1467 degrees of freedom respectively. Case B has a simple geometry composed by 8 sector, with 86 cyclic constraints, and the mesh contains only linear hexa elements. Figure 4 shows the first three modes for three nodal diameters and Table 2 summarizes the number of average iterations per mode using the five preconditioners. Case C is composed by tetra elements, 153 cyclic constraints, and it has a more realistic geometry with 24 sector, which resembles a blade-disk geometry. Figure 5 shows the first 3 modes for nodal diameter 0,1, and 2 for the case C. Table 3 presents the number of iteration by the PCG solver. It is clear that for all cases, the projection operation in the preconditioners, $P_n^H K^{-1} P_n$ and $P_n^H \hat{K}^{-1} P_n$ does not increase the performance of the PCG algorithm. Therefore, they must be avoid due to the additional computational cost. For case A and B, the precondition performance is almost constant with the

nodal diameters, whereas in the case C it is possible to see some discrepancies. For instance, the nodal diameter 1 and 4 converged with less than 81 iteration whereas $n = 2$ and $n = 3$ took more than 350 iterations to converge. This behavior can possibly be explained by the differences between free vibration modes without and with cyclic symmetry. If the complex cyclic symmetry constraint does not affect much the free vibration of the reference sector, then K^{-1} will be a good estimation of $(P_n^H K P_n)^{-1}$. Physically, this means that the projected and free modes are almost identical. This fact shows that finding efficient preconditioners for all nodal diameter indices remains a challenge. However, it might be possible to define a family of preconditioners which a more suitable for specific subsets of ND.

5 CONCLUSIONS

The cyclic symmetry constraints are presented using a substructuring framework, where primal and dual systems are formulated. These two approaches can be exploited and lead to different eigen-solvers strategies. The primal assembly formulation modifies the reference sector stiffness and mass matrices, which fully decouples the cyclic sectors by means of the unique set of primal variables. The $\bar{N}$ harmonic problems may be solved independently, but the similarity between the harmonic systems and the reference sector is usually not explored. On the other hand, the dual assembly formulation leads to a singular hybrid system of equations with the displacements and the Lagrange multipliers. In this case, the reference sector matrices, K and M are retained unchanged, whereas the complex cyclic constraint depends on the nodal diameter. Despite the singularity, the structure of the dual formulation allows to build a projected generalized eigenvalue problem. Using this technique, one can utilize the stiffness matrix of the reference sector, with some variations, as an efficient preconditioner. A total of five preconditioners namely, Identity (I), Incomplete Cholesky (IC), Complete Cholesky (CC), Projected Incomplete Cholesky (PIC) and Projected Cholesky (PC) were implemented and tested. The projected versions, PCI and PC, added unnecessary computational cost since they do not reduce the number of iterations when compared to IC and CC. The Cholesky preconditioner performed very well, where speed-ups could be seen in all developed test-cases when compared to pure CG (identity preconditioner). In the 2D case, the complete Cholesky is around 8 times faster than the identity preconditioner, whereas in the 3D case varies from 3 to 17 faster depending on the ND index. This suggests that finding suitable preconditioner for all nodal diameters spectrum is very challenging. Besides that, it is important to notice that, the incomplete Cholesky reveals an algorithmic trade-off with a less costly factorization, but more iterations in the PCG. In the future, it is intended to compare the eigen-solvers' computational efficiency for primal and dual formulation with respect to the number of eigen-pairs required. Furthermore, the projected Arnoldi algorithm will be extended to deal with blade-disk mistuning and quasi-cyclic geometries.

Abstract. *The wave finite element method (WFE) has been developed originally for one dimensional periodic structures with advantage in calculation time. However, this method cannot apply easily for 2D structures of arbitrary shape. This communication presents a new technique of WFE to calculate the dynamic responses of such a structure subjected to external loads. The structure is decomposed into rectangular domains which can be considered as periodic structures subjected to external loads and nodal reaction forces at the domains boundaries. Then, by using the WFE for theses domains, we can obtain a relation between the external loads, the DOF and the nodal reaction forces at the boundaries of the domains. Finally, by combining this relation with the dynamic equation of the rest of the structure, we obtain an equation of the whole structure to compute its response. This technique permits to reduce all the DOF of the rectangular domains of the structure. Examples showing the efficiency of the method are presented.*

1 INTRODUCTION

The wave finite element method has been developped originally for the wave propagation along one-dimensional periodic elastic structures [1]. From the finite element method for a period of the structure, we can obtain a relation (a transform) between the left and right boundaries of the period. This relation leads to a wave base which is obtain from the eignenvectors of the transform. Then, the response at the boundary of a period can be decomposed in this base to compute with different approaches [2]. Recently, this method has been applied for many different problem of periodic structures [3, 4, 5, 6, 7, 8, 9, 10]. For 2D structures, WFE has been developed by using superelements which are rectangular subdomains[11]. By considering each rectangular domain as a periodic structure, this technique permits to obtain the wave decompositions of the domain responses and to combine in the global dynamic equation. However, this technique cannot be applied easily when the structure is subjected to complex external loads or density loads.

In this article, we present another technique of WFE using superelements for 2D structures subjected to external loads. Let's consider a 2D structure containing a rectangular domain $\mathcal{P}$ with rectangular elements as shown in Figure 1 and the rest domain is denoted by $\mathcal{R}$. The domain $\mathcal{P}$ is subjected to external density force $\mathbf{F}_E$ and the reaction force $\mathbf{F}_\partial$ of the domain $\mathcal{R}$ at the common boundary of the two domains. We will use the wave finite element method to obtain a relation between the forces $\mathbf{F}_E, \mathbf{F}_\partial$ and the DOF at the boundary of the two domains $\mathbf{q}_\partial$.

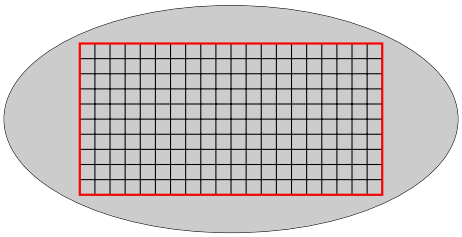

Figure 1: Structure including a rectangular domain $\mathcal{P}$ and the rest $\mathcal{R}$

The rectangular domain $\mathcal{P}$ is a periodic structure of N periods where each one is a column of elements with only nodes on the left and right boundaries as shown in Figure 2. The nodes of $\mathcal{P}$ are denoted by each column (n) with $0 \leq n \leq N$. From the dynamic equation of each

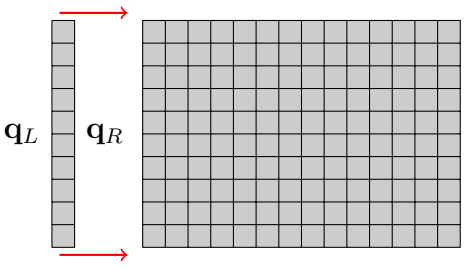

Figure 2: A periodic structure subjected to external loads

column, we get the relation $\mathbf{u}_R = \mathbf{S}\mathbf{u}_L$ with $\mathbf{u}_*$ is the column vector of DOF $\mathbf{q}_*$ and nodal loads $\mathbf{F}_*$. Moreover, the right boundary of the column (n) is also the left boundary of the column $(n+1)$ and we have

$$\mathbf{F}_L^{(n+1)} + \mathbf{F}_R^{(n)} = -\mathbf{F}_B^{(n)}$$

where $\mathbf{F}_B^{(n)}$ are the loads applying on the common boundary of (n) and $(n+1)$. Then, by using the wave analysis approach of the wave finite element method [12], we can obtain the wave bases $\mathbf{\Phi}, \mathbf{\Phi}^\star$ with eigenvalues $\boldsymbol{\mu}$ of the transform $\mathbf{S}$. The wave decomposition of the response can be written as follows

$$\mathbf{q}^{(n)} = \mathbf{\Phi}_q \boldsymbol{\mu}^n \mathbf{Q} - \mathbf{\Phi}_q^\star \boldsymbol{\mu}^{N-n} \mathbf{Q}^\star + \mathbf{\Phi}_q \sum_{k=1}^{n} \boldsymbol{\mu}^{n-k} \mathbf{Q}_B^{(k)} + \mathbf{\Phi}_q^\star \sum_{k=n+1}^{N} \boldsymbol{\mu}^{k-n} \mathbf{Q}_B^{\star(k)} \tag{1}$$

where $\mathbf{Q}, \mathbf{Q}^\star$ are the wave amplitudes of the left and right ends of the domain and $\mathbf{Q}_B, \mathbf{Q}_B^\star$ are the wave amplitude of the external loads which are calculated by

$$\begin{aligned} \mathbf{Q}_B^{(k)} &= \mathbf{\Phi}_q^{\star T} \mathbf{F}_B^{(k)} \\ \mathbf{Q}_B^{\star(k)} &= \mathbf{\Phi}_q^{T} \mathbf{F}_B^{(k)} \end{aligned} \tag{2}$$

where $\mathbf{F}_B^{(k)}$ is nodal loads on the right boundary of the period. Thus, we have

$$\mathbf{q}^{(n)} = \mathbf{\Phi}_q \boldsymbol{\mu}^n \mathbf{Q} - \mathbf{\Phi}_q^\star \boldsymbol{\mu}^{N-n} \mathbf{Q}^\star + \mathbf{\Phi}_q \sum_{k=1}^{n} \boldsymbol{\mu}^{n-k} \mathbf{\Phi}_q^{\star T} \mathbf{F}_B^{(k)} + \mathbf{\Phi}_q^\star \sum_{k=n+1}^{N} \boldsymbol{\mu}^{k-n} \mathbf{\Phi}_q^{T} \mathbf{F}_B^{(k)} \tag{3}$$

Equation (3) presents the response of the rectangular domain in function of the external loads applying on this domain and the wave ampltudes at the left and right ends of the domain.

2 FORMULATIONS

2.1 Wave analysis of rectangular domains

Now we will decompose the nodal loads $\mathbf{F}_B^{(k)}$ in function of the external loads and the reaction force of the domain $\mathcal{R}$. For $0 < n < N$, we can write

$$\mathbf{F}_B^{(n)} = \mathbf{F}_E^{(n)} + \tilde{\mathbf{F}}^{(n)} \tag{4}$$

where $\mathbf{F}_E^{(n)}$ are external loads at the column n and $\tilde{\mathbf{F}}^{(n)}$ is the reaction force of the domain $\mathcal{R}$ applying on the periodic domain which is almost zeros except the two nodes at the common boundary of the column n and the domain $\mathcal{R}$.

For the left boundary ∂L of the periodic domain $\mathcal{P}$, we have

$$\mathbf{F}^{(0)} = -\mathbf{F}_L^{(1)} = \mathbf{F}_E^{(0)} + \mathbf{F}_{\partial L} \tag{5}$$

where $\mathbf{F}_{\partial L}$ is the reaction of $\mathcal{R}$ at ∂L.

For the right boundary ∂R of the periodic domain $\mathcal{P}$, we need to find out the expression of the reaction force $\mathbf{F}_{\partial R}$ in function of $\mathbf{F}^{(N)}$ which is the nodal load of the left boundary of period $(N+1)$ (see Figure 3). We have

$$\begin{aligned} \mathbf{F}^{(N)} &= -\mathbf{F}_L^{(N+1)} = -\left(\mathbf{F}_{\partial R} - \dot{\mathbf{F}}^{(N)}\right) \\ \mathbf{F}_B^{(N)} &= \mathbf{F}_E^{(N)} + \dot{\mathbf{F}}^{(N)} \end{aligned} \tag{6}$$

where $\dot{\mathbf{F}}^{(N)}$ is the reaction forces of at the upper and lower node of ∂R. By combining equations in (6), we obtain

$$\mathbf{F}_B^{(N)} - \mathbf{F}^{(N)} = \mathbf{F}_E^{(N)} + \mathbf{F}_{\partial R} \tag{7}$$

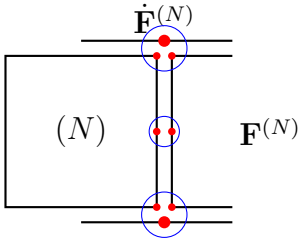

Figure 3: Nodal loads at the column (N) (right boundary of $\mathcal{P}$)

In addition, we obtain the following results from the definition of the wave amplitude [12]

$$\begin{aligned}\mathbf{Q} &= \mathbf{\Phi}^{\star T}\mathbf{J}\mathbf{u}^{(0)} = \mathbf{\Phi}_q^{\star T}\mathbf{F}^{(0)} - \mathbf{\Phi}_F^{\star T}\mathbf{q}^{(0)} \\ \mathbf{Q}^{\star} &= \mathbf{\Phi}^{T}\mathbf{J}\mathbf{u}^{(N)} = \mathbf{\Phi}_q^{T}\mathbf{F}^{(N)} - \mathbf{\Phi}_F^{T}\mathbf{q}^{(N)}\end{aligned} \tag{8}$$

Therefore, by combining equations (3), (4), (5), (7), and (8), we obtain

$$\begin{aligned}\mathbf{q}^{(n)} =& -\mathbf{\Phi}_q\boldsymbol{\mu}^{n}\mathbf{\Phi}_F^{\star T}\mathbf{q}^{(0)} + \mathbf{\Phi}_q^{\star}\boldsymbol{\mu}^{N-n}\mathbf{\Phi}_F^{T}\mathbf{q}^{(N)} \\ &+ \mathbf{\Phi}_q\sum_{k=0}^{n}\boldsymbol{\mu}^{n-k}\mathbf{\Phi}_q^{\star T}\left(\mathbf{F}_E^{(k)} + \tilde{\mathbf{F}}^{(k)}\right) + \mathbf{\Phi}_q^{\star}\sum_{k=n+1}^{N}\boldsymbol{\mu}^{k-n}\mathbf{\Phi}_q^{T}\left(\mathbf{F}_E^{(k)} + \tilde{\mathbf{F}}^{(k)}\right)\end{aligned} \tag{9}$$

where $\tilde{\mathbf{F}}^{(0)} = \mathbf{F}_{\partial L}$ and $\tilde{\mathbf{F}}^{(N)} = \mathbf{F}_{\partial R}$. We can rewrite the aforementioned equation in matrix form as follows

$$\begin{aligned}&\begin{bmatrix} \mathbf{I}+\mathbf{\Phi}_q\mathbf{\Phi}_F^{\star T} & 0 & 0 & 0 & -\mathbf{\Phi}_q^{\star}\boldsymbol{\mu}^{N}\mathbf{\Phi}_F^{T} \\ \vdots & \ddots & \vdots & \vdots & \vdots \\ \mathbf{\Phi}_q\boldsymbol{\mu}^{n}\mathbf{\Phi}_F^{\star T} & 0 & \mathbf{I} & 0 & -\mathbf{\Phi}_q^{\star}\boldsymbol{\mu}^{N-n}\mathbf{\Phi}_F^{T} \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ \mathbf{\Phi}_q\boldsymbol{\mu}^{N}\mathbf{\Phi}_F^{\star T} & 0 & 0 & 0 & \mathbf{I}-\mathbf{\Phi}_q^{\star}\mathbf{\Phi}_F^{T} \end{bmatrix}\begin{bmatrix} \mathbf{q}^{(0)} \\ \vdots \\ \mathbf{q}^{(n)} \\ \vdots \\ \mathbf{q}^{(N)} \end{bmatrix} \\ =& \begin{bmatrix} \mathbf{\Phi}_q\mathbf{\Phi}_q^{\star T} & \cdots & \mathbf{\Phi}_q^{\star}\boldsymbol{\mu}^{n}\mathbf{\Phi}_q^{T} & \cdots & \mathbf{\Phi}_q^{\star}\boldsymbol{\mu}^{N}\mathbf{\Phi}_q^{T} \\ \vdots & \ddots & \vdots & \vdots & \vdots \\ \mathbf{\Phi}_q\boldsymbol{\mu}^{n}\mathbf{\Phi}_q^{\star T} & \cdots & \mathbf{\Phi}_q\mathbf{\Phi}_q^{\star T} & \cdots & \mathbf{\Phi}_q^{\star}\boldsymbol{\mu}^{N-n}\mathbf{\Phi}_q^{T} \\ \vdots & \vdots & \vdots & \ddots & \\ \mathbf{\Phi}_q\boldsymbol{\mu}^{N}\mathbf{\Phi}_q^{\star T} & \cdots & \mathbf{\Phi}_q\boldsymbol{\mu}^{N-n}\mathbf{\Phi}_q^{\star T} & \cdots & \mathbf{\Phi}_q\mathbf{\Phi}_q^{\star T} \end{bmatrix}\begin{bmatrix} \mathbf{F}_E^{(0)} + \mathbf{F}_{\partial L} \\ \vdots \\ \mathbf{F}_E^{(n)} + \tilde{\mathbf{F}}_{\partial n} \\ \vdots \\ \mathbf{F}_E^{(N)} + \mathbf{F}_{\partial R} \end{bmatrix}\end{aligned} \tag{10}$$

Equation (10) is a relation between the DOF and nodal loads of the whole domain. Moreover, the matrix on the right side of equation (10) is a block Toeplitz matrix [13, 14].

2.2 Assembly of boundary nodes

We are interested in the boundary nodes of the domain. The left and right boundaries are $\mathbf{q}^{(0)}$ and $\mathbf{q}^{(N)}$. Otherwise, the up and down boundaries at the column n (noted by ∂n) are the first and the last nodes of the column and we can define a matrix $\mathbf{L}$ so that:

$$\mathbf{q}_{\partial n} = \mathbf{L}\mathbf{q}^{(n)}, \quad \mathbf{F}_{\partial n} = \mathbf{L}\tilde{\mathbf{F}}^{(n)} \quad 0 < n < N \tag{11}$$

If we note

$$\tilde{\mathbf{\Phi}}_q = \mathbf{L}\mathbf{\Phi}_q, \quad \tilde{\mathbf{\Phi}}_q^{\star} = \mathbf{L}\mathbf{\Phi}_q^{\star} \tag{12}$$

Equation (10) become

$$\begin{bmatrix} \mathbf{I}+\boldsymbol{\Phi}_q\boldsymbol{\Phi}_F^{\star T} & 0 & 0 & 0 & -\boldsymbol{\Phi}_q^{\star}\boldsymbol{\mu}^N\boldsymbol{\Phi}_F^T \\ \vdots & \ddots & \vdots & \vdots & \vdots \\ \tilde{\boldsymbol{\Phi}}_q\boldsymbol{\mu}^n\boldsymbol{\Phi}_F^{\star T} & 0 & \tilde{\mathbf{I}} & 0 & -\tilde{\boldsymbol{\Phi}}_q^{\star}\boldsymbol{\mu}^{N-n}\boldsymbol{\Phi}_F^T \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ \boldsymbol{\Phi}_q\boldsymbol{\mu}^N\boldsymbol{\Phi}_F^{\star T} & 0 & 0 & 0 & \mathbf{I}-\boldsymbol{\Phi}_q^{\star}\boldsymbol{\Phi}_F^T \end{bmatrix} \begin{bmatrix} \mathbf{q}_{\partial L} \\ \vdots \\ \mathbf{q}_{\partial n} \\ \vdots \\ \mathbf{q}_{\partial R} \end{bmatrix}$$

$$= \begin{bmatrix} \boldsymbol{\Phi}_q\boldsymbol{\Phi}_q^{\star T} & \cdots & \boldsymbol{\Phi}_q^{\star}\boldsymbol{\mu}^n\tilde{\boldsymbol{\Phi}}_q^T & \cdots & \boldsymbol{\Phi}_q^{\star}\boldsymbol{\mu}^N\boldsymbol{\Phi}_q^T \\ \vdots & \ddots & \vdots & \vdots & \vdots \\ \tilde{\boldsymbol{\Phi}}_q\boldsymbol{\mu}^n\boldsymbol{\Phi}_q^{\star T} & \cdots & \tilde{\boldsymbol{\Phi}}_q\tilde{\boldsymbol{\Phi}}_q^{\star T} & \cdots & \tilde{\boldsymbol{\Phi}}_q^{\star}\boldsymbol{\mu}^{N-n}\boldsymbol{\Phi}_q^T \\ \vdots & \vdots & \vdots & \ddots & \\ \boldsymbol{\Phi}_q\boldsymbol{\mu}^N\boldsymbol{\Phi}_q^{\star T} & \cdots & \boldsymbol{\Phi}_q\boldsymbol{\mu}^{N-n}\tilde{\boldsymbol{\Phi}}_q^{\star T} & \cdots & \boldsymbol{\Phi}_q\boldsymbol{\Phi}_q^{\star T} \end{bmatrix} \begin{bmatrix} \mathbf{F}_{\partial L} \\ \vdots \\ \mathbf{F}_{\partial n} \\ \vdots \\ \mathbf{F}_{\partial R} \end{bmatrix}$$

$$+ \begin{bmatrix} \boldsymbol{\Phi}_q\boldsymbol{\Phi}_q^{\star T} & \cdots & \boldsymbol{\Phi}_q^{\star}\boldsymbol{\mu}^n\boldsymbol{\Phi}_q^T & \cdots & \boldsymbol{\Phi}_q^{\star}\boldsymbol{\mu}^N\boldsymbol{\Phi}_q^T \\ \vdots & \ddots & \vdots & \vdots & \vdots \\ \tilde{\boldsymbol{\Phi}}_q\boldsymbol{\mu}^n\boldsymbol{\Phi}_q^{\star T} & \cdots & \tilde{\boldsymbol{\Phi}}_q\boldsymbol{\Phi}_q^{\star T} & \cdots & \tilde{\boldsymbol{\Phi}}_q^{\star}\boldsymbol{\mu}^{N-n}\boldsymbol{\Phi}_q^T \\ \vdots & \vdots & \vdots & \ddots & \\ \boldsymbol{\Phi}_q\boldsymbol{\mu}^N\boldsymbol{\Phi}_q^{\star T} & \cdots & \boldsymbol{\Phi}_q\boldsymbol{\mu}^{N-n}\boldsymbol{\Phi}_q^{\star T} & \cdots & \boldsymbol{\Phi}_q\boldsymbol{\Phi}_q^{\star T} \end{bmatrix} \begin{bmatrix} \mathbf{F}_E^{(0)} \\ \vdots \\ \mathbf{F}_E^{(n)} \\ \vdots \\ \mathbf{F}_E^{(N)} \end{bmatrix} \tag{13}$$

where $\tilde{\mathbf{I}} = \mathbf{L}\mathbf{I}\mathbf{L}^T$ which is also an identity matrix. We can rewrite the aforementioned equation as follows

$$\mathbb{A}\mathbf{q}_{\partial} = \mathbb{B}\mathbf{F}_{\partial} + \mathbb{C}\mathbf{F}_E \tag{14}$$

where $\mathbb{A}, \mathbb{B}, \mathbb{C}$ are defined corresponding to the matrices in equation (13).

2.3 Assembly of the whole structure

For the domain $\mathcal{R}$, we have

$$\begin{bmatrix} \mathbf{D}_{\partial\partial}^{\star} & \mathbf{D}_{\partial I}^{\star} & \mathbf{D}_{\partial B}^{\star} \\ \mathbf{D}_{I\partial}^{\star} & \mathbf{D}_{II}^{\star} & \mathbf{D}_{IB}^{\star} \\ \mathbf{D}_{B\partial}^{\star} & \mathbf{D}_{BI}^{\star} & \mathbf{D}_{BB}^{\star} \end{bmatrix} \begin{bmatrix} \mathbf{q}_{\partial} \\ \mathbf{q}_I \\ \mathbf{q}_0 \end{bmatrix} = \begin{bmatrix} \mathbf{F}_{\partial} \\ \mathbf{F}_0^{\star} \\ \mathbf{F}_B^{\star} \end{bmatrix} \tag{15}$$

where $\mathbf{q}_0, \mathbf{F}_0^{\star}$ are given by the boundary condition and the loads of the domain $\mathcal{R}$. From the aformentioned equation, we obtain

$$\begin{bmatrix} \mathbf{D}_{\partial\partial}^{\star} & \mathbf{D}_{\partial I}^{\star} \\ \mathbf{D}_{I\partial}^{\star} & \mathbf{D}_{II}^{\star} \end{bmatrix} \begin{bmatrix} \mathbf{q}_{\partial} \\ \mathbf{q}_I \end{bmatrix} = \begin{bmatrix} \mathbf{F}_{\partial} \\ \mathbf{F}_0^{\star} \end{bmatrix} - \begin{bmatrix} \mathbf{D}_{\partial B}^{\star}\mathbf{q}_0 \\ \mathbf{D}_{IB}^{\star}\mathbf{q}_0 \end{bmatrix} \tag{16}$$

Equations (14) and (16) decribe the relations between $\mathbf{q}_{\partial}$ and $\mathbf{F}_{\partial}$ with the external loads and the boundary conditions of the whole structure. We can have different methods to combine these two equations which cost different calculation times. It is possible to reduce the cost by using the properties of the Toeplizt block matrix $\mathbb{B}, \mathbb{C}$ [14]. However, this article is limited to a simple method by substituting equation (14) into equation (16) and we obtain

$$\begin{bmatrix} \mathbf{D}_{\partial\partial}^{\star} - \mathbb{B}^{-1}\mathbb{A} & \mathbf{D}_{\partial I}^{\star} \\ \mathbf{D}_{I\partial}^{\star} & \mathbf{D}_{II}^{\star} \end{bmatrix} \begin{bmatrix} \mathbf{q}_{\partial} \\ \mathbf{q}_I \end{bmatrix} = \begin{bmatrix} -\mathbb{B}^{-1}\mathbb{C}\mathbf{F}_E \\ \mathbf{F}_0^{\star} \end{bmatrix} - \begin{bmatrix} \mathbf{D}_{\partial B}^{\star}\mathbf{q}_0 \\ \mathbf{D}_{IB}^{\star}\mathbf{q}_0 \end{bmatrix} \tag{17}$$

Equation (17) permits to calculate the response of the domain $\mathcal{R}$. This technique permits to get the final expression of the dynamic stiffness matrix (DSM) of the whole structure by modifying only the diagonal block of DSM of $\mathcal{R}$ corresponding to the rectangular domain boundary.

When the structure has severalrectangular domains, we can use the same technique for each diagonal block to get the final DSM. For structures with connected rectangular domains, we need to combine these domains as superelements before replacing into the DSM.

3 EXAMPLE

Let's consider a 2D elipse of axes 6mx3m which contain a rectangular of size 4mx2m as shown in Figure 4. The mesh is created by using 1586 elements S4 of thickness 0.1m. The stiffness and mass matrices are generated by Abaqus and other calculations have been performed with Matlab. Figure 5 shows the results obtained by the finite element method (for the whole

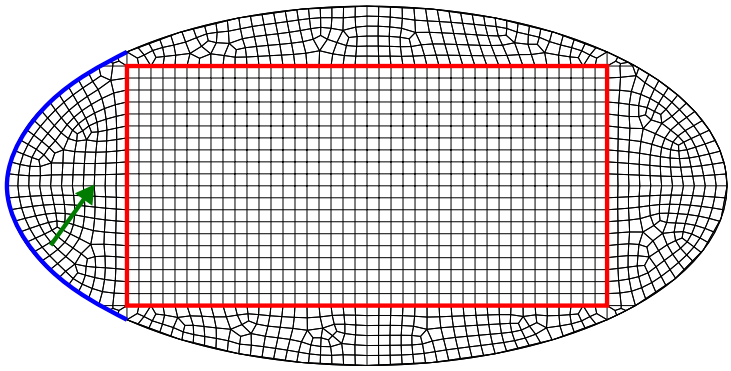

Figure 4: Example of 2D structure with a rectanglar domain (red), a fixed boundary (blue) and a load (green)

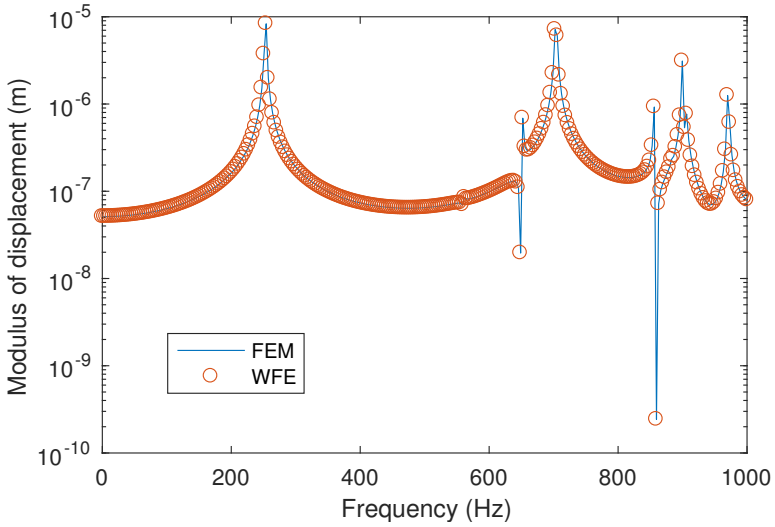

Figure 5: Response of one node calculated by the finite element method and the new method

structure) and the new method. The two results agrees well. Althought the new method can

reduce the number of DOF (from 3322 to 1840), the WFE cannot reduce the calculation time in comparing with FEM (5.4s vs 20.9s). One reason is that the calculation of Toeplitz matrices (which are full matrices) have not been optimized.

4 CONCLUSIONS

This article introduces a new technique for coupling the finite element method and the wave finite element method by using superelements. For a 2D structure of arbtrary shapes, we define superelements as rectangular domains. Each superelement is a periodic structure where we can apply WFE. We obtain then a relation between the DOF at the superelement boundary and the external nodal loads via Toeplitz matrices. The technique permits to reduce the number of DOF but it needs to optimize the calculation of Toeplitz matrices in order to reduce the calculation time.

Abstract

The many catastrophic earthquakes that occurred in Italy in the last fourty years underline how Italy is one of the European countries at the highest seismic risk. For this reason, the vulnerability of infrastructures needs to be investigated. This paper considers the railway network as a case study with a focus on railway bridges, which are neuralgic nodes of the whole system. The most common types of railway bridges in Italy are masonry arch bridges and girder bridges with either a continuous deck or a simply supported deck. Here, we specifically analyze railway girder bridges.

Eucentre evaluates the seismic vulnerability of railway bridges through the definition of fragility curves. Fragility curves result from analytical procedures that determine the seismic behaviour of structures according to the structural typology as well as the level of knowledge of the bridge. One step of these procedures is the simulated design, which aims at reducing the number of variables in the process and requires the knowledge of the regulatory limits used at the time of the design. This paper presents those regulatory limits that concern: (i) loads, (ii) materials resistance, (iii) longitudinal and transversal reinforcement percentages for reinforced concrete bridges, and (iv) bearings. These limits derive from a detailed bibliographic study on Italian regulations, concerning the design of railway bridges from the beginning of 1900 to the present.

Keywords: Railway Bridges, Italian Regulation, Simulated Design, Seismic Vulnerability.

1 INTRODUCTION

The Italian railway network is made up of about 17000 km of rail lines that are in operation and are largely developed in medium-to-high seismic hazard zones. Important elements of this network are viaducts. The most common types of railway bridges in Italy are masonry arch bridges and girder bridges with either a continuous deck or simply supported deck. In this paper, only the railway girder bridges are analyzed, a brief description of which is also given in relation to the deck material.

The seismic vulnerability of railway bridges is generally assessed through fragility curves. Fragility curves can be obtained through different methods, such as analytical methods that involve the mechanical modeling of the structure.

For the seismic behaviour of the modeled structure to be plausible, the characteristics of materials, the amount of reinforcement, and the types of bearings used in the modeling need to be as close as possible to the actual conditions of the bridge. This information is included in the project documents which are usually not available. To solve this problem, the simulated design of the structure is carried out using the limits imposed by the regulations in force at the time of design.

To this end, this paper provides a brief bibliographic review of the regulations used for the construction of reinforced concrete railway bridges from the beginning of the last century to the present day. The first Italian regulation available on the design of reinforced concrete railway bridges dates back to 1995. For this reason, the provisions on the reinforcement of piers as well as on the mechanical characteristics of materials derive from the regulations issued in Italy starting from 1907 concerning the construction of public reinforced concrete structures. For mobile loads, instead, specific technical standards have been considered starting from 1946.

The definition of the permanent load depends on the composition of the superstructure. For this purpose, this paper also provides the weights of the railway track and ballast, as well as the weight of noise barriers suggested by the latest technical specifications issued by the Italian State Railways ([1], [2], [3]).

Finally, this paper gives a brief bibliographic review of the standards on the types of bearings for railway girder bridges from 1972 onwards. It is very important to identify the geometrical and mechanical characteristics of these devices so that their actual function can be taken into account during their simulated design. A wrong modeling of bearings could affect the actual seismic response of a bridge because it changes the way in which mechanisms of the pier-bearing system are activated.

2 RAILWAY GIRDER BRIDGES

One of a widely used bridge typology in the Italian railway network is represented by girder bridges. The deck can consist of reinforced concrete, prestressed reinforced concrete, or steel, and generally lies on unreinforced concrete, reinforced concrete, or masonry piers. The deck can be simply supported or continuous, thus giving rise to an isostatic or hyperstatic static scheme, respectively. Between the deck and the vertical structure of the bridge are the bearings, the choice of which depends mainly on the type of deck and the type of constraint to be obtained.

In case of a reinforced concrete deck, the method of construction depends mainly on the length of the individual spans as well as on the total length of the bridge. Specifically, the deck can be made of: (i) a slab, (ii) steel girders embedded in concrete, and (iii) reinforced concrete plate girder. The bridge with slab deck is the simplest system used in rail transport, but only when the spans do not exceed 4 m. On the contrary, the deck with steel girders em-

bedded in concrete or reinforced concrete plate girder is used when, for orographic reasons, the deck cannot be very thick. In particular, the deck with steel girders embedded in concrete is no longer than either 13 m, in the case of "double T" beams, or 20 m, in the case of "double T" beams with wide wings. In presence of a deck with reinforced concrete plate girder, instead, the girders also have the function of parapet and can reach heights of also 3.5 m. The deck is continuous and supports the railway superstructure.

In addition to reinforced concrete, the deck can be realized with prestressed reinforced concrete beams. This deck can reach a length that ranges 35 m and 50 m and is generally made of isolated or box beams. When the beam has a box cross-section, the common practice provides for the use of a box for each track. In this case, the beams are connected among each other with cross-beams (which are prestressed, too) to guarantee the beams cooperation in the usual load conditions (e.g. the passage of a train) so that fatigue phenomena can be reduced. Nowadays, the prestressed reinforced concrete deck is really common on both ordinary and high-speed railway lines.

Another type of deck is the steel deck, which has been widely used in the past; nowadays, however, it is mainly used for long span bridges with reduced height or to replace pre-existing steel girders. Because of the high cost of construction and maintenance, steel decks have mostly been replaced by either the prestressed reinforced concrete decks for medium-to-long span bridges, or reinforced concrete and mixed structure decks for bridges with shorter spans. The most common railway steel bridges are made of straight girders lying on masonry or reinforced concrete piers. In the case of bridges with more than one span, however, it is preferable to create non-continuous decks on which the track can be either direct lying or ballasted. Depending on the length of the deck, the direct-laying girders can be twin-girders (for spans between 10-25 m), plate girders (for spans between 30-40 m), or truss girders (for spans between 35-100 m). For what concerns bridges with railway tracks lying on the ballast, they generally have a deck with steel-concrete composite girders. In this case, the beams can be "double T" or box section collaborating with the concrete slab and reach a length of about 20-25 m. To guarantee the interaction between all the girders of the deck, cross-beams are also used, especially in the presence of live loads.

3 ITALIAN REGULATIONS FROM 1900 TO NOWADAYS FOR RAILWAY GIRDER BRIDGES

3.1 Resistance of Materials

The first recommendations about the construction of reinforced concrete structures were issued in Italy with the Royal Decree 10/01/1907 [4]. This decree provided the first indications about the maximum strength to be considered in the structural calculation for both concrete and reinforcement. In particular, this standard stated that the compressive strength of concrete at 28 days of hardening $\sigma_{r,28}$ must not be less than 150 kg/cm^2, the fifth part of which corresponds to the simple compressive safety load of the concrete to be used in the calculation. Concerning the reinforcement, the regulation allowed the use of smooth steel rebars with a tensile strength between 36 kg/mm^2 and 45 kg/mm^2. The safety tensile and shear loads, instead, should not exceed 1000 kg/cm^2 and 800 kg/cm^2, respectively. For the reinforcement, the decree introduced a further limitation, namely the quality coefficient, which is obtained by multiplying the unit failure load per mm^2 by the percentage elongation. This coefficient, which should not exceed 900, was then replaced by the percentage of elongation at maximum tensile strength of the reinforcement in the Royal Decree issued on 4/09/1927 [5]. With the exception of this introduction, the Royal Decree 4/09/1927 [5] has not made substantial changes compared to what was already established by the previous decree [4]. In fact, the de-

cree only reduced and slightly increased the values of the safety concrete load (30 kg/m^2 and 40 kg/m^2 for 2nd and 1st quality concretes) as well as the tensile and shear steel ones (1200 kg/cm^2 and 960 kg/cm^2). As a result, the tensile strength of the steel changed slightly, i.e. 3800-5000 kg/cm^2, corresponding to a minimum elongation of 27% and 21%, respectively.

With the Royal Decree 23/05/1932 [6], the classification of concretes had been improved and divided into Portland, blast furnace, pozzolanic, and aluminous. Portland, blast furnace, and pozzolanic concretes could be of normal or high strength (see Table 1). The mechanical characteristics of steel, instead, did not change compared to what was already indicated in the Royal Decree 4/09/1927 [5].

Mechanical characteristics of concrete	Portland, blast furnace, pozzolanic concrete		Aluminous concrete
	Normal strength	High strength	
Crushing strength [kg/cm^2]	450	600	650
Compressive safety load [kg/cm^2]	40*-50**	50	65
Maximum tangential strength without reinforcement [kg/cm^2]	2	4	4
Maximum tangential strength with reinforcement [kg/cm^2]	14	16	16

*for structures under simple pressure; **for bent structures with a thickness not less than 10 cm.

Table 1: Mechanical characteristics of portland, blast furnace, pozzolanic, and aluminous concretes in the Royal Decree 23/05/1932 [6].

The Circular 17/05/1937 [7] introduced the use of medium carbon steel, only in absence of homogeneous steel. In terms of mechanical characteristics, the medium carbon steel had an ultimate tensile strength between 5000 kg/cm^2 and 6500 kg/cm^2 to which percentages of elongation corresponded to 21% and 14%, respectively. The safety load of the steel increased from 1200 kg/cm^2 to 1600 kg/cm^2.

In 1939 a new Royal Decree [8] was issued to regulate the construction of structures made of unreinforced or reinforced concrete. In this decree, the compressive strength of concrete at 28 days of hardening $\sigma_{r,28}$ had to be at least three times the safety load $\sigma_{c,a}$ adopted in the structural calculations, but never less than 120 kg/cm^2 and 160 kg/cm^2 for normal-strength concrete and high-strength or aluminous concrete, respectively. Regarding the reinforcement, the Royal Decree 16/11/1939 [8] introduced high carbon steel, which allowed to adopt smaller rebar sizes due to its high specific resistance [9].

Table 2 reports the mechanical properties of the three types of steel permitted by the Royal Decree 16/11/1939 [8].

Mechanical characteristics of steel	Mild Steel	Medium carbon steel	High carbon steel
Yield characteristic strength [kg/cm^2]	≥2300	≥2700	≥3100
Ultimate characteristic strength [kg/cm^2]	4200-5000	5000-6000	6000-7000
Elongation [%]	≥20	≥16	≥14
Safety load [kg/cm^2]	≤1400	≤2000	≤2000

Table 2: Mechanical characteristics of steels in the Royal Decree 16/11/1939 [8].

The Royal Decree 16/11/1939 [8] has remained in force until the first years of 1970s as a consequence of a regulatory gap due to the Second World War and the following period of

reconstruction. Between 1939 and the early 1970s, however, a series of circulars have been issued, among which it is necessary to mention the Circular 23/05/1957 [10]. This circular not only introduced a new denomination for smooth steel rebars, i.e. AQ42, AQ50 and AQ60, equivalent respectively to the mild, medium carbon, and high carbon steel of Table 2, but also introduced first indications on ribbed steel rebars [9]. The ribbed steel rebars were allowed in special cases, such as shaped or bent rebars, and with a minimum elongation percentage of 12%.

A substantial change with respect to the previous regulations occurred with the Ministerial Decree 30/05/1972 [11] which has laid the foundations of modern legislation. It introduced a classification of ribbed steel rebars as well as a calculation method at the limit states, which replaced the permissible stresses approach. This change defined the transition from a deterministic to a statistical calculation system due to the introduction of the characteristic value. As a consequence, the yield strength and the ultimate strength were not intended anymore as an average value but as the strength that had only a 5% probability of being lowered by the effective resistance [9]. The Ministerial Decree of 30/05/1972 [11] distinguished six classes of concrete by a number that expressed the characteristic cubic resistance at 28 days of hardening R'_{bk}, from which it was possible to obtain the mechanical characteristics of the concrete (e.g. compressive strength, tensile strength, etc.). For what concerns the reinforcement, smooth steels were divided in only two classes (i.e. Fe B 22 and Fe B 32), and the ribbed steel rebars into three classes (i.e. A 38, A 41, and Fe B 44) (see Table 3).

Mechanical characteristics of steel	Smooth steel rebars		Ribbed steel rebars		
	Fe B 22	Fe B 32	A 38	A 41	Fe B 44
Yield characteristic strength [kg/cm^2]	≥ 2200	≥ 3200	≥ 3800	≥ 4100	≥ 4400
Ultimate characteristic strength [kg/cm^2]	≥ 3400	≥ 5000	≥ 4600	≥ 5000	≥ 5500
Elongation [%]	≥ 24	≥ 23	≥ 14	≥ 14	≥ 12
Safety load [kg/cm^2]	1200	1600	2200	2400	2600

Table 3: Mechanical characteristics of smooth steel rebars and ribbed steel rebars in the Ministerial Decree of 30/05/1972 [11].

After 1972, other decrees were issued about the construction of reinforced concrete structures, but they have not considerably changed the provisions of the Ministerial Decree 30/05/1972 [11] in terms of mechanical characteristic of materials. This is evident in Table 4 and Table 5, which report the mechanical characteristics of the rebars defined in the latest standards on the construction of railway bridges, issued by Italian State Railways ([1], [2], [3]). The only significant difference between the Circular n. I/SC/PS-OW2298 1997 [1] and the newest Technical Specifications by Italian State Railways ([2], [3]) is the mechanical characteristics of ribbed steel rebars (see Table 5). As stated in the Italian Seismic Codes (NTC08) [12], the use of smooth steel rebars is definitely prohibited. Concerning concrete properties, no substantial changes were made.

Mechanical characteristics of steel	Smooth steel rebars		Ribbed steel rebars	
	Fe B 22k	Fe B 32k	Fe B 38k	Fe B 44k
Yield characteristic strength [kg/cm^2]	≥ 2150	≥ 3150	≥ 3750	≥ 4300
Ultimate characteristic strength [kg/cm^2]	≥ 3350	≥ 4900	≥ 4500	≥ 5400
Elongation [%]	≥ 24	≥ 23	≥ 14	≥ 12

Table 4: Mechanical characteristics of smooth steel rebars and ribbed steel rebars in the Circular n. I/SC/PS-OW2298 and following update of 1997 [1].

Mechanical characteristics of steel	B450C
Yield characteristic strength [kg/cm^2]	≥ 4500
Ultimate characteristic strength [kg/cm^2]	≥ 5400
Elongation [%]	≥ 7.5

Table 5: Mechanical characteristics of ribbed steel rebars in the newest technical specifications by Italian State Railways ([2], [3]).

3.2 Definition of loads

3.2.1 Permanent loads

The permanent loads are obtained from the structural and non-structural loads, to which the hydraulic and lateral earth pressures are added too, if existing.

The permanent structural loads are evaluated on the basis of the geometric characteristics of the elements constituting the deck of the bridge (i.e. girders, cross-beams, and slab) and the specific weights of the materials with which they are made. The latter are regulated by the codes in force at the time of the structure design.

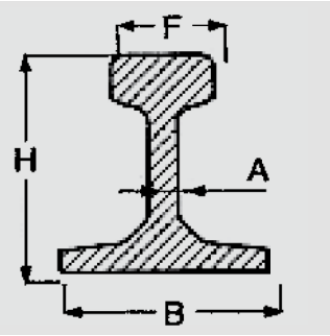
The non-structural load, instead, is obtained by adding the weight of all non-structural elements composing the superstructure, that are mainly: (i) the railway track, (ii) the ballast, (iii) the waterproofing, and (iv) the noise barriers.

A railway track is defined as the totality of rails, sleepers, and fasteners.

The first rails were entirely made of cast iron, were very short, and mounted on large stone blocks drowned in the ground. Due to the fragility of cast iron, it was later replaced by iron, which is, however, subjected to wear. The solution to the problem of wear was the “double headed rail”, which was mounted through hardwood wedges into special fixing plates, fixed in turn on wooden sleepers. When the upper table was worn out, the rail was inverted so that the lower table was ready to be used. As this process was complex and expensive, other solutions were developed, such as the “Vignoles rail” (named by the engineer who invented it), which has a “double-T” profile with a wider lower table than the upper one. Advances in material science led to the replacement of iron with steel: steel performs better than iron and deforms less at high speeds. The intended use of the tracks defines the type of steel used for the rails, their dimensions and, consequently, the weight and maximum permissible speed of the vehicles. The higher the linear weight of the rail, the higher are its performances. Initially, the rails had a weight of 18-25 kg/m or 27 kg/m. Later on, rails with a weight of 36 kg/m and 46-48 kg/m became very common for secondary and main railways, respectively.

Since the 1960s, during the maintenance of existing railway systems, Italian State Railways replaced the old rails with “Vignoles” types UIC 50 and UIC 60. In Italy, the code that describes the “Vignoles” type rails is UNI-3134 [13] which doesn't differ much from the Eu-

ropean and UIC (i.e. Union Internationale des Chemins de fer) regulations. Table 6 shows the weight of rails in kg/ml according to UNI-3141 [13].



Type	Weight [kg/m]	H [mm]	F [mm]	B [mm]	A [mm]
21	21.373	100	50	80	10
27	27.350	120	50	95	11
30	30.152	125	56	100	12
36	36.188	130	60	100	14
46	46.786	145	63.5/67.2	135	14
50	49.850	148	65.2/70	135	14
60	60.34	172	70.6/74.3	150	16.5

Table 6: Weight and geometrical properties of rails in kg/m according to UNI-3141 [13].

The sleepers, instead, can be made of wood or prestressed reinforced concrete.

Wooden sleepers are the oldest and still widespread. For reasons of cost, of supply as well as of a reduced service life due to adverse weather conditions, in the past wooden sleepers were replaced by iron ones. Nowadays, especially on high-speed rails, prestressed concrete mono-block or twin-block sleepers are used. The twin-block sleepers differ from the mono-block types because they consist of two parallelepiped prestressed concrete elements connected to each other by a steel bar.

Table 7 shows the geometric characteristics and the sleeper's weight in kilogram. To calculate the weight per meter, it is necessary to refer to the module, i.e. the number of sleepers that are in 6 m of track length. The module depends on the class of the railway line, and consequently on the maximum load and speed of the train, and can be:

- *Module 6/10*, i.e. 10 sleepers in 6 m (used for tracks belonging to the main rail network suitable for the highest speeds, for 18 t/axle in case of isolated axles, and for more than 18 t in case of locomotive axles);
- *Module 6/9*, i.e. 9 sleepers in 6 m (used for complementary rail network as well as for crossing or priority rails suitable for lower speeds, for 18 t/axis in case of isolated axles, and for more than 18 t in case of locomotive axles); and
- *Module 6/8*, i.e. 8 sleepers in 6 m (used for tracks belonging to the secondary rail network as well as for all other rails suitable for even lower speeds and 16 t/axis in case of isolated axles).

To connect the sleepers to the rails, and often to ensure electrical insulation, the used fasteners can be of different types; their weight has little impact on the non-structural load.

Type of sleeper	Length [mm]	Depth [mm]	Thickness [mm]	Weight [kg]
Wood	2600	260	160	80 – 100
Prestressed concrete mono-block	2300 - 2600	300	180 – 230	250 – 370
Prestressed concrete twin-block	2300	300	220	245

Table 7: Geometric characteristic of the sleepers.

The railway tracks generally lay on a layer of ballast; the latter can be replaced by a concrete plate in very special cases, such as viaducts with an isostatic structure and length span

not exceeding 30 m. The ballast is a layer of crushed stone with a thickness that can be about 50 cm or 35 cm, depending on whether the importance of the rail network is primary or secondary. The stone material has an internal friction angle of not less than 45° and an apparent volumetric mass of not less than 1.5 t/m^3.

Between the deck and the ballast exists a waterproofing layer consisting of two sheaths, one at the top and one at the bottom, and a protective layer of bituminous conglomerate about 5 cm thick. The membranes at the top and the bottom of the waterproofing layer have a thickness of about 5 mm and 3 mm, respectively, and a weight of 4 kg/m^2 and 3-3.5 kg/m^2, respectively. The bituminous conglomerate generally weighs 80-90 kg/cm^2.

Finally, the superstructure is also composed of noise barriers, the weight of which is usually taken from the manufacturer's data sheets.

Table 8 shows the weight and height to be considered for the design of the noise barriers provided by: (i) the Circular n. I/SC/PS-OW2298 1997 [1], (ii) the Technical Specification "RFI DTC INC PO SP IFS 001 A" 2011 [2], (iii) and the Manual for the Design of Civil Structures "RFI DTC SI PS MA IFS 001 A" 2016 [3].

Regulation	Weight [kN/m^2]	Height from the slab floor [m]
Circular 13/01/1997 [1]	2,0	4,0
Technical Specification "RFI-DTC-INC-PO-SP-IFS-001-A" 2011 [2]	4,0	4,0
Manual for the design of civil Structures "RFI DTC SI PS MA IFS 001 A 2016 [3]	4,0	4,0

Table 8: Prescriptions for noise barriers ([1], [2], [3]).

In the case of a superstructure consisting of ballast, railway track, and waterproofing (including the bituminous conglomerate), the non-structural load can be simply calculated by considering a total volume weight of 18 kN/m^3. This volume weight is applied over the entire average width between the paraballast walls, for an average height between the top rail and the extrados of the deck equal to 0.80 m. For bridges in curved railway sections, , the weight of the ballast used to create the superelevation must be added to the conventional weight indicated above, which is evaluated with its actual geometric distribution and with a volume weight of 20 kN/m^3 ([1], [2], [3]).

3.2.2 Train Live Loads

The simulated design of railway bridges requires an estimate of the train live loads used in the planning step according to the year of structure design.

For reinforced concrete bridges, the first regulation on this topic was issued in 1946, when Circular 30/10/1946 [14] introduced a formula for the evaluation of a dynamic increase coefficient φ to be used for reinforced concrete bridges:

$$\varphi = \frac{0.4}{1+0.2L} + \frac{0.6}{1+4P/S}, \tag{1}$$

in which L is the theoretical load capacity of the beam, P the overload, and S the permanent load. For the concrete structures design before the Circular n. I/SC/PS-OW2298 1997 [1], the increase in load due to the passage of trains was carried out by increasing the values of

overloading by 25%. This criterion derived from some regulations concerning the construction of concrete structures that were issued before 1945.

From 1945 until the following year, instead, the design of reinforced concrete bridges was carried out by using the dynamic increase coefficient φ defined in the Circular 15/07/1945 [15] for steel bridges: its value depended on both the design speed V and the theoretical capacity L of the structural element to be designed. Specifically, if rail joints were absent or only welded, the dynamic increase coefficient φ was assumed to be maximally of 40% to be associated to the elements of limited theoretical capacity L. This value was subsequently increased to 50% as well as the maximum design speed V_{max} that became equal to 100 km/h. As a consequence, the dynamic increase coefficient φ never exceeded 50%. Concerning the train live loads, Circular 15/07/1945 [15] defined two types of load in relation to the presumed railway traffic, i.e. "Type A" and "Type B" (see Figure 1). Alternatively, for the calculation of longitudinal ties, cross-beams, and structural elements with a low theoretical load capacity, the standard allowed the use of an isolated axle of 30 t and 25 t, instead of the train live loads "Type A" and "Type B", respectively.

Before the Circular 15/07/1945 [15], other regulations defining the train live loads were issued in Italy, but we did not consider them here as they concerned exclusively iron and masonry railway bridges, which were in the past much more common than the ones made of reinforced concrete. In Figure 2 we report only the train live loads used to design railway bridges before 1916, when the Italian State Railways was founded.

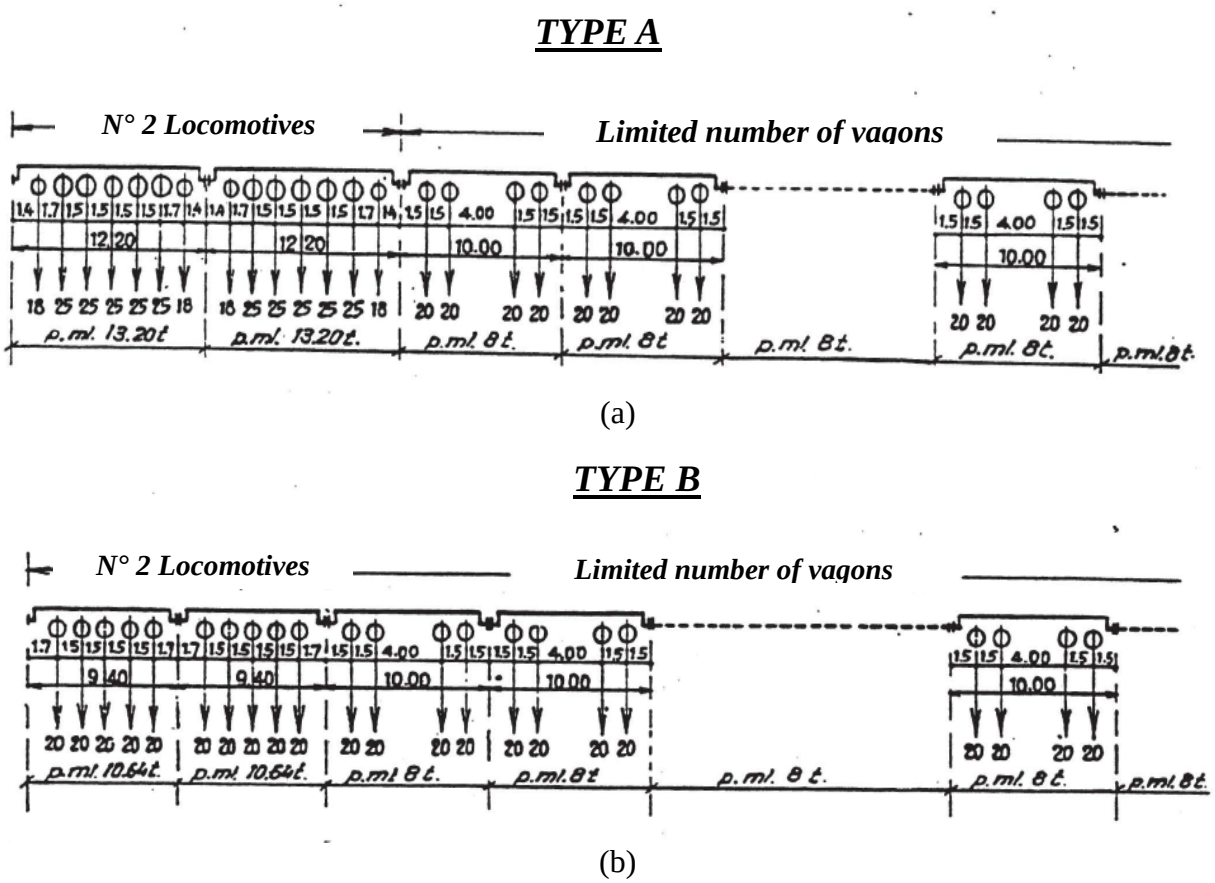


Figure 1: (a) "Type A" and (b) "Type B" train live loads, used for the design of railway bridges according to Circular 15/07/1945 [15].

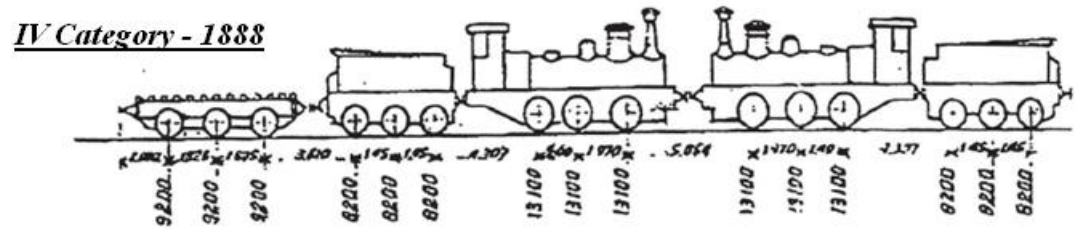
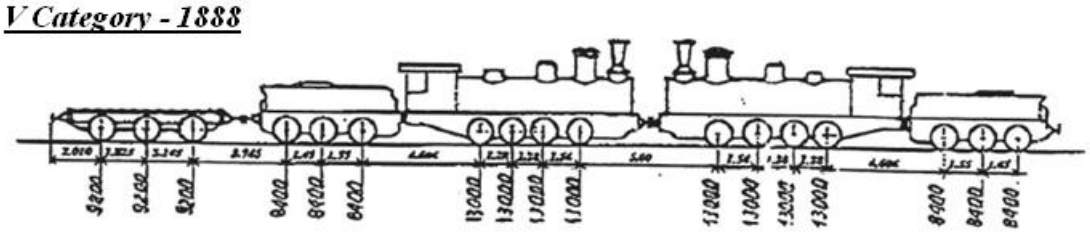


(a)



(b)

Figure 2: (a) “Category IV” and (b) “Category V” train live loads, used to design railway bridges before the standard issued in 1916.

The provisions of the Circular 15/07/1945 [15] have remained valid until 1995, when the Circular n. I/SC/PS-OW2298 *"Overloads for the calculation of railway bridges - Instructions for design, execution and testing"* were issued, and then updated in 1997 [1]. This Circular incorporated the instructions from the Eurocodes and introduced two new models of train live load that replaced the previous ones. The new models of train live loads were:

- for normal railway traffic “LM71”;
- for heavy railway traffic “SW”, which was available in two different configurations “SW1” and “SW2”.

The characteristic values attributed to the load models had to be multiplied by an adaptation coefficient α, which varied according to the category of the railway bridge to be designed (see Table 9). Bridges could belong to two different railway categories, i.e. “ Category A” and “Category B”. In particular, bridges in “Category A” applied to railways on which heaviest trains circulated or should be able to circulate; on the contrary, bridges in “Category B” applied to the secondary railways of normal gauge, not included in “Category A”.

Load model	Adaption coefficient α	
	Category A	Category B
LM71	1.1	0.83
SW/0	1.1	0.83
SW/2	1.0	0.83

Table 9: Adaptation coefficient α depending on the load model and the bridge category defined in Circular n. I/SC/PS-OW2298 " and its following update [1].

As it can be seen from Figure 3a, contrary to the provisions of the previous regulations, the train live load was represented by both axial and distributed loads.

In particular, the load model for normal traffic “LM71” consisted of four axles Q_{vk} of 250 kN, placed at a distance of 1.60 m from one another, and of a distributed load q_{vk} of 80 kN/m in both directions, starting from 0.8 m from the end axles Q_{vk} till an unlimited length. In addi-

tion, for this load model an eccentricity of the load towards the track axis was contemplated, depending on the gauge *s*, to take into account the displacement of loads.

The load model for the heavy traffic "SW" (see Figure 3b), instead, was characterized by two distinct configurations, as shown in Table 10.

Finally, for some particular controls, the Circular introduced a special train live load called "Unloading Train", represented by an uniformly distributed load equal to 12.5 kN/m.

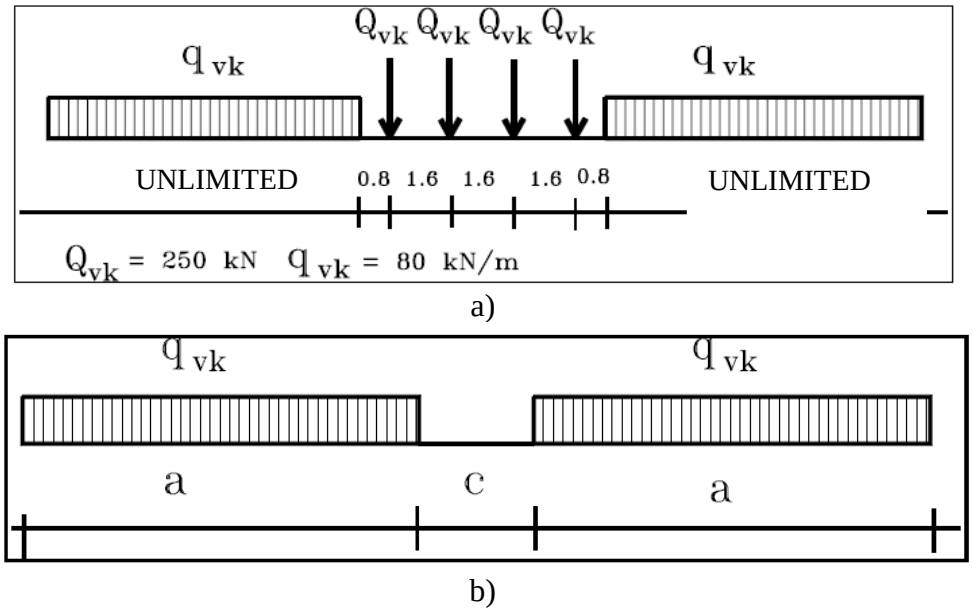


Figure 3: a) Load model for normal railway traffic "LM71" and b) Load model for heavy railway traffic "SW" defined in the Circular n. I/SC/PS-OW2298 and following update in 1997 [1].

Load model	Q_{vk} [kN/m]	a [m]	c [m]
SW/0	133	15.0	5.3
SW/2	150	25.0	7.0

Table 10: Load model for heavy railway traffic "SW" defined in the Circular n. I/SC/PS-OW2298 and following update in 1997 [1].

The Circular n. I/SC/PS-OW2298 1997 [1] further introduced two different dynamic increase coefficients φ in relation to the state of maintenance of the railway line which could be standard or reduced. These coefficients had to be applied to the theoretical load models "LM71" and "SW" in case of a static analysis, to take into account the movement effects and any imperfections of the rail, the wheels, and the suspension system. The Circular n. I/SC/PS-OW2298 1997 [1] also contemplated real dynamic increase coefficients φ_{real} to be multiplied to load models representing a real train. Real train load models are used in particular conditions of analysis (or for the design of specific bridge typologies) and are made of concentrated loads, variously spaced, that schematize the succession of the axes of convoys actually or potentially circulating; each of them was characterized by a maximum speed and a certain overall length [3].

Finally, the latest "RFI DTC INC PO SP IFS 001 A" 2011 [2] and "RFI DTC SI PS MA IFS 001 A" 2016 [3] assume the same load models defined in the Circular n. I/SC/PS-OW2298 1997 [1]. The only differences are: (i) the adaptation coefficient α, which herein depends only on the load model (see Table 11), (ii) the calculation of the real dynamic coefficient φ_{real}, and (iii) the value corresponding to the unloading train, which became 10.0 kN/m.

Load model	Adaption coefficient α
LM71	1.1
SW/0	1.1
SW/2	1.0

Table 11: Adaptation coefficient α depending on the load model defined in "RFI DTC INC PO SP IFS 001 A" 2011 [2] and in "RFI DTC SI PS MA IFS 001 A" 2016 [3].

3.3 Longitudinal and transverse reinforcement

In the seismic assessment of existing reinforced concrete bridges through analytical methods, the amount of longitudinal and transverse reinforcement in the piers needs to be known. This information is usually given in construction plans, but not often available. To fill this gap, the amount of the reinforcement can be derived from the appropriate code that was in use at the time of the structure design.

Table 12 reports the minimum values of both longitudinal and transverse reinforcement defined from the Royal Decree 16th November 1939 [8] to the Ministerial Decree 4th 1992 [16]. The Royal Decree 10th January 1907 [4] is excluded since it does not contain any information on the reinforcement to be placed in the reinforce concrete structural vertical elements. Instead, we deal separately with the Circular n. I/SC/PS-OW2298 1997 [1], the Technical Specification "RFI DTC INC PO SP IFS 001 A" 2011 [2], and the Manual for the Design of Civil Structures "RFI DTC SI PS MA IFS 001 A" 2016 [3] because they are regulations issued directly by Italian State Railways.

In particular, for all viaducts built in territories seismically classified in 1st category (S=12, where *S* represents the seismicity level), 2nd category (S=9), 3rd category (S=6), the Circular n. I/SC/PS-OW2298 1997 [1] defined the minimum quantity of longitudinal reinforcement as 0.6%A_{eff}, where A_{eff} is the area of the effective concrete cross-section. This limit changed to 0.4%A_{eff} for all viaducts designed in the 4th seismic zone category (i.e. not classified zone), with the exception of the Sardinia region. In addition, the longitudinal rebars had not to be more than 300 mm apart. The diameter of the stirrups and transverse ligatures, instead, had not to be less than 8 mm and was obtained according to relationships that depended on the cross-section type of the pier, i.e. whether they were rectangular or circular, in both cases solid or hollow. Furthermore, in piers with a solid or hollow circular cross-section the use of spirals was not permitted anymore and were replaced by circular stirrups. To increase the level of ductility of the structure, the distance *s* between the stirrups had to be more than 10 times the minimum diameter of the vertical rebars.

The Technical Specification "RFI DTC INC PO SP IFS 001 A" 2011 [2] and the Manual for the Design of Civil Structures "RFI DTC SI PS MA IFS 001 A" 2016 [3] resumed with the established values from the Circular n. I/SC/PS-OW2298 1997 [1]. Regardless of the seismic category for which the viaduct was designed, both Technical Specification and Manual for the Design of Civil Structures ([2], [3]) fix a minimum longitudinal reinforcement value of 0.6%A_{eff}. As established in the Circular n. I/SC/PS-OW2298 1997 [1], the longitudinal rebars should be connected by stirrups, which should have a diameter greater than 8 mm, but a pitch neither greater than 10 times the diameter of the longitudinal bars they connect nor 1/5 of the diameter of the section core inside them. In addition, piers with hollow section should have at least 6 ties per square meter connecting the longitudinal reinforcements. Finally, the limitations to define the diameter of pier stirrups provided by the Circular n. I/SC/PS-OW2298 1997 [1] were also present in the Technical Specification [2] and the Manual for the Design of Civil Structures [3]. The only difference was that such limitations only applied if the bridge design required the use of a structure factor *q* equal or less than 1.5.

Code	Longitudinal reinforcement	Transversal reinforcement
R.M.D. 16/11/1939 [8]	$A_s \geq 0.8\ \% A_c$ ($A_c \leq 2000$ cm^2) $A_s \geq 0.5\ \% A_c$ ($A_c \geq 8000$ cm^2) $0.8\%A_c < A_s < 0.5\%A_c$ ($2000\text{cm}^2 < A_c < 8000\text{cm}^2$)	$p \leq \min(1/2L_{min}, 10\phi_l)$
M.D. 30/05/1972 [11]	$0.6\ \%A_c \leq A_s \leq 5\ \%A_c$ $A_s \geq 0.3\ \% A_{eff}$ $\phi_l \geq 12$ mm	$p \leq \min(15\phi_{l,min}; 25\text{cm})$ $\phi_t \geq 6$ mm
M.D. 30/05/1974 [17] M.D. 16/06/1976 [18]	$A_s \geq 0.6\%A_c$ $0.3\%A_{eff} \leq A_s \leq 5\%A_{eff}$ $\phi_l \geq 12$ mm	$p \leq \min(15\phi_{l,min}; 25\text{cm})$ $\phi_t \geq 6$ mm
M.D. 26/03/1980 [19] M.D. 01/04/1983 [20] M.D. 27/07/1985 [21] M.D. 14/02/1992 [16]	$A_s \geq 0.8\%\ A_c$ $0.3\%A_{eff} \leq A_s \leq 6\%A_{eff}$ $\phi_l \geq 12$ mm	$p \leq \min(15\phi_{l,min}; 25\text{ cm})$ $\phi_t \geq \max(6\text{mm}; 1/4\phi_{l,max})$

A_s=Total steel area in a reinforced concrete pier cross-section; A_c=Concrete area strictly necessary for the axial load; ϕ_l=Diameter of the longitudinal steel in the pier cross-section; A_{eff}=Effective concrete cross-section; p=Stirrups pitch; ϕ_t=Stirrups diameter; L_{min}=Smallest size of the pier cross-section; $\phi_{l,min}$, $\phi_{l,max}$ =Smallest and biggest diameter of the longitudinal steel in the pier cross-section.

3.4 Bearings

Another necessary specification for the seismic verification of existing bridges relates to the actual function of supports in the structural response. The structural response cannot properly model the reality in case of inadequate modelling of support devices.

To this end, this section contains a brief description of the state of the art of bearings available in the Italian regulations from 1972 to the present.

The Technical Instructions CNR 10018/72 [22] provided guidance for the calculation, acceptance, and installation of elastomeric bearings, which could also be reinforced. To design this type of bearing required to define: (i) the normal force due to vertical loads acting on the support surface, (ii) the horizontal force due to permanent loads and thermal variations, and (iii) the horizontal force depending only on accidental loads and maximum rotation expected in the beam plane. Considering the most unfavorable combinations of the above mentioned loads and deformations, it was possible to calculate: (i) the normal tension due to the vertical load, (ii) the tangential tensions produced by the vertical load, the horizontal loads and the rotation, and (iii) the shortening and the elastic sliding due to the vertical load and the horizontal forces, respectively. These stress values were then used to carry out strength, sliding, and stability analyses in case of elastomeric bearings. In case of reinforced elastomeric devices, the verification of reinforcement was added to the analyses [23].

In 1985, Technical Instructions CNR 10018/72 [22] was updated. Specifically, in addition to elastomeric devices, the Technical Instructions CNR 10018/85 [24] allowed also the use of confined elastomeric disc bearings as well as PTFE slide bearings (PTFE stands for polytetrafluoroethylene, commonly known as teflon).

The confined elastomeric disc bearings allow rotations around any horizontal axis due to the deformability of an unreinforced rubber disc, confined within a steel monolithic base.

PTFE slide bearings, on the other hand, use sliding surfaces that consist of a layer of PTFE sliding on a surface with a flat, cylindrical, or spherical shape and that is usually made of stainless steel or aluminum alloy. To increase the load resistance, teflon is often combined with other materials (e.g. graphite, glass fibers, etc.), which can bring its load resistance up to

1000 daN/cm^2. Although they have mostly good properties, the negative characteristic of these bearings is that they deplete due to their highly viscous behavior, especially if subjected to reciprocal translations [25].

In 1987 the Technical Instructions CNR 10018 instructions were updated again: in this case the changes mainly concerned the level of the maximum horizontal forces that the supports could transmit to the structure [26]. In particular, bearings with metal plates solidified with reinforced concrete structures with cement or epoxy malt could transfer shear stresses of no more than 25% of the normal concurrent action. For supports with ribbed steel plates as well as with appropriate cavities or prominences, this limit could be increased by up to 35%. For shear stresses exceeding the above limits, mechanical connections had to be used (e.g. pins, clamps, etc.), especially in presence of bridges located in zones of high seismic hazard or when potentially exposed to significant dynamic actions [23].

In 1996, the Technical Instructions FS 44/B [27] were issued and incorporated all the innovations introduced by the Decree of the Ministry of Public Works 16.1.96 [28] in case of under-track structures designed in zones of high seismic hazard.

In 1998, the Technical Instructions CNR 10018 were improved again [29]. An important change compared to the latest version of the instructions, i.e. CNR 10018/85 [24], was that the use of natural rubber or neoprene devices was prohibited in favor of reinforced elastomeric bearings. Initially, natural rubber or neoprene devices were considered a valid alternative to steel devices, characterized by phenomena such as slippage (for cylindrical steel devices) or corrosion (both punctual and uniform). However, they were abolished because they showed several problems, such as deterioration due to atmospheric agents, hardening of the rubber, sliding of the support, as well as phenomena of fatigue and creep. These negative aspects were greatly reduced in reinforced elastomeric devices, which were capable of withstanding simultaneous loads and displacements in any direction and of restoring the undeformed configuration after the permitted displacements. Moreover, being immersed in the rubber, the steel of the reinforced elastomeric bearings is preserved from the phenomenon of corrosion. The only phenomenon that can cause the collapse of such devices is the delamination between elastomer and steel, which, depending on the entity, can cause the total or partial loss of compressive strength without additional deformation. Finally, for the design and verification of the elastomeric devices, the Technical Instructions CNR 10018/85 [24] considered the actions to which they are subjected as well as the permitted displacements, both of which had to be calculated using a three-dimensional analysis of the structure.

In addition to the different types of bearings already described in the previous versions, the Technical Instructions CNR 10018/98 [29] provided new information on bridge bearings made entirely of steel. The functioning of the steel devices is based on the physical rolling phenomenon of two or more steel surfaces in contact with each other.

In 2002 the Technical Instructions FS 44/E were issued [30] that initially defined and described in detail which bearings had to be used for railway bridges, also according to the type of movement allowed in the plane. In particular, the bearings could be fixed or movable. If they are fixed, all the translations are prevented, otherwise translations in one or more directions of the plane are allowed. The Technical Instruction FS 44/E [30] also stated that all bearings had to be capable of rotation in accordance with the values given in the instruction itself and that, if bearings were required to transmit high horizontal forces, it might be convenient to use seismic restraints (fixed or movable).

Finally, the recommendations defined in the Technical Instructions FS 44/E [30] were also included in the Technical Specification "RFI DTC INC PO SP IFS 005 A" 2011 [2], and then later replaced by the Manual for the Design of civil Structures “RFI DTC SI PS MA IFS 001 A” 2016 [3]. The latter provides the requirements for the calculation, construction, installation,

and control of bearings used for railway bridges in accordance with the New Technical Regulations [12], and following the Ministerial Circular 2 February 2009 no. 617 [31].

4 CONCLUSIONS

This paper gave a bibliographic review about the regulations on the design of railway girder bridges, issued in Italy from 1900 to the present.

In particular, the paper intended to report the main changes that have occurred at the regulatory level on the construction of reinforced concrete railway bridges, especially in terms of mechanical characteristics of materials, loads, longitudinal and transverse reinforcements, as well as bearings.

The first Italian regulation on the design of reinforced concrete railway girder bridges that is publicly available dates back to 1995. The provisions on the reinforcement of piers and on the mechanical characteristics of materials derived from regulations that had been issued in Italy starting from 1907. For mobile loads and bearings, technical standards specifically issued for railway bridges had been taken into account from 1946 until 1972.

The definition of the permanent load depends on the composition of the superstructure. For this purpose, this paper also provided information about the weights of the railway track and ballast, as well as the weight of noise barriers.

The bibliographic review of the Italian regulations given in this paper provides a collection of data that is necessary for the simulated design of railway reinforced concrete girder bridges in Italy using analytical methods. The presented data depend on the year of design and the type of railway bridge and eventually define the likely seismic behavior of these structures.

Abstract

The aim of this work is to present an application developed by Eucentre (EUropean CENtre for Training and Research in Earthquake engineering) to define fragility curves for RC railway bridges in the framework of large scale vulnerability assessment.
The application creates a digital model of the analyzed structure automatically assembling the representative objects which constitute the bridge, such as decks or piers, and the mutual relationships that each object has with the others. Then, the application generates a sequence of nodes and beams, placed on a horizontal plane corresponding to the added planimetric layout and, given the bridge coordinates, defines the site reference seismic hazard.
The obtained digital model allows to convert the structure individual components' description into a useful and functional finite element model. After selecting a certain number of return periods corresponding to the reference seismic action, the application generates several spectrum-compatible accelerograms to perform nonlinear time history analysis. Nonlinear dynamic analyses are preferred to others to better detect the seismic behaviour of bridges whose vulnerability is herein evaluated through the definition of fragility curves. In case of partial level of knowledge, the finite element model cannot be defined. Hence, ad hoc simplified mechanic-based methodologies have been developed.
Two levels of capacity for the seismic verification are considered: one regarding the functionality (damage limit state) and the other regarding the bridge safety (collapse limit state).
These limit states, considered in the fragility curves derivation, essentially concern the piers' deformation and resistance capacity (ductile and brittle failures) and the girders' loss of support.

Keywords: Fragility curves, Railway bridges, Seismic vulnerability.

1 INTRODUCTION

This work deals with the description of the development of an application for the determination of fragility curves for large-scale assessment of reinforced railway bridges.

Several studies on seismic risk assessment of infrastructures have been done in the past on Italian infrastructures which mainly concerned the seismic assessment of highway and road bridges [2][4][16][19][20]. Hence the need to deepen the seismic assess of railway bridges through a methodology that allows a large-scale study of the seismic vulnerability of such structures through the construction of fragility curves. The goal of the work is to create a tool able to generate the numerical model of a bridge through the execution of numerous non-linear time-history analyzes to derive the bridge-specific fragility curves.

The application performs the structural calculations using OpenSEES [17] finite element analysis program and generates a digital model of the analyzed structure, automatically constructing the representative objects of its parts, such as the deck, the piers and mutual relationships that each object has with the others. This digital model makes it possible to convert the description of the individual components of the bridge into a useful and functional finite element model in order to carry out the simulations for the calculation of fragility curves.

The aim of the work is to provide specific fragility curves for individual railway bridges of which complete data are known. The study of the methods of analysis of the seismic vulnerability of railway bridges object started by studying the structural typologies prevalently widespread in Italy. Among all the typologies, girder bridges were taken into account.

Girder bridges are generally formed by a deck constituted by multiple beams which can be simply supported or continuous, in such a way as to have an isostatic or hyperstatic structural scheme. Due to static and seismic loading, beams are subject to shear and bending forces. In girder bridges, the deck it's supported by unreinforced or reinforced concrete piers and can be constituted by reinforced concrete, prestressed reinforced concrete or steel.

Between the deck and the vertical structure of the bridge there are the support devices, the choice of which depends mainly on the type of deck and the type of constraint required. In the case of a reinforced concrete deck, the adopted construction technologies are dependent mainly on the total length of the bridge and the individual bays.

For spans over 4 m the simplest system used in the railway infrastructures consists of girder deck and upper flange. The beams can have a double "T" or a box section and reach a length of about 20-25 m. Cross beams are used to guarantee the collaboration between all the beams of the deck: generally they have a height equal to that of the concrete ribs to which they are connected both in the head and in intermediate positions.

In addition to ordinary reinforced concrete, the deck can be made of prestressed concrete beams. This type of deck allows to cover spans between 35 and 50 m and is used both in ordinary and high speed railway rail.

Another type are the steel decking bridges which have been widely used in the past; nowadays, however, these decks are mainly used for large-span bridges with reduced height or to replace pre-existing metal girders.

Regarding decks with ballast presence, they are usually with a box or a mixed structure, or composed of double "T" or box beams with a concrete flange slab.

2 MODELING

The application divides the bridge into three areas: super-structure, connections and sub-structures, where for connection area is intended all that is in between the super-structure and

the sub-structures. These three areas are treated and processed in sequence because the geometric construction of the bridge is from top to bottom and the underlying parts depend on those above them.

The elements constituting the super-structure are organized in a rigid hierarchy: the bridge tracking is composed by decks, which are composed by one or more bays, divided into bay segments. It is assumed that at the beginning and at the end of each bay there is a sub-structure (pier or abutment). It is not necessary to specify either the planimetric position or the orientation of these sub-structures, since it can be automatically deduced from the terminal position of bays (the latter derives from the planimetric layout already known at the modeling of the sub-structures). The spans' division into segments is useful for several reasons: to change the structural section within a single bay; to insert internal releases (such as Gerber saddles); to follow a plan curve layout; to obtain a discretization of the masses along the span to capture the dynamic response of super-structure modes.

The application allows the maximum flexibility of definition of the super-structure: it allows, in fact, to alternate both supported and continuous decks as well as to alternate straight or curved (mixed pattern), even within the same bay.

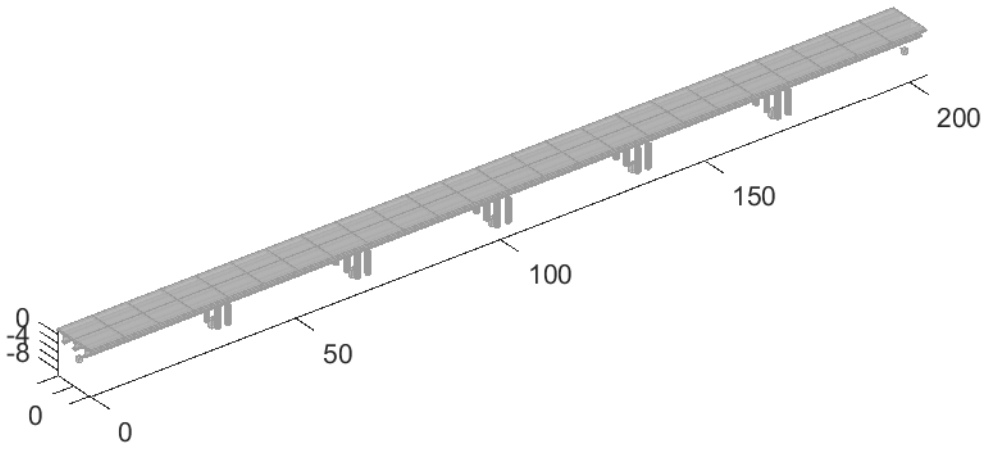

Figure 1: Extruded view of a modeled bridge.

Each railway line of the bridge is modeled with an elastic single-line model consisting of only finished beam elements (Figure 1).

For the geometric construction of the path, the application automatically calculates the planimetric angle that is tangent to the path in each node of the superstructure. This procedure allows to define an intrinsic reference in the same point (horizontal axes tangent and orthogonal to the bridge direction, plus the vertical axis) that is automatically assigned as a natural reference also for the connecting elements and for the substructures. In other words, substructures are naturally and automatically rotated in their local reference to follow the trend of a curvilinear path.

The connection between the superstructure and the substructure is made by two objects: connections and supports. The connection has the function of rigidly transferring the load transmitted by the end node of a span to the extrados of the substructure. This transfer is regulated by two geometric quantities: one horizontal (ΔL) and one vertical (ΔZ). The latter consists of two quantities: the distance of the center of gravity of the section measured by the deck intrados (ΔZ_G) and the distance between the extrados of the pier cap and the intrados of the deck (ΔZ_C). The ΔL and ΔZ_C values are input data, the ΔZ_G value is calculated automatically by the appli-

cation. In a real bridge, the value ΔL represents the distance between the alignment of the supports and the end of the deck, while ΔZ_C is usually the vertical encumbrance of the bearings plus the supports (Figure 2).

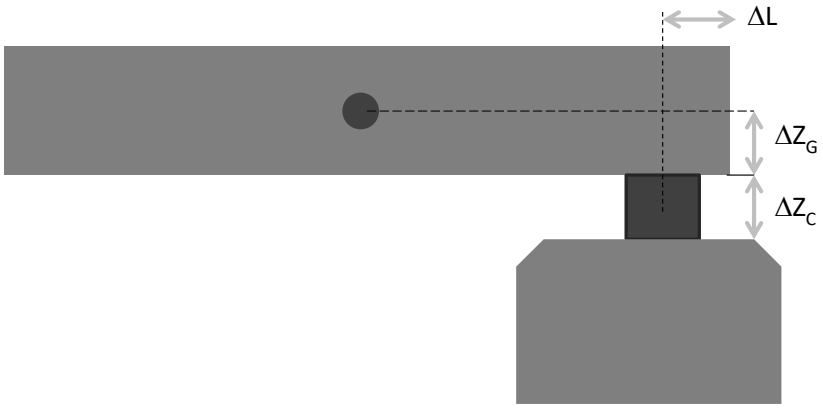

Figure 2: Deck and bearing geometry.

Figure 3 represents a simple substructure (single pier); in the case of portal, frame or multiple-frame piers, different assumptions are made for the connection between the nodes of the pier and the lower ones of the supports.

In both articulated and simplest cases, it is always assumed that the axis of the substructure is placed in the center of gravity of the master nodes of the respective connections that converge to it.

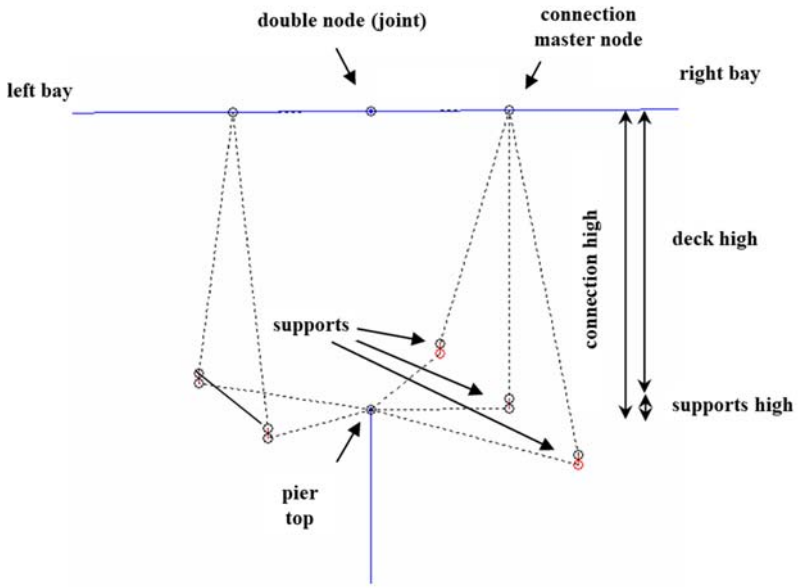

Figure 3: Connection modeling scheme.

The element used for modeling the piers is the BeamWithHinges element of the OpenSEES library [17]. It is formulated with an optimized integration scheme along its development that employs non-linear fiber sections at the ends and elastic sections in the central part. The model

considers a non linear behaviour that occurs in piers and supports. This limit is imposed by the need to automatically manage numerous non-linear finite element time-history analyses.

To define the concrete material, the application employs a very small set of parameters.

For the definition of elastic properties it is necessary to specify the Young's modulus, the Poisson's module and the unit weight.

For the definition of the non-linear properties, it is assumed a nonlinear stress-strain law (the application uses OpenSEES's Concrete01 material [17]) for which, in addition to the weight density, four values need to be specified: the concrete compressive strength at 28 days, the concrete strain at maximum strength, the concrete crushing strength and the concrete strain at crushing strength.

It is assumed that the mechanical properties of the concrete follow a lognormal distribution. For each numerical simulation different sampled values are adopted.

For example, the case of the concrete compressive strength is illustrated:

$$f_{co\ simulation,i} = f_{co} \times \varepsilon_{f_{co},i} \tag{1}$$

where:

$$\varepsilon_{f_{co}} \sim LN\left(0, \beta_{f_{co}}\right) \tag{2}$$

where β_{fco} parameter is the standard deviation of the logarithmic distribution assumed for the peak resistance of the concrete.

Similar to concrete, the application uses a very small set of parameters to define the steel material. Also in this case, for the definition of the elastic properties, it is necessary to specify the Young's modulus, the Poisson's modulus and the unit weight.

For the definition of the non-linear properties, the application uses OpenSEES's Steel01 material [17] with uniaxial bilinear steel material object with kinematic hardening for which it is necessary to specify the yield stress and the hardening in addition to the unit weight and the Young's modulus. Also in this case, the mechanical properties follow a lognormal distribution defined in the same way as concrete.

2.1 Supports

The first support devices used for reinforced concrete bridges, with a span less than 18 meters, were those made of two lead sheets of one centimeter each, between which was interposed or a steel sheet thick one millimeter (fixed type support) or two steel sheets with graphite contact faces (mobile type support).

Nowadays, steel support devices are spherical, hinged or pendulum type and are used in the presence of steel decks or high reactions transmitted by the deck.

The support constraints of girder bridges vary according to the type of deck. They can be classified in relation to the physical principle used (i.e. rolling, deformation, and sliding), to the degrees of freedom (i.e. fixed supports and mobile bearings) to the transmission of the load (i.e. punctual, linear, and superficial) and to the material they are made (i.e. steel, aluminum, natural or synthetic rubbers).

For the support devices, the application foresees that the constitutive law of the two degrees of freedom associated with horizontal translations is specified, since the remaining DOF are either completely rigid (vertical or rotational DOF) or completely flexible (rotational DOF).

The types of support that have been implemented in the program have been chosen according to the most common types of support in Italian railway bridges and are summarized in Table 1.

Type of support	Description
Fixed	the translational DOF and all the rotational DOF are fixed
Spherical hinge	both the DOF (in plan) are fixed and all the rotational DOF are free
Cylindrical hinge	both the DOF (in plan) are fixed and a single free rotational DOF
Mobile	both DOF (in plan) are free
Unidirectional longitudinal	the longitudinal DOF (in the local reference) is free, the transverse one is fixed
Unidirectional transversal	the transverse DOF (in the local reference) is free, the longitudinal one is fixed
Anisotropic elastoplastic	the two DOF have two elastic perfectly plastic constitutive laws decoupled
Isotropic elastoplastic	the two DOF have isotropic elastic perfectly plastic constitutive law
Friction	the two DOF have a friction isotropic constitutive law

Table 1: Typologies of supports.

With reference to the OpenSees calculation engine [17], the finite elements used for each type of support are constituted by TwoNodeLink finite elements: depending on the type of constraint and on the degrees of freedom, materials that represent a linear or fixed DOF are assigned. In the case of anisotropic elastic a ElastomericBearing finite element is used in the two direction, while in isotropic only one typology is defined. In the case of friction support a FlatSliderBearing finite element is used.

2.2 Definition of loads

The weights and permanent loads are calculated directly in the hypothesis of standard configurations provided by the application for super-structures and sub-structures. For what concerns super-structures, the application allows two different ways to define the contribution due to the dead load. The first is the direct specification of total weight per meter of deck: this condition makes it possible to generalize the application to all those configurations that are explicitly provided for. The second is the specification of the weight only of the carried permanent loads, assigning to the application the automatic calculation of the weight contribution of the structural section of the deck.

The determination of the carried permanent loads referring to the ballast, the railway track and the waterproofing has been carried out assuming a volume weight equal to 18 kN/m^3 applied over the entire average width between the ballast retaining walls for a medium height between rail level and deck extrados of 0.80 m, as indicated in § 5.2.2.1.1 of DM2018 [11]. In particular, the ballast load was defined per unit length of longitudinal development of the bridge (in kN/m), considering an average width of the ballast equal to 4.90m.

In addition to its own weights and permanent vertical loads and masses, the application allows to apply a portion of the vertical loads and masses associated with the transit of the train. The loads used in the application are those in § 5.2.2.2.1 of the Italian DM2018 [11] code by

means of different load models representing the different types of rail traffic: normal and heavy. Three types of load can be considered: LM71, SW/0 and SW/2. The loads' values have to be multiplied by an adaptation coefficient "α", variable according to the type of infrastructure, and by a coefficient φ, which takes into account the dynamic nature of the trains transit.

In order to evaluate the overloads associated with the transit of trains and the part of them to be used for seismic checks, the value of the q_{tr} load per unit of length was assumed equal to:

$$q_{tr} = q_{eq,tr} \cdot \alpha \cdot \varphi \tag{3}$$

where α and φ are respectively the adaptation coefficient and the dynamic coefficient described above, while $q_{eq,tr}$ represents the equivalent uniformly distributed load per unit of length defined as a function of load models LM71, SW/0 and SW/2.

The loads associated to the transit of trains are applied to the bridge as loads per unit of longitudinal development length (in kN/m) and assumed ones equal to $\psi_2 \cdot q_{tr}$.

In the seismic vulnerability calculations the condition that involves the presence of the overloads and the masses associated with the transit of the train convoys is assumed by adopting ψ_2 equal to 0.2 according to § 5.2.2.8 of the Italian DM2018 [11].

3 DEFINITION OF LIMIT STATES

The limit states considered in the calculation of fragility curves vary in relation to structural elements and are:

1) for piers: the ductile and fragile mechanisms. The ductile mechanisms depend on the total chord rotation amount while the fragile ones depend on the element shear.

2) for decks: the loss of support mechanism towards the supports or the pier cap, controlled by the relative excursion of the support devices.

3) for supports bearings the achievement of the maximum capacity in terms of resistance.

For all the limit states considered, two levels of capacity are foreseen during the verification: one related to the necessity to carry out repair interventions (damage limit state) and the other concerning the safety of the bridge (collapse limit state). An exception to this rule is the fragile shear mechanism on the piers, for which only the collapse limit state is defined. The operation limit state is, instead, linked to the deformations limit defined in relation to the train's safe transitability of the bridge and the limits imposed are not connected with the damage to the structures.

The expressions of capacity used for the calculation of the mechanisms inherent to the piers are those reported in DM2018 [11] and described in §3.1.

These capacities are to be understood different according to the two directions of the cross section of the pier. When verifying the overall limit state of the section, it is assumed that the risk indicator ρ, understood as the ratio between demand and capacity, is obtained, for each time step, by the SRSS combination of the results of the checks on the two main flexion plans. As an alternative to the SRSS combination rule, the rule for combining the directional maximum is used, for example in the loss of support verification. With reference to the three mechanisms examined ("θ" ductile mechanism, "V" fragile mechanism, "d" loss support mechanism), is obtained:

$$\begin{aligned}
\rho_{\theta,x} &= \frac{\theta_{demand,x}}{\theta_{capacity,x}} \quad \rho_{V,x} = \frac{V_{demand,x}}{V_{capacity,x}} \quad \rho_{d,x,SL} = \frac{d_{demand,x}}{d_{capacity,x,SL}} \\
\rho_{\theta,y} &= \frac{\theta_{demand,y}}{\theta_{capacity,y}} \quad \rho_{V,y} = \frac{V_{demand,y}}{V_{capacity,y}} \quad \rho_{d,y,SL} = \frac{d_{demand,y}}{d_{capacity,y,SL}} \\
\rho_{\theta} &= \sqrt{\rho_{\theta,x}^2 + \rho_{\theta,y}^2} \quad \rho_{V} = \sqrt{\rho_{V,x}^2 + \rho_{V,y}^2} \quad \rho_{d,SL} = max\left(\rho_{d,x,SL}, \rho_{d,y,SL}\right)
\end{aligned} \tag{4}$$

The application optionally allows to replace the directional combination rule related to the SRSS shear with the most usual rule that uses the directional maximum:

$$\rho_V = max\left(\rho_{V,x}, \rho_{V,y}\right) \tag{5}$$

The loss-of-support mechanism of decks, although rare, is very dangerous in bridges and occurs when there is an excess of relative excursion between the super-structure and the sub-structure. This eventuality can occur either on alignments of mobile bearings, when they don't guarantee an appropriate restraining retention or they collapse, or on alignments of fixed bearings when they collapse.

The loss of support can have a different degree of severity if referring to the support or pier cap. In the first case, the span falls from its natural seat but does not collapse because supported by the pier cap while, in the second case, the falls of the deck from the pier cap implies the partial collapse of the bridge. This substantial differentiation is maintained during the verification by associating the fall from the support to the damage limit state and the fall from the pier cap to the collapse limit state.

Finally, the assumptions regarding the definition of the limit states concerning the bridge as a whole and not just its components (piers and supports) are illustrated. As already highlighted, each of the controlled mechanisms on the components is a main mechanism, i.e. the achievement of the corresponding limit state on the component implies the achievement of the same limit state on the bridge. This hypothesis is known in the theory of systems as a series arrangement of the components and, although it is the simplest hypothesis that can be formulated, it is quite adherent to the physical reality of bridges, especially in the collapse limit state. It is normal, in fact, to assume a collapsed bridge when one of its piers or girders has collapsed.

3.1 Ductile and brittle mechanisms

The capacities, in terms of total yield and ultimate rotation, are given by the expressions:

$$\theta_y = \phi_y \frac{L_V}{3\nu} \tag{6}$$

$$\theta_u = \theta_y + \left(\phi_u - \phi_y\right) L_{pl} \left(1 - \frac{L_{pl}}{2L_V}\right) \tag{7}$$

where the length of plastic hinge was evaluated as:

$$L_{pl} = 0.1L_V + 0.17h + 0.24\frac{d_{bL} f_y}{\sqrt{f_c}} \tag{8}$$

where φ_y and φ_u are the yield and the ultimate curvatures; h is the height of the section, d_{bL} is the diameter of the longitudinal bars; f_y and f_c are the strengths of the materials; L_V is the shear span at member end and is equal to M/V. L_V can be approximated to L (for single beam and frame piers) and to L/2 (for frame piers) in the longitudinal and transversal direction, respectively.

These capacity expressions are evaluated separately for longitudinal and transverse direction of the base section of each pier.

The application provides for the adoption of different expressions for the shear capacity (resistance): the expressions in the DM2018 [11] (attached to the Circular § C8.8.5.5 [9]), the expressions referable to Priestley-Kowalski [21]or those present in the Eurocode 8 part 3[6].

The shear capacity V_u is always calculated according to the expression:

$$V_u = V_c + V_s + V_N \tag{9}$$

where V_C, V_S and V_N are the contributions of concrete, stirrups and normal stress.

3.2 Loss of support

The amount of demand for determining the risk related to the loss of support mechanism is the relative excursion between super-structure and sub-structures for each alignment of supports, equal to the average deformation of the bearings of each alignment.

This excursion is verified both in the longitudinal direction (parallel to the bridge axis) and in the transversal direction, since the two directions can have different capacity limits. In particular, these capacities must be specified in each alignment, as well as for the two main directions, also for both the verified limit states (SLD and SLC): $d_{SLD,longitudinal}$, $d_{SLC,longitudinal}$, $d_{SLD,transverse}$, $d_{SLC,transverse}$.

Normally, it is assumed, as a capacity to the damage limit state, the limit that implies the non-damage of the devices and in any case the fall from any supports, and as limit of the collapse limit state, the limit of fall from the pier cap which implies collapse.

In the absence of input data, the application estimates the capacities for the loss of support mechanism based on the geometrical data of the bridge. In this case, it is advisable to carefully evaluate the engineering consistency of these quantities. As an example, Figure 4 reports a typical case for the loss of support of the span from the pier cap in the longitudinal direction; in this case the application simply estimates a capacity equal to b/2-e according to Figure 4.

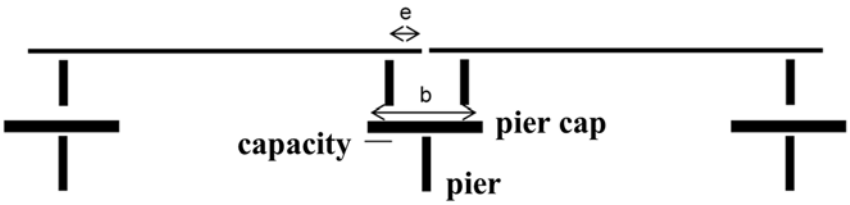

Figure 4: Scheme for the loss of support in the longitudinal direction.

4 GENERATION OF FRAGILITY CURVES

For girder bridges the application generates fragility curves, defined by cumulative probability distributions that allow to estimate the probability of reaching or exceeding a given level of damage for a given severity of ground shaking, for each boundary state analyzed through the following steps. The bridge is modeled for non-linear analyzes in the time domain.

The seismicity of the national zonation site is acquired, i.e. on the basis of the seismic hazard related to the site of the bridge as well as of the local amplification effects due to the soil. Then it is possible to select n periods of return of the seismic action and calculate the corresponding elastic response spectra (n ~ 9). The maximum number of selectable return periods is 9 in line with national technical standards (DM2018 [11]). Spectrum compatible signals (m ~ 10) are generated on the basis of the elastic projections for each return period.

Simulations are performed and the application proceeds with the extraction of the time history of the variables and the quantity of demand (N, V, θ for piers and d for supports), where N is the normal stress acting on the elements, V is the shear and d is the excursion of the supports.

Subsequently the capacity vectors are calculated for each verified limit state, generally dependent on the time history of the variables (θ_{SO}, V_{SLC}, θ_{SLD}, θ_{SLC}, d_{SLD}, d_{SLC}). At this point, risk indicators (ρ) are calculated as the ratio between demand and capacity for each limit state verified for each component of the bridge. Each risk indicator depends on five indices: the period of return of the seismic action (i1); the analyzed signal (i2); the time step of the signal (i3); the component of the bridge (pier or support) (i4) in hypothesis of state limit of damage (SLD) and collapse (SLC), while monitoring only the displacement at the top of the piers in hypothesis of operation limit state (SLO); the verified direction (i5), indicating more simply X or Y. At this point a directional combination of the risk indicators is made according to whether they are piers or supports. The Y risk indicators of the system are calculated from the component indicators (envelope of the mechanisms). Subsequently, the normal fit log of the Y risk indicators is performed with respect to the signals analyzed and the calculation of the probability of exceeding the verified limit state, conditioned to the return period (point of the fragility curve).

Figure 5 shows the risk indicators for the damage limit state (sx) and the collapse limit state (dx), and at the bottom the relative fragility curves for a specific bridge analyzed.

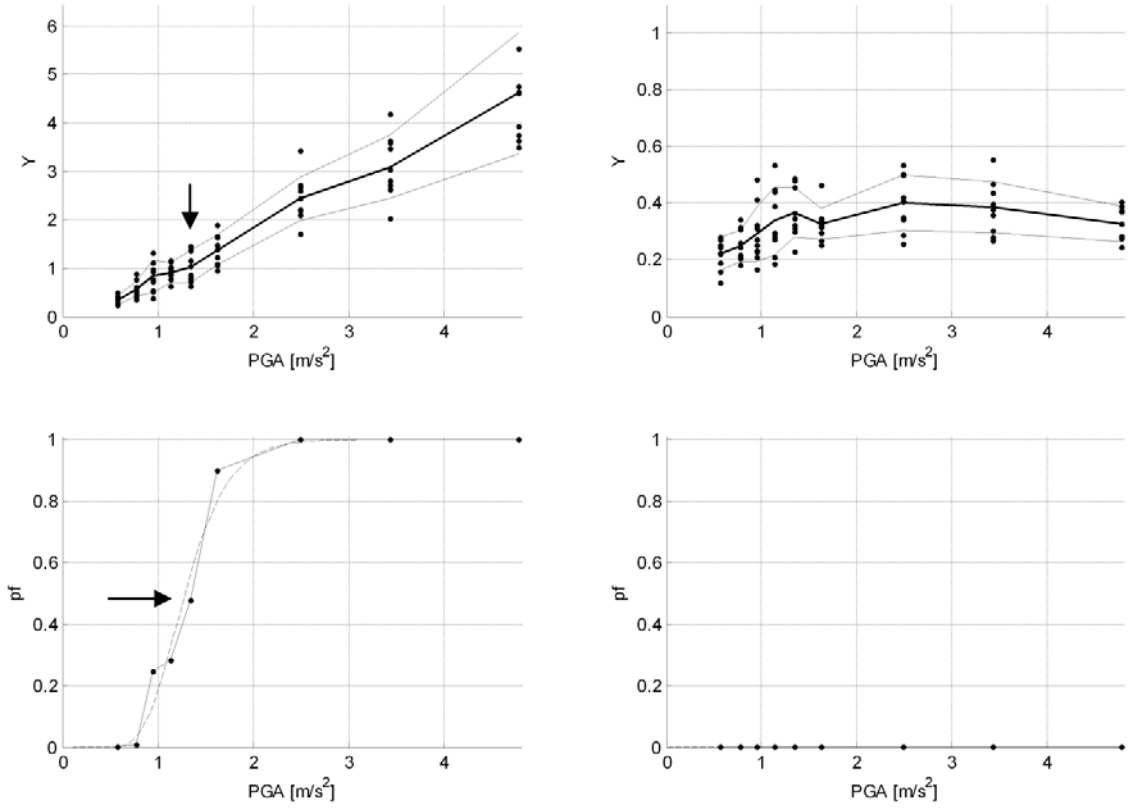

Figure 5: Risk indicator and fragility curve example.

For the calculation of the fragility curves shown in Figure 5, nine return periods of the reference input motion were adopted, and for each of them 10 simulations were carried out.

The application provides a report for each of the four phases of analysis: data acquisition, static analysis, seismic input, and dynamic analysis.

5 CONCLUSIONS

The paper deals with the development of an application for the automatic calculation of fragility curves of railway bridges in the hypothesis of complete knowledge of the bridge. The main hypotheses adopted in the structural modeling of bridges are illustrated.

The FEM analyzes are carried out in the time domain with partially degrading hysteretic constitutive laws, using the OpenSEES [17] code: a description is given of the main analytical options used in the calculation models. The application automatically manages numerous non-linear finite element time-history analyses after carrying out the static analysis and calculating the curvature moment relationship of each pier.

For each simulation, the input motion is obtained from a pair of artificial spectral-compatible accelerograms generated by the application and applied to the structure fixed at the base in two horizontal and orthogonal directions. The adopted reference spectra are those contained in the current national code (DM2018 [11]).

The limit states considered in the calculation of the fragility curves essentially concern the deformation and resistance capacity of the piers (ductile and fragile mechanisms) as well as the loss of support of the deck towards the supports (bearing device or pier cap), due to the excessive horizontal excursion induced by seismic motion. These limit states are defined and checked for the individual components of the bridge (piers and supports); since these components are all main elements of the bridge, the achievement of a limit state on a component automatically determines the achievement of the same limit state on the bridge (system in series).

The procedure for calculating fragility curves is described with particular reference to the articulated use of risk indicators. These indicators are instantaneous quantities defined as the relationship between the seismic demand and the capacity of the components for each verified limit state. Their elaboration allows the production of fragility curves.

A SIMPLE PROCEDURE FOR EMBEDDING SEISMIC LOADS IN FOUNDATION SUPERELEMENTS FOR COMBINED WIND, WAVE AND SEISMIC ANALYSIS OF OFFSHORE WIND TURBINE STRUCTURES

Martin B. Nielsen[1*], **Emrah Sahin**[1]

Keywords: Offshore wind turbines, earthquakes, superelements.

Abstract. *A simple approach for integrating loads associated with seismic excitation of offshore wind turbine structures into foundation superelements is presented. This allows the load calculation process for combined wind, wave and seismic loads typically conducted in collaboration between the foundation and the wind turbine designers to be performed similarly to the conventional sequential procedure used for combined wind and wave loads. It is illustrated how a time-varying seismic acceleration field can be converted into ground displacement time series that can be used to excite the integrated wind turbine structure through a superelement representation of the foundation. In contrast to the conventional approach where an acceleration field is applied to a local frame of reference, the present approach operates in an absolute reference frame such that the kinematic variables – displacements, velocities and accelerations – include the overall rigid body contribution from the prescribed ground motion. It is shown that the proposed method exactly matches the results from the conventional approach based on an acceleration field applied to a local frame of reference in absence of damping/or with deformation proportional damping only. Furthermore, it is illustrated for a more realistic example of a jacket-founded multi-MW turbine model including a both mass and stiffness proportional damping matrix that both methods still yield very similar results.*

1 INTRODUCTION

A key aspect in design and analysis of offshore wind turbine structures in seismically active regions such as the rapidly growing new markets in Southern Europe, East Asia and Western United States is to properly account for the loading associated with earthquakes. While the governing standards for offshore wind structures such as DNVGL-ST-0126, [1] are highly developed for design load cases combining wind and hydrodynamic loads, less detailed guidelines are available for earthquake design and reference is instead made to EN 1998-5, [2] or ISO 19901-2, [3] for detailed design criteria. However, these are mainly developed for building structures or offshore oil & gas platforms, respectively, and not particularly suited for slender offshore wind structures as also highlighted in e.g. [4, 5]. Nor do they consider the practical issue that the design responsibility of the combined wind turbine and foundation structure typically is split between the wind turbine and the foundation designers, such that each has their own structural analysis model in different special purpose software packages.

In contrast to hydrodynamic loads where the fluid-structure interaction is often ignored for small structural deformations, the nature of earthquake-induced inertia loads requires the seismic analysis to be conducted on an integrated model representing the combined dynamic behavior of the substructure, here defined as the foundation including piles or buckets below mudline, and the superstructure, i.e. the tower and rotor-nacelle-assembly (RNA). The traditional approach adopted for modeling seismic loads is to apply a uniform acceleration field representing the ground motion to the integrated structure, [6, 7], whereby the kinematic results – displacements, velocities and accelerations – refer to a local accelerated frame of reference, [8]. However, due the split of responsibilities, no unified model accounting for combined seismic and wind and wave loads exist. Instead, the aero-servo-elastic analysis conducted by the turbine designer is performed on a superstructure model with a so-called superelement representation of the substructure serving as boundary condition, [9, 10]. Therefore, application of a simultaneous acceleration field to both the substructure by the foundation designer before model reduction and to the superstructure in the aero-elastic model by the turbine designer is complicated due to the fact that commonly used software packages in the industry do not accommodate the necessary modeling or validation features across the split interface. To circumvent this issue in practice, a simplified design approach is to perform the seismic analysis on a separate model in either time of frequency domain and superimpose static wind/wave loads e.g. corresponding to a 1-year return period, see [7]. However, neglecting the lack of correlation between the extrema for each of the environmental load contribution significantly increases the conservatism inherent in the design.

In this paper a practical solution to the above described problem is presented. It is illustrated how a time-varying seismic acceleration field can be converted into ground displacements that can be used to excite the integrated structure solely through the foundation, thereby permitting the loads to be embedded into a superelement representation hereof. In contrast to the conventional approach where an acceleration field is used to accelerate the structure in a local frame of reference, the present approach operates in absolute frame of reference such that the kinematic results include the overall contribution from the ground motion. An overview of the conventional procedure for foundation design is given in section 2, while the theoretical framework for extension to seismic analysis and the validation hereof by means of representative numerical examples are presented in sections 3 and 4, respectively.

2 DESIGN PROCESS FOR OFFSHORE WIND TURBINE FOUNDATIONS

As mentioned in the introduction, it is common practice to split the responsibility between the wind turbine and the foundation designers such that the former is responsible for the superstructure as well as the coupled aero-elastic simulations, while the latter performs the detailed design of the substructure. For this purpose, it is convenient to exchange the computer model of the substructure along with associated loads in a condensed form typically referred to as a superelement that can be included in the aero-elastic software used by the wind turbine designer. This sequential approach serves two purposes: It significantly reduces the computational effort needed to perform the integrated aero-elastic analysis, and it provides a clear split between the responsibilities of the wind turbine and the foundation designers, see e.g. [11] for further details.

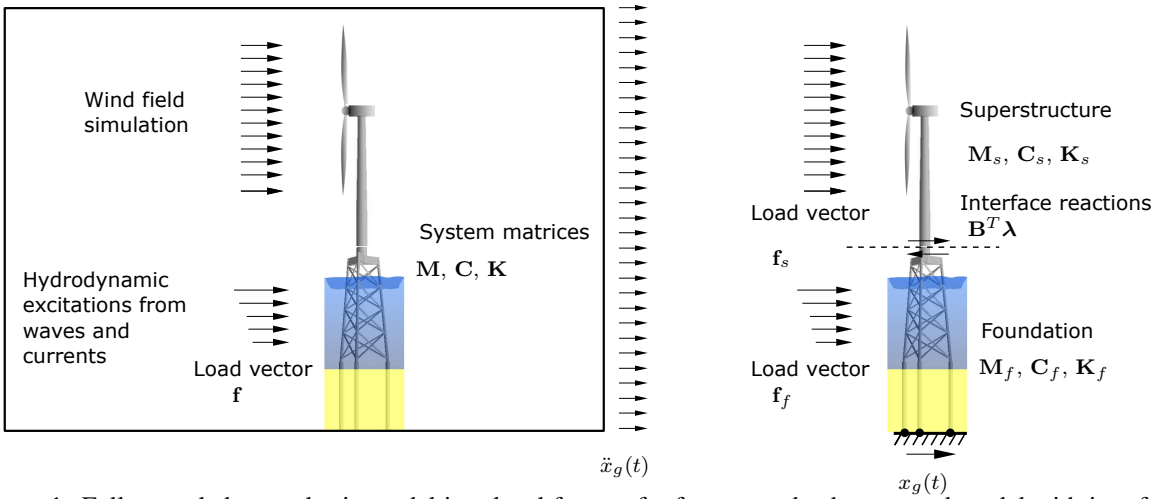

Figure 1: Fully coupled aero-elastic model in a local frame of reference and substructured model with interface section forces $\mathbf{B}^T\boldsymbol{\lambda}$ in a global frame of reference.

The details of the procedure can be summarized in the following three steps:

- Foundation model: The foundation designer prepares a detailed computer model of the foundation that closely represents the geometry, relevant structural details, local joint flexibility and pile-soil interaction as well as the excitations acting directly on the foundation such as gravity, buoyancy, wave/current loads.

- Aero-elastic simulation: A superelement representation of the detailed foundation model and the associated load time series is prepared – typically according to the Craig-Bampton reduction method, [10] – and delivered to the wind turbine designer, who performs coupled aero-elastic simulations of the full wind turbine model subject to combined wind and other environmental loadings from the previous step.

- Recovery-run: The foundation designer performs a dynamic time domain analysis where dynamic section force time series, extracted at the tower-bottom from the integrated aero-elastic analysis, are applied on a foundation-only model along with correlated permanent and environmental loads. Hereby, the response of the full (non-reduced) foundation structure is recovered and can be used as basis for detailed design of individual members and joints.

The approach has been adopted by the industry for a wide range of detailed designs of offshore foundations and has further been validated within the scientific community e.g. in [11, 12].

3 DESIGN PROCESS FOR SEISMICALLY-INDUCED LOADS

3.1 Equations of motion in local frame

Consider a discretized system representing an offshore wind turbine model including tower, RNA and foundation to be used for aero-elastic analysis as illustrated in Fig. 1a. The full model is described in terms of the mass matrix $\mathbf{M}$, the damping matrix $\mathbf{C}$ and the stiffness matrix $\mathbf{K}$, while the associated degrees of freedom (DoF) – typically accommodating both translations and rotations with respect to a local frame of reference – are stored in the vector $\mathbf{u}$.

A seismic event acting on such a system is often modeled as a time-varying base motion $x_g(t)$, which may be interpreted as a forced translation of the reference frame in which the structure is defined, such that absolute displacement may be expressed, as

$$\mathbf{x} \,=\, \mathbf{u} \,+\, \mathbf{r}x_g(t)\,. \tag{1}$$

The vector $\mathbf{r}$ is introduced as an influence vector that picks out the relevant degrees of freedom, i.e. of the form $[\,1,0,0,0,0,0,1,0,\ldots]^T$ for translations in the x-direction.

Lagrange's equations provide a classic and fairly general method for deriving the equations of motion for a mechanical system. For motion in the local frame of reference these can be expressed in terms of the variable $\mathbf{u}$ and its time derivative $\dot{\mathbf{u}}$ in the form

$$\frac{d}{dt}\left(\frac{\partial L}{\partial \dot{\mathbf{u}}^T}\right) \,-\, \frac{\partial L}{\partial \mathbf{u}^T} \,=\, \mathbf{f}(t) \,-\, \mathbf{C}\dot{\mathbf{u}}\,, \tag{2}$$

where L denotes the *Lagrangian*:

$$L \,=\, T \,-\, G\,, \tag{3}$$

in terms of the kinetic energy T and the elastic potential G. See e.g [13] for further details. The right-hand side of (2) holds the time-varying external force vector $\mathbf{f}(t)$ representing direct external loads on the structure such as wind, waves and gravity as well as the dissipative forces $\mathbf{C}\dot{\mathbf{u}}$ associated with local viscous damping.

The kinetic energy T for the integrated system expressed in terms of absolute velocities $\dot{\mathbf{x}}$ yields

$$T \,=\, \tfrac{1}{2}\dot{\mathbf{x}}^T\mathbf{M}\dot{\mathbf{x}}\,. \tag{4}$$

The mass matrix $\mathbf{M}$ is here constant as it refers to initial local geometry, hence the first term in Lagrange's equations follow as the time-derivative of the expression

$$\frac{\partial L}{\partial \dot{\mathbf{u}}^T} \,=\, \mathbf{M}\dot{\mathbf{x}} \,=\, \mathbf{M}[\dot{\mathbf{u}} \,+\, \mathbf{r}\dot{x}_g(t)]\,, \tag{5}$$

while the second term defines the internal forces

$$\frac{\partial G}{\partial \mathbf{u}^T} \,=\, \mathbf{K}\mathbf{u}\,. \tag{6}$$

In this context, the procedure is illustrated for a linear system, i.e. without a time- or state-dependent stiffness matrix $\mathbf{K}$, however, the extension to general systems accounting for both material and geometrical non-linearities is straightforward. The internal forces are expressed solely in terms of the local displacements $\mathbf{u}$ since the contribution from the base displacements $\mathbf{r}x_g(t)$ merely results in a rigid body translation of the local frame, and thus does not contribute to the elastic energy.

Upon substitution of (5) and (6) into Lagrange's equations (2), the dynamic equations of motion are obtained in the form

$$\mathbf{M}\ddot{\mathbf{u}} + \mathbf{C}\dot{\mathbf{u}} + \mathbf{K}\mathbf{u} = \mathbf{f} - \mathbf{M}\mathbf{r}\ddot{x}_g(t)\,. \tag{7}$$

This corresponds to the classical format adopted for seismic analysis where the inertia loads on the right hand side appear as a uniform acceleration field that has to be applied simultaneously to the substructure and the superstructure. However, as mentioned introductory, this does not fit within the framework for the split approach used in practice.

By substitution of the relative displacements $\mathbf{u}$ defined as the difference between the absolute displacements $\mathbf{x}$ and the ground motion $x_g(t)$ via the relation (1), the equations of motion (7) can be recast into a format in terms of absolute displacements $\mathbf{x}$, as

$$\mathbf{M}\ddot{\mathbf{x}} + \mathbf{C}\dot{\mathbf{x}} + \mathbf{K}\mathbf{x} = \mathbf{f} + \mathbf{K}\mathbf{r}x_g(t)\,. \tag{8}$$

It is here assumed that the damping forces are associated with local deformation only such that no dissipation occurs for rigid body motion, whereby $\mathbf{C}\dot{\mathbf{x}} = \mathbf{C}\dot{\mathbf{u}}$. A similar argument is valid for the term $\mathbf{K}\mathbf{r}x_g(t)$ representing loads associated with seismic excitation – now expressed in terms of base displacements $x_g(t)$ – which would also vanish for an unsupported structure. However, when support conditions are imposed e.g. via a rigid spring k at mudline, a translation of the base of x_g would require an elastic force of the form kx_g to be applied locally on the foundation. It is illustrated explicitly in the following section how this enters as a term appearing solely in the equations associated with the foundation, and thus can be embedded in a superelement representation of the substructure.

3.2 Split approach in absolute frame

For sake of argument it is now assumed that the system degrees of freedom $\mathbf{x}$ are divided into DoF associated with the superstructure $\mathbf{x}_s$ and the foundation $\mathbf{x}_f$, respectively, as illustrated in Fig. 1b:

$$\mathbf{x}^T = [\,\mathbf{x}_s^T,\, \mathbf{x}_f^T]\,, \tag{9}$$

where the matrices with subscripts s and f refer to the superstructure and foundation, respectively. Similarly, the system mass, stiffness and damping matrices for the combined system may be expressed in the block-diagonal format,

$$\mathbf{M} = \begin{bmatrix} \mathbf{M}_s & \\ & \mathbf{M}_f \end{bmatrix}, \quad \mathbf{K} = \begin{bmatrix} \mathbf{K}_s & \\ & \mathbf{K}_f \end{bmatrix}, \quad \mathbf{C} = \begin{bmatrix} \mathbf{C}_s & \\ & \mathbf{C}_f \end{bmatrix}. \tag{10}$$

The associated load vector combining wind loads on the superstructure $\mathbf{f}_s$ and foundation loads $\mathbf{f}_f$ also takes the form

$$\mathbf{f}^T = [\,\mathbf{f}_s^T,\, \mathbf{f}_f^T]\,. \tag{11}$$

In this format the two substructures are uncoupled. However, a necessary condition when linking the wind turbine tower to the foundation is that the common interface DoF shared between the two substructures are equal, i.e.

$$x_i^s - x_j^f = 0\,. \tag{12}$$

This is commonly known as the compatibility condition, which may be enforced via a homogeneous constraint equation formally expressed as

$$\mathbf{B}\mathbf{x} = [\,\mathbf{B}_s \quad \mathbf{B}_f\,] \begin{bmatrix} \mathbf{x}_s \\ \mathbf{x}_f \end{bmatrix} = \mathbf{0}\,, \tag{13}$$

where $\mathbf{B}$ is a Boolean matrix that operates solely on the interface degrees of freedom.

It is here convenient to introduce the link between the local and global reference frames in a similar format. Since the absolute displacements of the base components in the vector $\mathbf{x}_f$ associated with the supported DoF must equal the time varying base excitations $x_g(t)$, this can be expressed as

$$\mathbf{D}_f(\mathbf{x}_f - \mathbf{r}x_g) \,=\, \mathbf{0}\,, \tag{14}$$

with $\mathbf{D}_f$ being a Boolean matrix that picks out the supported DoF in the foundation only. Similarly to the derivation of the classical format for the coupled equations of motion (7) presented in the previous section, the equivalent format for the partitioned system can be derived via Lagrange's equations (2) based on the augmented Lagrangian

$$L \,=\, T \,-\, G \,+\, (\mathbf{B}\mathbf{x})^T\boldsymbol{\lambda} \,+\, [\mathbf{D}_f(\mathbf{x}_f \,-\, \mathbf{r}x_g)]^T\boldsymbol{\Lambda}\,, \tag{15}$$

where the constraint equations (13) and (14) are included via Lagrange multipliers collected in the vectors $\boldsymbol{\lambda}$ and $\boldsymbol{\Lambda}$, respectively. The kinetic energy T and the elastic energy G of the system can still be expressed in the form (4) via the partitioned system matrices and vector described by (9) and (10), respectively.

While the interpretation of the energy terms in (15) is rather straightforward, the two latter terms represent the vanishing work done by the homogeneous constraints (13) and (14), hence these can be added without changing the Lagrangian of the system. In this context, the Lagrange multipliers λ serve as generalized reaction forces needed to enforce the compatibility condition at the interface, and thus directly represent the internal forces at interface that are interchanged between the superstructure s and the foundation f. Similarly, the Lagrange multipliers Λ represent the forces required for imposing the base motion to the integrated system through the foundation.

By substitution of the augmented Lagrangian (15) into Lagrange's equation (2) and differentiation, the coupled dynamic equations follow as

$$\mathbf{M}\ddot{\mathbf{x}} \,+\, \mathbf{C}\dot{\mathbf{x}} \,+\, \mathbf{K}\mathbf{x} \,=\, \mathbf{f} \,+\, \mathbf{B}^T\boldsymbol{\lambda} \,+\, \mathbf{D}^T\boldsymbol{\Lambda}\,. \tag{16}$$

Together with the compatibility equation (13) and the support constraint condition (14), these constitute the coupled equations of motion equivalent to (8). When the partition (9) is introduced, the equations of motion take the form:

$$\mathbf{M}_s\ddot{\mathbf{x}}_s \,+\, \mathbf{C}_s\dot{\mathbf{x}}_s \,+\, \mathbf{K}_s\mathbf{x}_s \;\;=\, \mathbf{f}_s \,+\, \mathbf{B}_s^T\boldsymbol{\lambda}\,, \tag{17a}$$

$$\mathbf{M}_f\ddot{\mathbf{x}}_f \,+\, \mathbf{C}_f\dot{\mathbf{x}}_f \,+\, \mathbf{K}_f\mathbf{x}_f \,=\, \mathbf{f}_f \,+\, \mathbf{B}_f^T\boldsymbol{\lambda} \,+\, \mathbf{D}_f^T\boldsymbol{\Lambda}\,, \tag{17b}$$

$$\mathbf{B}\mathbf{x} \,=\, \mathbf{0}\,, \tag{17c}$$

$$\mathbf{D}_f(\mathbf{x}_f - \mathbf{r}x_g) \,=\, \mathbf{0}\,, \tag{17d}$$

where the first two equations are the dynamic equations for the superstructure and the foundation, respectively. This form is often referred to as the *dual* format, i.e. in which the equations of motion are augmented by the compatibility equations (13) and (14), see [14] for further details. It is noted that the base excitation forces only appear explicitly in the foundation equations of motion (17b), yet their influence will be reflected in the response of the entire structure similar to the case when the seismic loading is applied as a uniform acceleration field as described in (7). The advantage is that the seismic loads only have to be applied to the foundation, and thus may be embedded in a superelement representation hereof as explained in the following section.

3.3 System reduction compatibility

As outlined in section 2 it is common practice that the aero-elastic simulations of the integrated structure are performed by the turbine designer, which amounts to solving the full set of equations (17). In these simulations, the foundation part (17b) is typically represented in the form of a superelement based on either the Guyan-Irons or the Craig-Bampton reduction techniques [9, 10]. Common for these (and other methods) are that they permit the full set of DoF contained in the vector $\mathbf{x}$ – conveniently divided into interface (or boundary) DoF $\mathbf{x}_b$ and internal Dof $\mathbf{x}_i$ – to be expressed solely in terms of a generalized boundary DoF vector $\tilde{\mathbf{x}}$, as

$$\mathbf{x} = \mathbf{T}\tilde{\mathbf{x}} \,. \tag{18}$$

The reduction basis $\mathbf{T}$ is typically formed by a combination of static constraint modes and dynamic pseudo modes improving the description of the internal flexibility. By substitution of (18) into (17b) and pre-multiplication with the reduction basis $\mathbf{T}^T$, the reduced system matrices $\tilde{\mathbf{M}}$, $\tilde{\mathbf{C}}$ and $\tilde{\mathbf{K}}$ and associated load vector $\tilde{\mathbf{f}}_f$ constituting the superelement are identified as

$$\begin{aligned} \tilde{\mathbf{M}} = \mathbf{T}^T\mathbf{M}\mathbf{T} \quad , \quad \tilde{\mathbf{C}} = \mathbf{T}^T\mathbf{C}\mathbf{T} \quad , \quad \tilde{\mathbf{K}} = \mathbf{T}^T\mathbf{K}\mathbf{T} \,, \\ \tilde{\mathbf{f}}_f = \mathbf{T}^T(\mathbf{f}_f + \mathbf{D}_f^T\boldsymbol{\Lambda}) \,. \end{aligned} \tag{19}$$

The actual foundation equations of motion solved in the integrated aero-elastic simulations instead of (17b), hereby yields

$$\tilde{\mathbf{M}}_f\ddot{\tilde{\mathbf{x}}}_f + \tilde{\mathbf{C}}_f\dot{\tilde{\mathbf{x}}}_f + \tilde{\mathbf{K}}_f\tilde{\mathbf{x}}_f = \tilde{\mathbf{f}}_f + \mathbf{T}^T(\mathbf{B}_f^T\boldsymbol{\lambda}) \,, \tag{20}$$

such that the external loads representing the effect of the base excitation have been embedded in the reduced load vector $\tilde{\mathbf{f}}_f$, and thus constitutes a part of the superelement that is typically prepared by the foundation designer.

3.4 PRACTICAL DESIGN PROCEDURE

Based on the theoretical framework developed in sections 3.1–3.3, an approach applicable for integrated load calculations combining seismic, wind and wave loads is illustrated in Fig. 2.

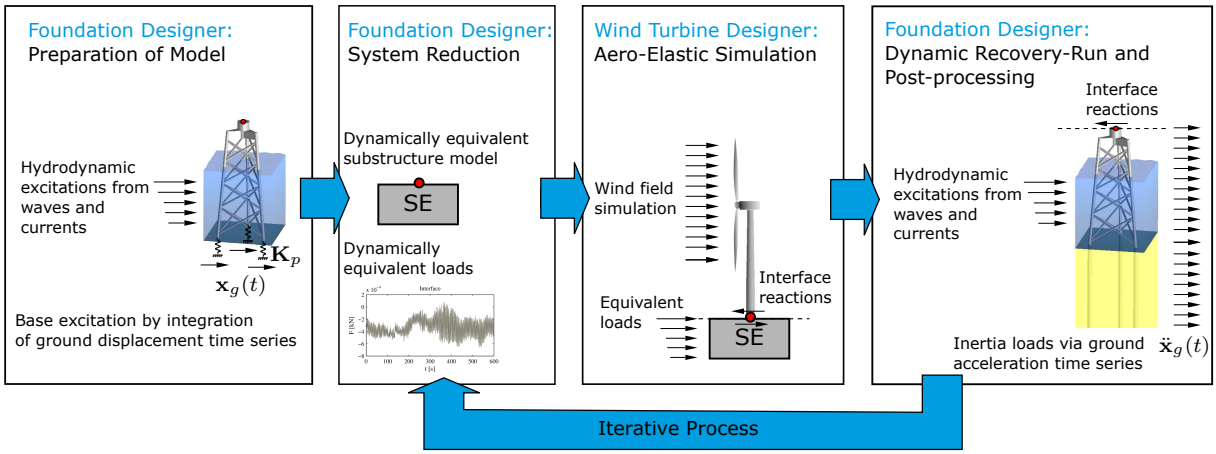

Figure 2: Flow chart for load calculation including seismic loads.

First, a detailed model of the substructure in line with the first step in section 2 is established. However, the combined simultaneously occurring actions now also include earthquake-induced

loads applied as time series. The substructure as well as the associated load time series are then condensed into a superelement in line with (19) via the Craig-Bampton system reduction approach, [10], and provided to the turbine designer, who performs the aero-elastic simulation.

A key aspect is that the pile-soil interaction in general exhibits a non-linear relationship. However, the superelement approach is by default linear hence the pile-soil interaction curves are linearized based on either the initial tangent stiffness or a secant stiffness associated with a representative deformation level. In essence this allows the pile supports to be represented by a 6×6 stiffness matrix in the form,

$$\mathbf{K}_p \;=\; \begin{bmatrix} k_{xx} & & & & & \\ & k_{yy} & & & sym & \\ & & k_{zz} & & & \\ & k_{x'y'} & & k_{x'x'} & & \\ k_{y'x'} & & & & k_{x'x'} & \\ & & & & & k_{z'z'} \end{bmatrix}, \tag{21}$$

where the subscripts x, y, z refer to directions for translational stiffnesses, while x', y', z' refer to directions for rotational stiffnesses. This is conveniently implemented in the structural model as general stiffness elements linking the foundation structure to fixed support node(s) on which ground displacements can be imposed, as illustrated in the first step in Fig. 2. Hereby the forces associated with base excitation of the support node(s) as described in section 2 can be embedded in the superelement permitting the aero-elastic simulations to be performed in the conventional way.

It should be noted that earthquake motion typically is measured in terms of acceleration time series $\ddot{x}_g(t)$, however, the associated displacement records are readily available by integrating the accelerations twice, which under the assumption of homogeneous initial conditions follow as

$$x_g(t) \;=\; \int\int \ddot{x}_g(t)\, dt\, dt\,, \quad x_0 = \dot{x}_0 = 0\,. \tag{22}$$

For an arbitrary acceleration record, direct integration may lead to a so-called baseline drift such that the obtained displacement (and velocity) time series do not represent the physical behavior. However, several methods for baseline correction exist, yet this is outside the scope of the present paper. A review discussing this particular issue can e.g. be found in [15].

The last step in Fig. 2 illustrating the recovery-run can finally be performed either based on the original foundation model subject to displacement-controlled base excitation in an absolute frame of reference and with the linearized pile-soil interaction represented via generalized stiffness elements or based on a foundation model where the piles are modeled explicitly and the structure is excited by a uniform acceleration field in a local frame of reference. As illustrated in the previous section, the two methods are equivalent, however, the latter approach has the advantage that the performance of the piles can be assessed directly during the recovery-run.

4 NUMERICAL EXAMPLES

This section presents two numerical examples. The first example illustrates the basics of the approach in the absence of viscous damping via a simplified monopile structure clamped at mudline. The second example considers a more realistic jacket structure subject to combined earthquake and wave loads. A comparison of the results obtained via the conventional approach based on a uniform acceleration field and the approach where seismic loads associated with base motion are embedded in a superelement representation of the foundations is presented for

combined mass and stiffness proportional damping. Simulations are performed as dynamic time domain analysis in Ramboll's in-house offshore structural analysis program package (ROSAP). These are in general conducted with a time step of 0.02 s using the generalized-α method with a high frequency spectral radius limit $\lambda_\infty = 0.8$, [16].

4.1 Monopile

In this example a simplified monopile model as illustrated in Fig. 3 is considered.

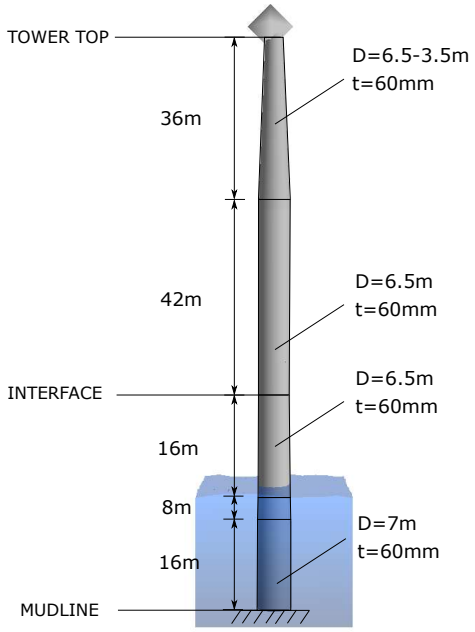

Figure 3: Simplified monopile geometry.

The monopile model is without a transition piece and directly connected to the tower e.g. by means of a bolted flange connection at the interface level. The outer diameter varies from 7.0 m at mudline to 6.5 m at interface level. The diameter transition is introduced via a conical section defined by a cone angle of approximately $1.8°$ and a length of 8 m, and the total length of the foundation is 40 m. The monopile is located on a generic site with a water depth of 25 m with respect to mean sea level (MSL). It supports a 78 m long tower structure with a diameter varying from 6.5 m at the interface level to 3.5 m at tower top. For simplicity purposes, a wall thickness of 60 mm is used for all members of the integrated structure and neither secondary steel structures nor marine growths and corrosion allowances have been included on the foundation. The monopile is clamped at mudline as illustrated in Fig. 3 and generic tower internals and RNA properties have been adopted to ensure representative dynamic properties for the integrated model. For the present case, the natural frequencies associated with the first and second global bending modes are around 0.32 Hz and 1.80 Hz, respectively. For simplicity no structural damping is included.

The external loads are here limited to a strong seismic loading in the global x-direction based on the historically measured accelerogram for El Centro 1940 (NW), which has been scaled to a peak ground acceleration of $0.51g$. Three different models are considered:

ACC: An integrated model where the seismic loads are applied as a uniform acceleration field according to (7).

DISP: An integrated model where the seismic loads are imposed as ground displacements through the clamped support node according to (8).

SE: A reduced model where the monopile is represented as a superelement with inherent seismic loads according to the procedure outlined in section 3.4.

As a validation of the approach presented throughout this paper, results for the relative lateral displacement $\mathbf{u}_x$ in the loading direction at tower top as well as the governing design load component – overturning moment at interface – have been extracted for each of the three different configurations as shown in Fig. 4. A perfect match is found for all cases, however, it should be noticed that while internal forces – like the overturning moment depicted here – are invariant to rigid body motion, the tower top displacement $\mathbf{x}_x$ extracted from the models DISP and SE refer to absolute frame of reference and thus have to be corrected for the base displacements $x_g(t)$ according to (1).

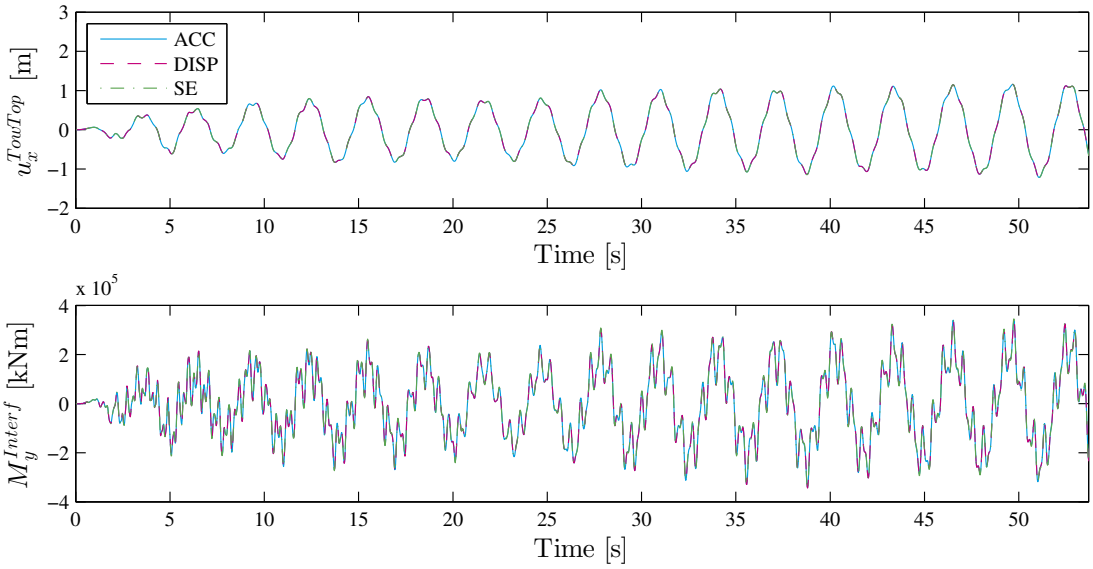

Figure 4: Lateral displacement in x-direction at tower top and overturning moment around y-axis at interface for monopile model.

4.2 Jacket

As a more realistic example for validating the presented approach, a generic, yet realistic 3-legged pile-jacket model supporting an 8-9 MW offshore wind turbine, is used as illustrated in Figure 5. The governing structural parameters for the jacket are summarized in Table 1. The jacket structure is located on a generic site with a water depth of 40 m and soil conditions represented by medium sand with a friction angle of $\phi = 35^o$. Pile-soil interaction is included in the foundation model, yet linearized based on the initial slope.

The structure is excited by the same seismic load time series based on a scaled El Centro accelerogram as described for the monopile example in section 4.1. This is combined with aligned waves in the global x-direction. The hydrodynamic loading is calculated according to Morison's equation where the wave kinematics for the irregular sea-state is modelled via the JONSWAP-spectrum according to [1]. Relevant metocean data are given in Table 1. Both added mass, contained mass and 100 mm marine growth are taken into account.

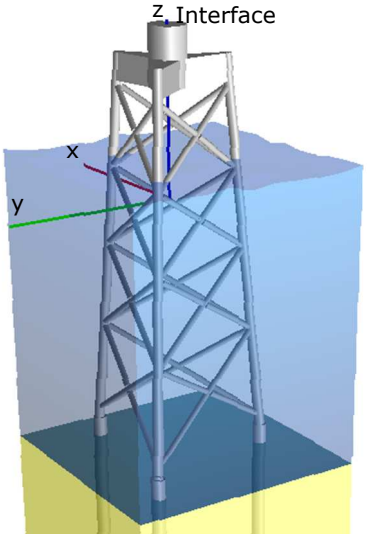

Figure 5: Jacket geometry.

Table 1: Generic jacket and loading parameters.

Geometry		Site conditions	
Parameter	Value	Parameter	Value
Footprint	25.0 m	Water depth	40.0 m
Topprint	16.0 m	Spectrum	JONSWAP
Leg diameter	1620 mm	Sign. wave height	10.0 m
Leg thickness	40 mm	Peak period	11.0 s
Brace diameter	1016 mm	Wave direction	x-dir
Brace thickness	25 mm	Accelerogram	El Centro
Tubular joint Chord thickness	70 mm	PGA	$0.51g$
		EQ direction	x-dir

In contrast with the previous example, structural damping is included via the Rayleigh approach of the form:

$$\mathbf{C} = \alpha\mathbf{M} + \beta\mathbf{K}$$

The Rayleigh parameters α and β have been calculated to provide damping ratios of 0.5% and 1.0% of critical for the first and second global bending modes, respectively. For the present structure, the associated frequencies are 0.28 Hz and 1.16 Hz, respectively.

Results for three different configurations – equivalent to the definitions of ACC, DISP and SE described in section 4.1 – are presented in Fig. 6. A very good match is obtained for cases DISP and SE to within the accuracy of the superelement, while minor differences are observed with respect to ACC.

As discussed in section 3.1, the transition from the equations of motion (7) in relative components $\mathbf{u}$ to the equations of motion (8) in absolute components $\mathbf{x}$ does not introduce any approximation for pure deformation/stiffness proportional damping. Contrary, introduction of mass proportional damping would lead to the term $\alpha\mathbf{M}\mathbf{r}\dot{x}_g(t)$ on the right-hand-side, which is not included in the present simulations. However, since the mass proportional contribution to the damping ζ decreases with the angular frequency ω_j, i.e. $\zeta \propto \alpha/(2\omega_j)$, this typically only has an influence on the dynamic response of the first vibration mode. Therefore, the difference is most pronounced for the lateral displacement at the tower top, where the lowermost mode has

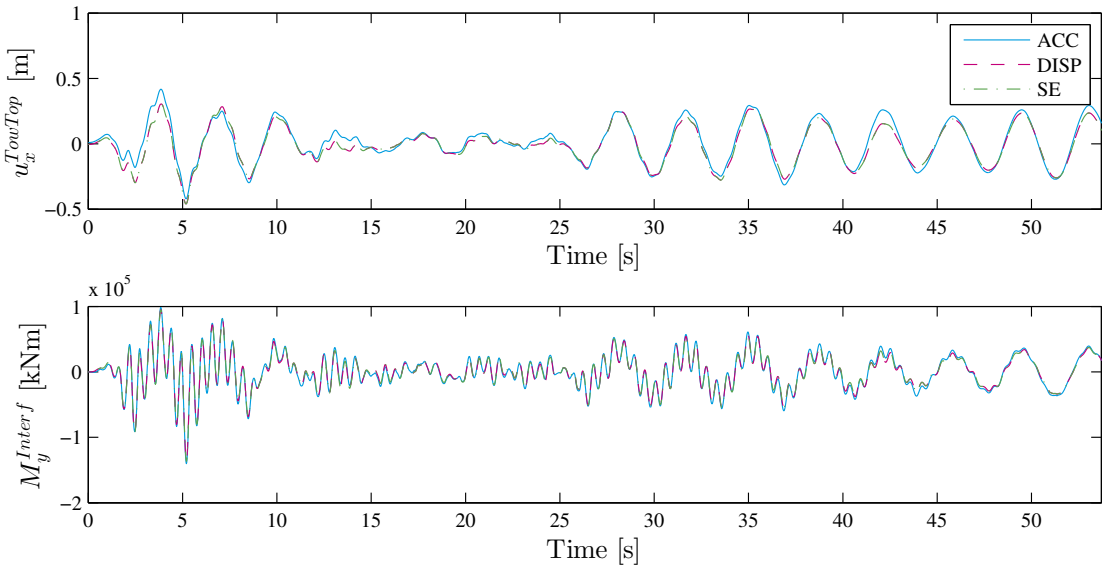

Figure 6: Lateral displacement in x-direction at tower top and overturning moment around y-axis at interface for jacket model including Rayleigh damping.

the largest modal displacement, while the effect is less significant at the interface, as illustrated by the overturning moment. Furthermore, it should be noted that the important contribution from aerodynamic damping has not been included here, hence the minor discrepancy associated with the mass proportional part of the damping will not have any significant impact on the design in practice.

5 CONCLUSIONS

A procedure for embedding earthquake-induced loads on an offshore wind turbine structure into a superelement representation of the foundation is presented. This permits the load calculation process, typically performed collaboratively by the foundation and the wind turbine designers, to be conducted via the conventional approach used for combined wind and wave loads. Rather than representing the seismic excitation by an uniformly distributed time-varying acceleration field applied to the full structure in a local frame of reference, base displacements – obtained by integrating the acceleration time series – are imposed through the supports of the foundation such that the measured kinematics includes the rigid-body motion of the local frame. It is illustrated explicitly by presenting the equations of motion for the coupled system in the so-called dual format how the loads required for exciting the structure solely enter the equations of motion associated with the substructure, and thereby can be embedded in the condensed load vector constituting a part of the superelement representation of the foundation. Since the internal forces forming the basis for design of the individual members are invariant to the rigid body motion, the present method yields equivalent results as the traditional approach where loads are introduced in the form of an acceleration field. This has successfully been validated by two representative examples considering multi-MW wind turbines founded on a simplified monopile and a generic, yet representative jacket, respectively.

Keywords: API, nonlinear oscillators, SAP2000, software development, structural analysis.

Abstract. *Ancillary software tools are developed for the analysis and response quantification of structural systems in a systematic and automated fashion. The open application programming interface (OAPI) of the structural analysis software SAP2000 is exploited for this purpose and a procedure is presented for the analysis of linear systems in conjunction with MATLAB, featuring model updating, analysis execution and extraction of the results. This is facilitated by the development of ancillary functions that complement and extend existing capabilities of the OAPI. Standalone solvers are next presented for the dynamic response evaluation of bilinear hysteretic, rigid-plastic, and rocking oscillators with arbitrary excitation force. The dynamical systems considered, are indicative of distinct nonlinear behaviour and representative of a wide spectrum of structures of engineering interest. The features at the current development stage are finally showcased on the response-surface-based reliability analysis of a truss structure and the response quantification of stochastically driven nonlinear secondary oscillators. The ancillary tools developed allow convenient simplifications in the modelling and analysis process, error tractability, and can assist learning on the subject of structural dynamics. They may find application in parametric and stochastic analysis and form the basis for the development of additional modules.*

1 INTRODUCTION

In engineering practice, the analysis and design of structural systems is conventionally carried out with the aid of commercial structural analysis software. These are usually treated as black boxes with models of varying degrees of complexity that have to be extensively and often iteratively run in parallel by different design teams. Although such software are reliable in the functionalities they offer, they are usually limited by the exclusion of state-of-the-art advanced analysis features that become available within the academic community. Nevertheless, they benefit from the use of general-purpose solvers which comes at the expense of prohibitively time-consuming runs as well as strenuous pre- and post-processing tasks.

In an attempt to circumvent these limitations, the vast majority of software packages offer complementary open application programming interfaces (OAPI) that permit the development of custom engineering applications. In the case of the structural analysis software SAP2000 [1], for instance, this is solely left to the discretion of the user which encounters limited support and guidelines. Despite the apparent value, only a handful of the contributions available in the literature take advantage of the OAPI [2] and at present, none of these assistant simulation-based tools is designed to be extended by the structural engineering research community.

In this paper, we present ancillary computational tools for the analysis and response quantification of structural systems in a systematic and automated fashion. In a first stage, an overview of the SAP2000 OAPI is provided, and a procedure is presented for the analysis of linear systems in conjunction with MATLAB [3], featuring model updating, analysis execution and extraction of the results. This is facilitated by the use of ancillary functions that are developed to complement and extend existing capabilities of the SAP2000 OAPI. In a second stage, standalone solvers are presented for the dynamic response evaluation of bilinear hysteretic, rigid-plastic and free-standing rocking oscillators in presence of a general-type of excitation. The dynamical systems considered, are indicative of distinct nonlinear behaviour and representative of a wide spectrum of primary as well as secondary structures of engineering interest. Finally, the features at the current development stage are showcased on two examples: *i*) the response-surface-based reliability analysis of a truss structure facilitated through the use of the SAP2000 OAPI; and *ii*) the use and interoperability of the standalone solvers developed with SAP2000 for the response quantification of nonlinear cascaded secondary oscillators due to stochastic excitation. Basis of this contribution are the preliminary investigations carried out in [4, 5].

The proposed procedure, suited for both the industrial and research communities, allows convenient simplifications in the modelling and analysis process, error tractability, extendibility and can assist learning on the subject of structural dynamics in graduate and post-graduate level. It is particularly useful for parametric, stochastic analysis and optimisation and will form the basis for the development of additional modules.

2 ANCILLARY TOOLS FOR STRUCTURAL ANALYSIS WITH SAP2000

2.1 SAP2000 Open Application Programming interface

The Open Application Programming Interface (OAPI) of SAP2000 is a programming tool that permits coupling of SAP2000 with third-party software, thus providing a path for two-way exchange of model information, for automating the processes required for the construction, analysis, and design of structural models with SAP2000 as well as retrieval of customised results (Figure 1). Numerous programming languages can be used for this purpose, including Visual Basic for Applications (VBA), Visual Basic, Visual C#, Visual Fortran, Visual C++, MATLAB and Python.

Initiation of the link process requires pre-existing installation of the SAP2000 software and the integrated development environment (IDE). The procedure then requires initialisation of the IDE-SAP2000 assembly and sequential run of a set of predefined functions, each corresponding to one task within SAP2000, closely resembling the point-and-click procedure followed during conventional use of the SAP2000 software. It is noted that the syntax of each function depends on the choice of the IDE, and that not all the functionalities of SAP2000 are supported by the OAPI. The *CSi OAPI Documentation.chm* file, however, provides a list of the supported functions along with the syntax and description of the arguments it handles, as well as basic example code for each programming language supported.

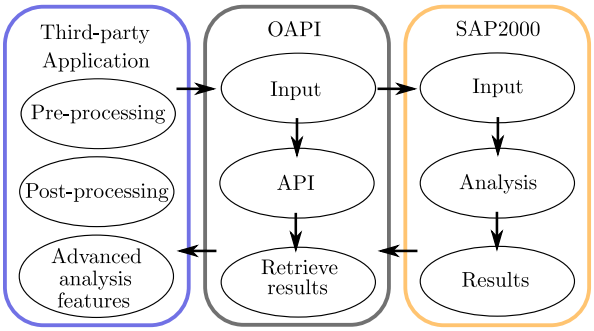

Figure 1: Schematic of the SAP2000 OAPI.

2.2 Using the SAP2000 OAPI for the analysis of linear systems

A procedure is presented in the following for automated analysis of linear structural systems with SAP2000 and MATLAB. The procedure is decomposed in the following main steps:

A: Construct the structural model in SAP2000. This typically consists of model generation, definitions as well as assignments. Preparing the model through the IDE is in most cases permissible, however, it can be cumbersome and it is therefore avoided.

B: Initialise the MATLAB-SAP2000 link. The function ***fx_intlSAP.m*** has been prepared for this purpose which requires an input directory of the pre-existing SAP2000 model. It is worth noting that the analyst is encouraged to use the $.sdb$ model file rather than importing the $.\$2k$ one. Use of the latter was found problematic in models with general frame sections.

C: Update the model. A new iteration of the model is obtained by updating the model input parameters via the OAPI. For a structure whose joint loads are to be varied, for instance, the function ***fx_JntLF.m*** has been prepared for assigning loads to point objects.

To proceed further, distinction is made on whether the analysis can be carried out externally. If the finite element model remains unchanged for each model iteration, then the analysis can be performed directly in MATLAB. This can be advantageous, as it provides the analyst with control and flexibility, limiting strenuous pre- and post-processing tasks.

D1: Analyse the structure in MATLAB. This is facilitated by the use of the function ***fx_getMK.m*** which has been prepared to construct the mass matrix and the global stiffness matrix by exporting and ordering these from the SAP2000 model. It is noted that this functionality further complements the existing capabilities of the OAPI.

D2: Analyse the structure in SAP2000. The function ***fx_runSAP.m*** runs the analysis in SAP2000. The load cases to run and the analysis options used are those configured in step **A**.

E: Retrieve analysis results. To reduce transferring times, the analyst is encouraged (in step **A**), to define a group containing the joints where the response is to be measured. The function ***fx_getJD*** can then be used to extract the diplacement response envelope, time history or the last step, for the joints of this group. This function has been constructed by piecing together various contributions from the *CSi OAPI Documentation.chm* file. Similar functions can be constructed to retrieve velocity or acceleration results.

F: Unlock model and break the MATLAB-SAP2000 link. If further analyses are to be carried out, the SAP2000 model is unlocked via the existing function ***SetModelIsLocked*** and the procedure is repeated from step **C**. When no more analyses are required, the MATLAB-SAP2000 link is interrupted through the function ***fx_closeSAP.m***.

Use of the functions presented in the previous has been tested with SAP2000 v.20 [1]. They extend, facilitate and simplify the existing capabilities of the SAP2000 OAPI, offering efficiency and readability, thus encouraging future developments for other IDEs. The proposed procedure, aimed at parametric, stochastic and optimisation analysis, provides recommendations to the user and has been successfully employed in our previous investigations on the dynamic analysis of composite beam structures [5] as well as the dynamic analysis of steel frames [4]. It will be demonstrated next through two illustrative examples.

3 SOLVERS FOR BILINEAR, RIGID-PLASTIC AND ROCKING OSCILLATORS

In this section, solvers are presented for the dynamic response evaluation of bilinear hysteretic, rigid-plastic and free-standing rocking oscillators, due to a general-type of excitation. The dynamical systems considered herein are indicative of distinct nonlinear behaviour, representative of a wide spectrum of primary and secondary structures of engineering interest.

3.1 Governing equations

3.1.1 Bilinear oscillator

The case of a bilinear oscillator is first considered, as depicted in Figure 2(a), whose vibration is ruled by:

$$\ddot{u}_{\mathrm{s}}(t) = -2\,\zeta_{\mathrm{s}}\,\omega_{\mathrm{s}}\,\dot{u}_{\mathrm{s}}(t) - \frac{f_{\mathrm{b}}\left(u_{\mathrm{s}}(t),\dot{u}_{\mathrm{s}}(t)\right)}{m_{\mathrm{s}}} - \ddot{\xi}(t)\,, \tag{1}$$

in which $\ddot{\xi}(t)$ is the horizontal base acceleration, where the overdot denotes differentiation with respect to time; $u_{\mathrm{s}}(t)$ is the unidirectional displacement, relative to the ground; ζ_{s} and $\omega_{\mathrm{s}} = \sqrt{k_{\mathrm{s}}/m_{\mathrm{s}}}$ are the viscous damping ratio and circular frequency, k_{s} and m_{s} being the elastic stiffness and mass, respectively.

In the above, f_{b} represents the bilinear restoring force (Figure 2(d)), given by:

$$f_{\mathrm{b}}\left(u_{\mathrm{s}}(t),\dot{u}_{\mathrm{s}}(t)\right) = \psi\,\omega_{\mathrm{s}}^2\,m_{\mathrm{s}}\,u_{\mathrm{s}}(t) + a_{\mathrm{s}}\,m_{\mathrm{s}}\,(1-\psi_{\mathrm{s}})\,z_{\mathrm{s}}(t)\,, \tag{2}$$

where ψ, in the range $0 \leqslant \psi \leqslant 1$, is the post-to-pre-yield stiffness ratio; a_{s} is the specific strength of the system; and $z_{\mathrm{s}}(t)$ is an auxiliary state variable satisfying $|z_{\mathrm{s}}(t)| \leq 1$, ruled by:

$$\dot{z}_{\mathrm{s}}(t) = \frac{\dot{u}_{\mathrm{s}}(t)\,\omega_{\mathrm{s}}^2}{a_{\mathrm{s}}}\left[1 - H\left(\dot{u}_{\mathrm{s}}(t)\right)H\left(z_{\mathrm{s}}(t)-1\right) - H\left(-\dot{u}_{\mathrm{s}}(t)\right)H\left(-z_{\mathrm{s}}(t)-1\right)\right]\,, \tag{3}$$

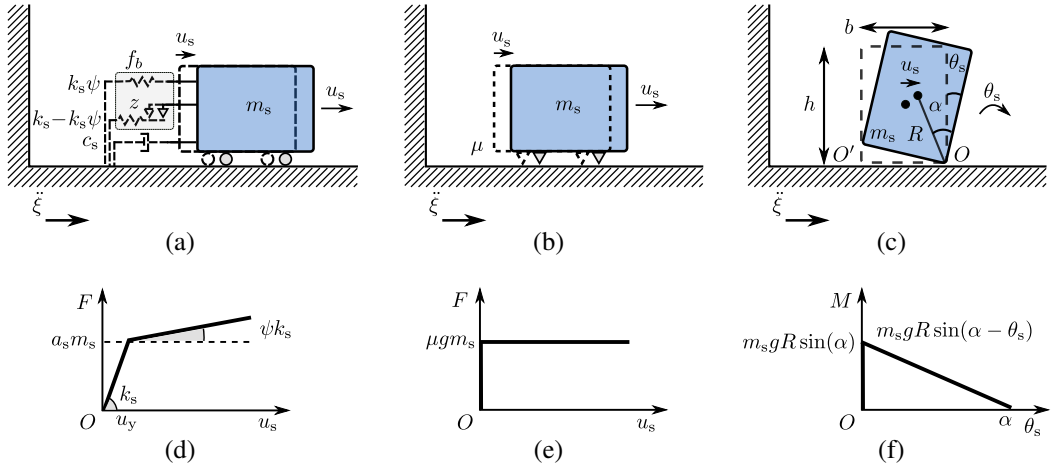

Figure 2: Bilinear (a), sliding (b) and rocking (c) oscillators and corresponding free-body diagrams (d, e, f).

where $H(\bullet)$ denotes the Heaviside unit step function, such that $H(x) = +1$ if $x \geq 0$ and $H(x) = 0$ if $x < 0$.

Setting $\psi = 0$ in Eq. (2) results to an elastic-perfectly-plastic oscillator; alternatively, setting $\psi = 1$ results to a linear one, with $f_{\mathrm{b}}(t) = \omega_{\mathrm{s}}^2 \, m_{\mathrm{s}} \, u_{\mathrm{s}}(t)$.

3.1.2 Sliding block

The rigid-perfectly plastic oscillator is considered next (Figure 2(b)). The system exhibits infinite pre-yielding stiffness and infinite ductility, and no motion during the sticking phase (i.e. $u_{\mathrm{s}} = \dot{u}_{\mathrm{s}} = 0$). During the sliding motion regime (i.e. $\dot{u}_{\mathrm{s}}(t) \neq 0$) its vibration is governed by:

$$\ddot{u}_{\mathrm{s}}(t) = -\frac{f_{\mathrm{s}}(\dot{u}_{\mathrm{s}}(t))}{m_{\mathrm{s}}} - \ddot{\xi}(t)\,, \tag{4}$$

where f_s is the associated restoring force (Figure 2(e)) and can be regarded as the limiting case of Eq. (2), when $\psi = 0$ and $\omega_{\mathrm{s}} \to +\infty$, given by:

$$f_{\mathrm{s}}(\dot{u}_{\mathrm{s}}(t)) = a_{\mathrm{s}} \, m_{\mathrm{s}} \, \mathrm{sgn}(\dot{u}_{\mathrm{s}}(t))\,; \quad |\dot{u}_{\mathrm{s}}(t)| > 0\,, \tag{5}$$

in which $\mathrm{sgn}(\bullet)$ is the signum function (i.e. $\mathrm{sgn}(x) = +1$ if $x > 0$, $\mathrm{sgn}(x) = -1$ if $x < 0$, and $\mathrm{sgn}(x) = 0$ if $x = 0$), and the specific strength is given by $a_{\mathrm{s}} = \mu \, g$, μ being the coefficient of sliding friction assuming horizontal contact surface and g the acceleration due to gravity.

The condition of initiation for sliding motion is $\left|\ddot{\xi}(t)\right| = a_{\mathrm{s}}$. Following initiation, an instantaneous stop or a full stop can occur in the system once the velocity drops to zero. In the former case, the motion will reverse or it will continue in the same direction, while in the latter case the system will remain at rest until the initiation condition is meet again.

3.1.3 Rocking block

The case of a rectangular free-standing block exhibiting pure rocking motion, is finally considered. In this regard, the coefficient of sliding friction is assumed to be sufficiently large (i.e. $\mu \to +\infty$), and the block oscillates about its centres of rotation O and O', as illustrated in Figure 2(c).

The equation governing the response during the rocking regime of motion is given by:

$$\ddot{\theta}_{\mathrm{s}}(t) = -p^2 \left[\sin\left(\alpha \,\mathrm{sgn}\left(\theta_{\mathrm{s}}(t)\right) - \theta_{\mathrm{s}}(t)\right) + \frac{1}{g} \cos\left(\alpha \,\mathrm{sgn}\left(\theta_{\mathrm{s}}(t)\right) - \theta_{\mathrm{s}}(t)\right) \ddot{\xi}(t) \right] , \tag{6}$$

where $\theta_{\mathrm{s}}(t)$ is the response rotation of the block; $\alpha = \tan^{-1}(b/h)$ is the slenderness angle, being a function of the width b and height h; $p = \sqrt{3\,g/(4\,R)}$ is a geometrical parameter, where R is half the block's diagonal.

As shown in Figure 2(f), the block initially possess infinite rotational stiffness until the applied moment about one of the pivot points O and O' reaches the value $|M_{\mathrm{s}}| = m_{\mathrm{s}}\, g\, R \sin(\alpha)$, and a softening branch initiates, reaching $M_{\mathrm{s}} = 0$ at the tipping condition $|\theta_{\mathrm{s}}| = \alpha$.

The initiation condition for Eq. (6) is $\left|\ddot{\xi}(t)\right| = g\,\tan(\alpha)$. Following initiation, a change in the sign of the rotation $\theta_{\mathrm{s}}(t)$ will correspond to an impact and (assuming that the block does not bounce back) the pivot point will switch from O to O' (or vice versa). It is assumed that the post-impact rotational velocity, $\dot{\theta}_{\mathrm{s}}^{+}$, is a fraction of the velocity prior to impact, $\dot{\theta}_{\mathrm{s}}^{-}$, that is: $\dot{\theta}_{\mathrm{s}}^{+} = \varepsilon\, \dot{\theta}_{\mathrm{s}}^{-}$, where ε is the coefficient of restitution, with $0 < \varepsilon \leq \varepsilon_{\max} < 1$, $\varepsilon_{\max} = 1 - 3\sin^2(\alpha)/2$ being the maximum value allowed.

3.2 Solvers for nonlinear dynamic response quantification

The dynamical systems considered in the previous are of piecewise linear form and therefore a highly efficient numerical procedure can be employed for quantifying the response. Specifically, each regime of motion is separately considered, and the solution is developed by interpolating the excitation over each time interval. Accordingly, recurrence formulae are derived for the response state vector of each system from exact solution of the associated equation of motion. To this end, the only requirement is that the time step is sufficiently small to closely approximate the excitation. The overall time history is finally constructed by piecing together the individual segments. Details on the methodology and the resulting expressions are provided in [6].

The solutions presented in [6] have been implemented in C++ along with an iterative procedure based on the bisection method [7] to identify state events (i.e. transition points of piecewise solutions such as the initiation and change in the regime of motion) and break down the solution in parts which have been later pieced together.

In order to confirm the validity of the solvers the solution has been compared to a MATLAB [3] implementation that has been prototyped using build-in Ordinary Differential Equation solvers. Specifically, ODE45 has been used, which is based on an explicit fourth- and fifth-order Runge-Kutta formulation. The implementation has been performed with consistent initial conditions and by setting MATLAB's odeset parameter values AbsTol = RelTol = 10^{-8} and Refine = 4, which refer to relative and absolute solution tolerances and interpolation output, respectively. The option 'Events' has been invoked to approximately identify state events.

The resulting standalone executables ***B1.exe***, ***S1.exe*** and ***R1.exe*** corresponding to the bilinear, rigid-plastic and rocking oscillators, respectively, accept their input arguments and export their results in standard fixed-length txt files which can be further processed by third-party software. Details on accessing the solvers along with their user instructions are provided in § 5.

They facilitate accurate and efficient dynamic analysis of the systems under consideration in presence of a general-type of base excitation and may find application in the stochastic analysis and optimisation of structural systems.

Table 1: Input random variable definition.

Variable	Distribution	Mean	CoV
E_1, E_2 $[\mathrm{N/m^2}]$	Lognormal	2.1×10^{11}	0.10
A_1 $[\mathrm{m^2}]$	Lognormal	2.0×10^{-3}	0.10
A_2 $[\mathrm{m^2}]$	Lognormal	1.0×10^{-3}	0.10
$f_1 - f_6$ $[\mathrm{N}]$	Gumbel	5.0×10^{4}	0.15

4 ILLUSTRATIVE EXAMPLES

Two examples are presented in the following for the analysis of structural systems with the ancillary tools developed. In the first example, the linear static analysis of a truss structure is facilitated through the use of the SAP2000 OAPI, with the purpose of quantifying the response statistics due to system uncertainties. The second example demonstrates the use and interoperability of the solvers presented in the previous with SAP2000, for the response quantification of nonlinear cascaded secondary oscillators in presence of stochastic excitation.

4.1 Example 1: Reliability analysis of a truss structure

4.1.1 Problem statement

The case of a truss structure is considered [8, 9], comprising of 11 horizontal and 12 diagonal members, as depicted in Figure 3. A finite element (FE) model is constructed in SAP2000 using 23 bar elements. The model is characterised by the input random variable vector $\mathbf{X} = \{E_1, E_2, A_1, A_2, f_1, \ldots, f_6\}$, consisting of a set of $n = 10$ independent random variables, where E_1, E_2 denote the Young's moduli and A_1, A_2 the cross sectional areas, of the horizontal and diagonal members, respectively, and $f_1 - f_6$ are applied loads, whose probabilistic definition is summarised in Table 1.

Requirement for this problem is the quantification of the response statistics of the midspan deflection u and the probability of failure $P_f = \mathrm{Prob}\left[g(\mathbf{X}) < 0\right]$, $g(\mathbf{X})$ being the limit state function, defined as:

$$g(\mathbf{X}) = u_{\max} - |u(\mathbf{X})| \leq 0\,, \tag{7}$$

where $u_{\max} = 0.11$ is the maximum permissible value of u.

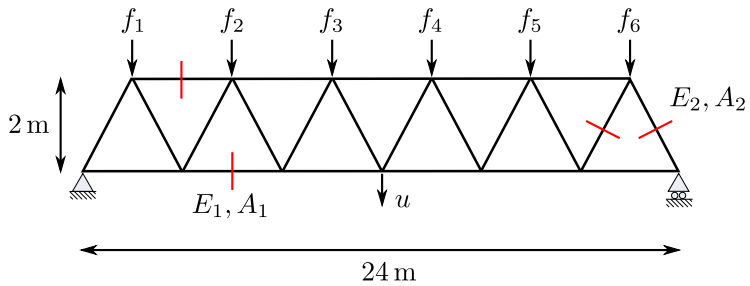

Figure 3: Truss structure [8].

4.1.2 Response surface-based metamodel

Owing to the presence of system uncertainties, the stiffness matrix is a random variable and therefore analysis is required within SAP2000. As $g(\mathbf{X})$ is algorithmically known, a response surface (RS) metamodel is constructed with the purpose of limiting the number of FE runs. Provided the fitted surface is an adequate approximation of the true response function, the analysis will be approximately equivalent to the one of the actual system.

In doing this, $g(\mathbf{X})$ is approximated with a quadratic polynomial of the form:

$$\tilde{g}(\mathbf{X}) = \alpha_0 + \sum_{i=1}^{n} \alpha_i x_i + \sum_{i=1}^{n} \alpha_{i,i} x_i^2 + \sum_{i=1}^{n-1} \sum_{j>i}^{n} \alpha_{i,j} x_i x_j \,, \tag{8}$$

where α_i, $\alpha_{i,i}$ and $\alpha_{i,j}$ are a set of $s = 1 + (n^2 + 3\,n)/2 = 66$ coefficients to be identified, conveniently collected in the vector:

$$\boldsymbol{\alpha} = \begin{bmatrix} \alpha_0 & \alpha_1 & \cdots & \alpha_n & \alpha_{1,1} & \cdots & \alpha_{n,n} & \alpha_{1,2} & \cdots & \alpha_{n-1,n} \end{bmatrix}^\top . \tag{9}$$

The values of the coefficients are determined via a set of sample points from the true limit state function, $g(\mathbf{X})$. In doing this, a circumscribed central composite design is adopted, widely used for fitting a second-order RS. This requires r FE runs with SAP2000 for evaluation of $g(\mathbf{X})$ symmetrically around the mean values of the random variables i.e. $x_i^{\pm} = \mu_i \pm h\,\sigma_i$, where $h = 0.95$ controls the size of the sampling domain. It is worth noting here that, if the shape of the true limit state function is not linear or quadratic the choice of h can significantly affect the accuracy of the approximation.

On minimising the error,

$$\varepsilon(\boldsymbol{\alpha}) = \sum_{k=1}^{r} \left(g(\mathbf{x}_k) - \tilde{g}(\mathbf{x}_k) \right)^2 , \tag{10}$$

with respect to $\boldsymbol{\alpha}$, the solution is given by,

$$\boldsymbol{\alpha} = \left(\mathbf{V}^\top \cdot \mathbf{V} \right)^{-1} \cdot \mathbf{V}^\top \cdot \mathbf{y} \,, \tag{11}$$

where $\mathbf{y}$ is a vector whose generic component is $g(\mathbf{x}_k)$, for the set of fitting points $\mathbf{x}_k, k = 1, \ldots, r$, and $\mathbf{V}$ is a matrix of size $(r \times s)$ collecting the associated polynomial terms:

$$\mathbf{V} = \begin{bmatrix} 1 & x_{1,1} & \cdots & x_{n,1} & x_{1,1}^2 & \cdots & x_{n,1}^2 & x_{1,1}x_{2,1} & \cdots & x_{n-1,1}x_{n,1} \\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots \\ 1 & x_{1,r} & \cdots & x_{n,r} & x_{1,r}^2 & \cdots & x_{n,r}^2 & x_{1,r}x_{2,r} & \cdots & x_{n-1,r}x_{n,r} \end{bmatrix} . \tag{12}$$

Analysis is finally performed using the fitted surface $\tilde{g} = \tilde{\mathbf{V}} \cdot \boldsymbol{\alpha}$, where $\tilde{\mathbf{V}}$, of size $(N \times s)$, retains a similar form as in Eq. (12) and is populated using N realisations of the vector of random variables.

4.1.3 Response quantification

The response probability density function (PDF) of u and the probability of failure P_f have been quantified using the RS model ($r = 178$ FE runs have been used with SAP2000) and have been compared to the reference FE solution. The results for both the RS and reference solution

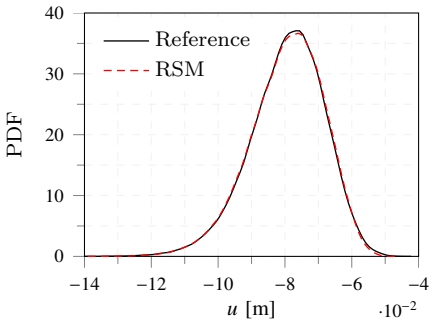

Figure 4: Response probability density function.

were obtained via crude Monte Carlo simulation with $N = 1 \times 10^6$ realisations. Analysis with SAP2000 was facilitated by use of the OAPI.

Figure 4 shows that the RS closely approximates the response PDF of u. Specifically, the calculated values of the first three statistical moments are in excellent agreement with the reference values reported in [9]. Further, the calculated $P_f = 0.00814$ is in good agreement with the reference FE solution $P_f^{\text{ref}} = 0.00898$.

4.2 Example 2: Stochastic response quantification of nonlinear cascaded secondary oscillators to white-noise and filtered-white noise process

4.2.1 Problem statement

The case of a multi-degree-of-freedom primary system [6] is next considered, comprising of a planar 5-storey single-bay moment-resisting frame, as depicted in Figure 5. A linear model of the structure is constructed using SAP2000. Floors are assumed rigid in their own plane, and the self-weight and super-dead load are the two sources of mass, lumped at the floor level. The total number of DoFs is $n_{\text{p}} = 75$ (i.e. 15 DoFs per storey, 2 finite elements are used for each frame element) and the fundamental circular frequency in the direction of interest x is $\omega_{\text{p}} = 14.76\,\text{rad/s}$, corresponding to a participation of 84% of the modal mass.

The structure is subjected to the unidirectional action of a horizontal ground acceleration, successively modelled as white noise and filtered white noise processes, commonly used in earthquake engineering applications. The latter is characterised by the well-known Kanai-

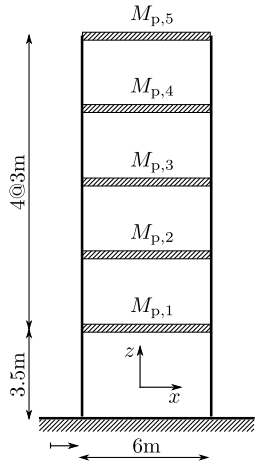

Figure 5: Primary structure [6].

Tajimi [10, 11] spectral density function:

$$S_{\ddot{\xi}}(\omega) = S_0 \cdot \frac{1 + 4\,\zeta_g^2\,(\omega/\omega_g)^2}{\left(1 - (\omega/\omega_g)^2\right)^2 + 4\,\zeta_g^2\,(\omega/\omega_g)^2}\,; \quad -\infty < \omega < \infty\,, \tag{13}$$

where S_0 represents a constant power spectral density level due to white noise, and the parameters ω_g and ζ_g denote the characteristic frequency and damping ratio of the soil layer, respectively. The filter represented by the second term in Eq. (13), thus attenuates the frequency content for $\omega > \omega_g$ as $\omega \to \infty$, and amplifies the frequencies in the vicinity of $\omega = \omega_g$. Neglecting the presence of the filter results to white noise modelling of the excitation, which implies infinite power of the resulting process, an unphysical yet mathematically convenient idealisation.

A secondary system is attached to the primary structure, at roof level, and is successively modelled as (i) linear, (ii) bilinear and (iii) sliding SDoF oscillator in cascade (see: § 3.1). Neglecting the feedback action of the secondary oscillator onto the primary one is in fact admissible provided the oscillator is sufficiently light and it does not vibrate close to or is in tune with the primary structure [6].

Requirement for this problem is the quantification of the full probabilistic structure of the response of each secondary system, due to white noise and filtered white noise modelling of the earthquake excitation.

4.2.2 Response quantification

Due to the linearity and deterministic form of the primary system considered, the analysis is carried out externally after extracting the mass and stiffness matrices from the SAP2000 model (see: § 2), thus avoiding strenuous pre- and post-processing tasks required by the Monte Carlo simulations. Further, owing to the cascade approximation, the analysis is independently carried out for the primary structure by means of classical modal analysis, retaining only a single mode of vibration. Such an approximation is permissible due to the high participation of modal mass.

A suite of 5000 synthetic ground motions are first generated through the summation of cosines with amplitudes and frequencies characterised by the power spectrum under consideration, and uniformly distributed over the interval $[0, 2\pi]$ [12]. In doing this, the frequency

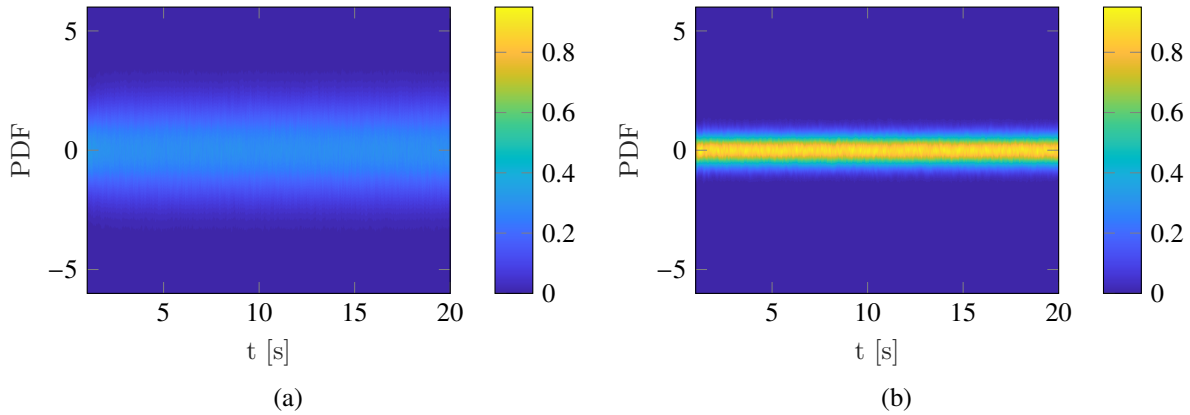

Figure 6: Response PDF of the absolute acceleration of the primary structure ($\omega_\mathrm{p} = 14.76\,\mathrm{rad/s}$, $\zeta_\mathrm{p} = 0.05$) due to: (a) white noise ($S_0 = 0.00214\,\mathrm{m^2/s^3}$); and (b) filtered white noise ($S_0 = 0.00214\,\mathrm{m^2/s^3}$, $\omega_g = 5\,\mathrm{rad/s}$, $\zeta_g = 0.2$) base excitation evaluated through 5000 Monte Carlo realisations.

interval $[0, \tilde{\omega}]$ is considered, where $\tilde{\omega} = 100$ is an upper cut-off frequency, beyond which the spectral density is regarded negligible. Furthermore, a soft soil is assumed with parameters $S_0 = 0.00214\,\mathrm{m}^2/\mathrm{s}^3$, $\omega_g = 5\,\mathrm{rad/s}$ and $\zeta_g = 0.2$ [13]. The resulting generated ground motions of variance $\sigma^2_{\ddot{u}_\xi} = 0.428$ and $\sigma^2_{\ddot{u}_\xi} = 0.097$, corresponding to white noise and filtered white noise, respectively, closely approximating the variance of the power spectrum.

The absolute acceleration response time history of the primary structure is then numerically determined at roof level. Figure 6 shows the evolution of the resulting stationary response PDF for $t \geq 1$, quantified through the kernel nonparametric probability density esimate, for the two forms of excitation under consideration.

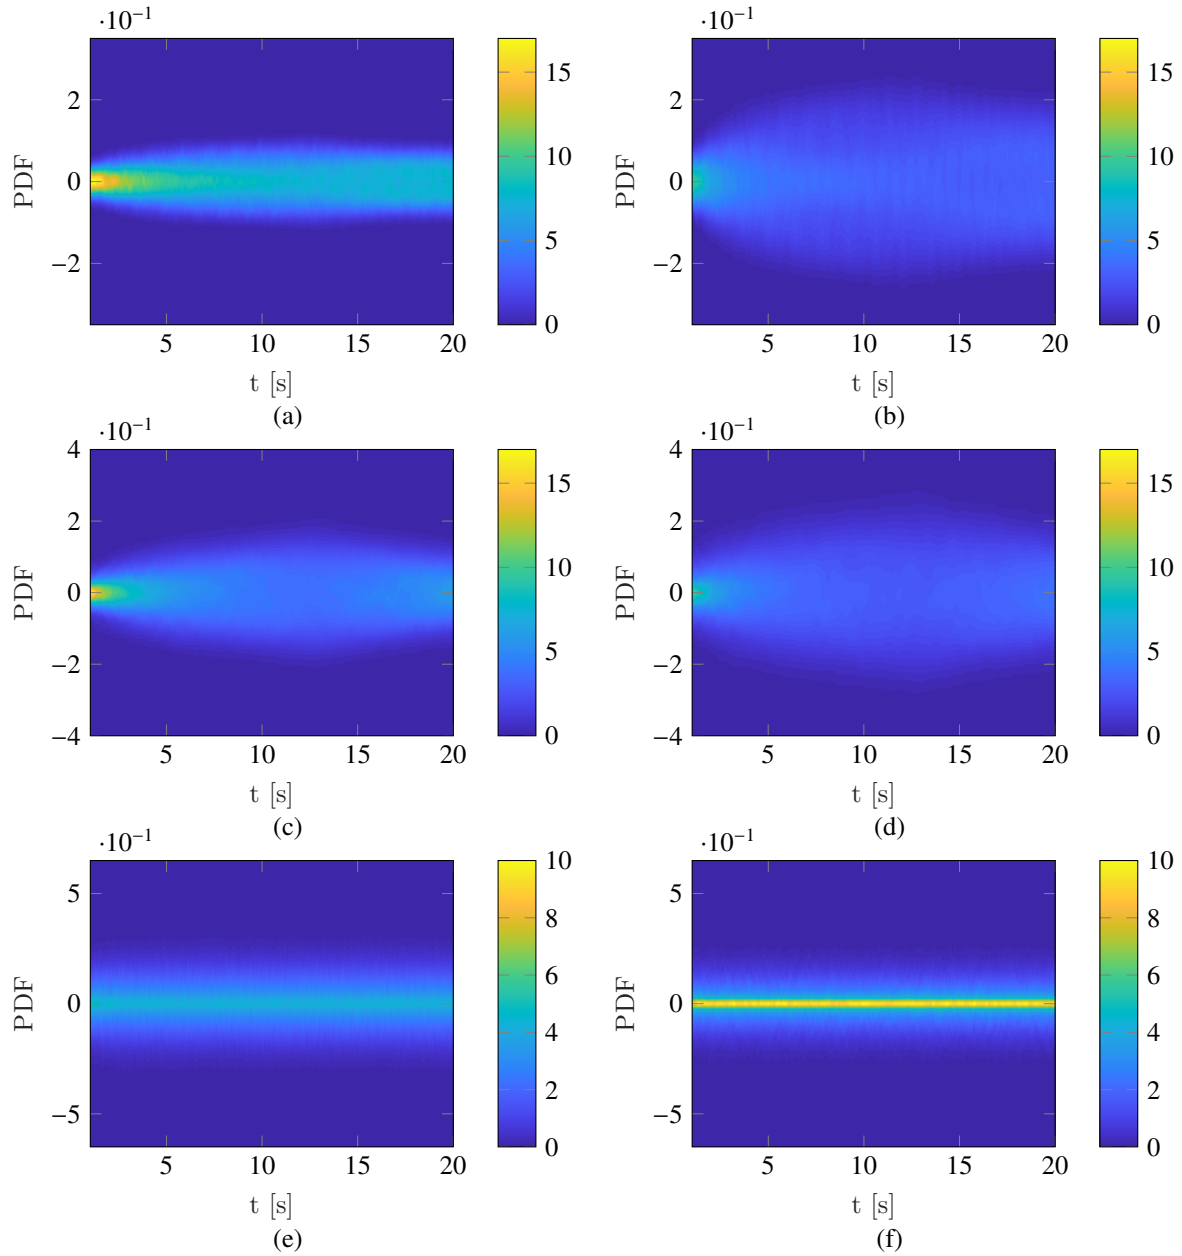

Figure 7: Response PDF of the (a, b) linear ($\omega_\mathrm{s} = 4.43\,\mathrm{rad/s}$, $\zeta_\mathrm{s} = 0.02$, $\psi = 1$), (c, d) bilinear ($\omega_\mathrm{s} = 4.43\,\mathrm{rad/s}$, $\zeta_\mathrm{s} = 0.02$, $a_\mathrm{s} = 0.3$, $\psi = 0.01$) and (e, f) sliding ($\mu = 0.02$) secondary oscillators, due to white noise (left) and filtered white noise (right) base excitation ($S_0 = 0.00214\,\mathrm{m}^2/\mathrm{s}^3$, $\omega_g = 5\,\mathrm{rad/s}$, $\zeta_g = 0.2$) evaluated through 5000 Monte Carlo realisations.

The analysis of the three secondary systems under consideration is carried out next. We circumvent the prohibitively time-consuming runs typically encountered in conventional analysis of such strongly-nonlinear systems by exploiting the solvers presented in § 3. In doing this, each response time history of the primary structure is successively used as input to the associated solver which is treated as black box model. For the linear and bilinear system, the parameters considered are $\psi = 1$ and $a_{\mathrm{s}} = 0.3$, $\psi = 0.01$, respectively, as well as $\omega_{\mathrm{s}} = 0.3$, $\omega_{\mathrm{p}} = 4.43\,\mathrm{rad/s}$ and $\zeta_{\mathrm{s}} = 0.02$. For the sliding system a friction coefficient of $\mu = 0.02$ is assumed.

Figures 7(a) - 7(d) plot the evolution of the displacement response PDF for the linear and bilinear secondary oscillators for $t \geq 1$. The velocity response PDF of the sliding oscillator is plotted in Figures 7(e) - 7(f). The results are quantified through the 5000 Monte Carlo realisations, and are presented for the two forms of excitation considered.

5 CONCLUSIONS

Assistant computational tools have been developed for the analysis and response quantification of structural systems in a systematic and automated fashion.

The open application programming interface (OAPI) of the commercial structural analysis software SAP2000 has been exploited and a procedure has been presented for the analysis of linear systems in conjunction with MATLAB, featuring model updating, analysis execution and extraction of the results. In-house ancillary functions have been developed for this purpose, that complement and extend existing capabilities of the OAPI.

Standalone solvers have been presented for the dynamic response analysis of bilinear hysteretic, rigid-plastic, and rocking oscillators subjected to an arbitrary excitation force. Such dynamical systems, are indicative of distinct nonlinear behaviour and representative of a wide spectrum of primary as well as secondary structures of engineering interest. The solvers developed herein can be used in a black-box type approach with third-party software.

The features at the current development stage have been showcased on the response-surface-based reliability analysis of a truss structure, facilitated through the use of the SAP2000 OAPI, and the response quantification of stochastically driven nonlinear secondary oscillators. The second application further demonstrates interoperability of the solvers with SAP2000.

The tools developed are available, along with user instructions, at this link. They allow convenient simplifications in the modelling and analysis process, error tractability, and can assist learning on the subject of structural dynamics. They may find application in parametric and stochastic analysis and form the basis for the development of additional modules.

Abstract. *In the framework of a EU-funded research project for the enhancement of the cooperation between academic institutions and private firms, the research team is currently enhancing the capabilities of an existing commercial code for the seismic design of buildings. Among the various tasks, a major one is the implementation of shell finite elements in the existing code, to be used, among others, for linear and nonlinear dynamic analyses of structural systems. In the present research effort, we present various aspects of the implementation process, starting from the criteria used for the selection of a suitable finite element among those proposed in the literature, the issues raised and the validation procedures used during the numerical implementation of the underlying theoretical aspects pertaining to dynamic analysis issues, and finally the incorporation of the numerical model into the existing code. In the present paper the four-node MITC4 shell element is presented. The MITC element formulation is based on the idea of degenerating a 3D solid finite element into a shell element by using special shape functions that are related to the Reissner-Mindlin kinematic assumption, and by introducing a zero stress assumption for the out of plane normal stress. To overcome the shear locking problem, a mixed interpolation of tensorial components is used resulting in an overall simple and transparent formulation, which gives the element a good predictive capability without containing spurious zero energy modes. The element is implemented into an existing commercial finite element code and several implementation aspects are discussed. The implementation is then tested against a selected problem in structural dynamics and its overall performance is assessed.*

1 INTRODUCTION

Four main approaches to applying finite element methods to shell structures can be found in the literature:

1. Shells are seen as an assembly of *flat elements* [1]. Coupling of membrane and bending effects due to curvature of the shell is inherently absent (except perhaps of the cases of composite laminated materials, see [2]). This approach is known to suffer from discontinuous bending moments between elements, while achieving convergence only for fine meshes [3].

2. *Axisymetric shells*, which refer to curved shell elements that exhibit symmetry about an axis of rotation [2]. These elements suffer from difficulties in describing complex geometries and/or complex loads, in achieving inter-element compatibility and from spurious effects as transverse shear and membrane locking.

3. *Solid shell elements*, which form a class of finite element models intermediate between conventional shell and solid models [4]. The inclusion of additional degrees of freedom renders this approach computationally ineffective. Furthermore, shear and membrane locking, trapezoidal locking caused by the deviation of the midplane from rectangular shape and thickness locking due to coupling of Poisson's ratio of the inplane and transverse normal stresses, make the element formulation a challenging task.

4. *Degenerated shell elements*, *i.e.* elements that are derived by degenerating a 3D solid element into a shell surface element. These are originating from the work of Ahmad, Irons and Zienkiewicz in 1970 [5] which still constitutes the basis for modern finite element analysis of shell structures. It has been shown [6] that there is a practical coincidence between degenerated shell elements and those based on standard Reissner-Mindlin/Naghdi type shell theory. This favours using the former for practical purposes as their formulation is generally simpler.

In the framework of a EU-funded research project for the enhancement of the cooperation between academic institutions and private firms, the research team is currently enhancing the capabilities of an existing commercial code for the seismic design of buildings. Among the various tasks, a major one is the implementation of shell finite elements in the existing code, to be used, among others, for linear and nonlinear dynamic analyses of structural systems. The MITC4 element [7, 8] has been selected for this purpose, which belongs to the class of the degenerated shell elements, presented above. The element formulation and a validation example is presented in what follows.

2 ELEMENT FORMULATION

Assuming small displacements/deformations, the *geometry* of the element is given as (see Figure 1):

$$x_i = \sum_{k=1}^{4} h_k x_i^k + \frac{r_3}{2} \sum_{k=1}^{4} a_k h_k V_{ni}^k \tag{1}$$

where x_i the Cartesian coordinates of any point in the element, x_i^k the Cartesian coordinates of nodal point k, V_{ni}^k the components of the so-called *director* vector $\boldsymbol{V}_n^k$, which is not required to be normal to the element's midsurface, a_k the thickness of the element at nodal point k measured

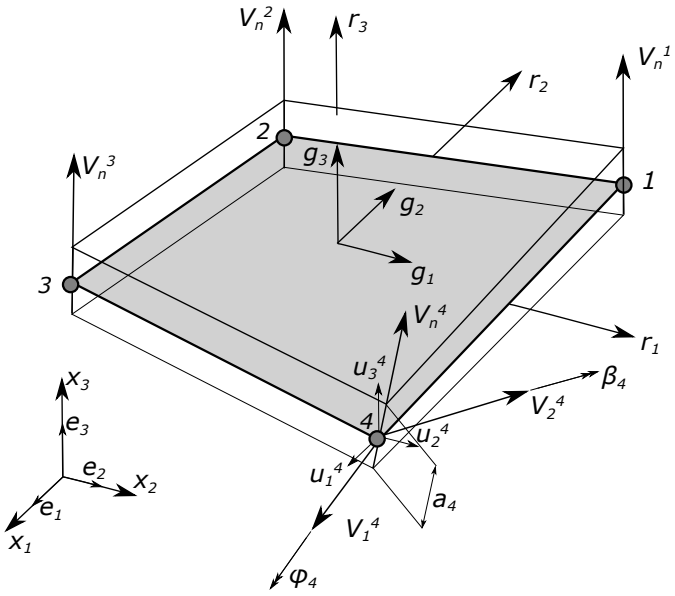

Figure 1: Element description

along the director vector and $h_k(r_1, r_2)$ the two-dimensional Lagrange interpolation functions in the $r_1 - r_2$ coordinate system (natural) corresponding to node k. For the MITC4 element h_k functions are defined as:

$$h_1 = \frac{1}{2}(1+r_1)(1+r_2) \qquad h_2 = \frac{1}{2}(1-r_1)(1+r_2) \tag{2}$$
$$h_3 = \frac{1}{2}(1-r_1)(1-r_2) \qquad h_4 = \frac{1}{2}(1+r_1)(1-r_2)$$

The *displacements* u_i of a point of the shell element with natural coordinates r_i $(i = 1, 2, 3)$ is given to the Cartesian coordinate system as:

$$u_i = \sum_{k=1}^{4} h_k u_i^k + \frac{r_3}{2} \sum_{k=1}^{4} a_k h_k \left(-V_{2i}^k \alpha_k + V_{1i}^k \beta_k\right) \tag{3}$$

where V_{1i}^k and V_{2i}^k the components of the vectors $\boldsymbol{V}_1^k$, $\boldsymbol{V}_2^k$ at point k (see Figure 1) defined as:

$$\boldsymbol{V}_1^k = \frac{\boldsymbol{e}_2 \times \boldsymbol{V}_n^k}{|\boldsymbol{e}_2 \times \boldsymbol{V}_n^k|}, \quad \boldsymbol{V}_2^k = \boldsymbol{V}_n^k \times \boldsymbol{V}_1^k \tag{4}$$

while α_k and β_k are the rotations in element k associated with vectors V_{1i}^k and V_{2i}^k respectively. Furthermore, $\boldsymbol{e}_2$ is the basis vector of Cartesian coordinate system, which is replaced by $\boldsymbol{e}_3$ in case that is collinear to the the director vector $\boldsymbol{V}_n^k$.

The strains are related to the displacement derivatives which are given as [8]:

$$\begin{bmatrix} \dfrac{\partial u_i}{\partial x} \\ \dfrac{\partial u_i}{\partial y} \\ \dfrac{\partial u_I}{\partial z} \end{bmatrix} = \sum_{k=1}^{4} \begin{bmatrix} \dfrac{\partial h_k}{\partial x} & g_{1x}^k G_x^k & g_{2x}^k G_x^k \\ \dfrac{\partial h_k}{\partial y} & g_{1x}^k G_y^k & g_{2x}^k G_y^k \\ \dfrac{\partial h_k}{\partial z} & g_{1x}^k G_z^k & g_{2x}^k G_z^k \end{bmatrix} \begin{bmatrix} \boldsymbol{u}_{ik} \\ \alpha_k \\ \beta_k \end{bmatrix} \tag{5}$$

where:

$$\frac{\partial h_k}{\partial x} = J_{11}^{-1}\frac{\partial h_k}{\partial r_1} + J_{12}^{-1}\frac{\partial h_k}{\partial r_2}, \quad G_x^k = r_3\left(J_{11}^{-1}\frac{\partial h_k}{\partial r_1} + J_{12}^{-1}\frac{\partial h_k}{\partial r_2}\right) + J_{13}^{-1}h_k \tag{6}$$

where J_{ij}^{-1} is the element (i,j) of $\mathbf{J}^{-1}$, $\mathbf{J}$ being the Jacobian matrix of the transformation between the Cartesian and the natural coordinate systems:

$$\mathbf{J} = \frac{\partial \boldsymbol{x}}{\partial \boldsymbol{r}} \tag{7}$$

Finally, the constitutive equation needs to be modified in order to enforce the *zero normal force condition* [9], which assuming its *reduced* form as

$$\tilde{\boldsymbol{\sigma}} = \tilde{\mathbf{C}}\tilde{\boldsymbol{\varepsilon}} \tag{8}$$

with

$$\tilde{\boldsymbol{\sigma}} = \left[\begin{array}{ccccc} \sigma_{xx} & \sigma_{yy} & \sigma_{xy} & \sigma_{yz} & \sigma_{zx} \end{array}\right], \quad \tilde{\boldsymbol{\varepsilon}} = \left[\begin{array}{ccccc} \varepsilon_{xx} & \varepsilon_{yy} & \varepsilon_{xy} & \varepsilon_{yz} & \varepsilon_{zx} \end{array}\right] \tag{9}$$

yields for the isotropic elasticity case:

$$\tilde{\mathbf{C}} = \frac{E}{(1-\nu)^2}\begin{bmatrix} 1 & \nu & 0 & 0 & 0 \\ & 1 & \nu & 0 & 0 \\ & & \dfrac{1-\nu}{2} & 0 & 0 \\ & & & \dfrac{1-\nu}{2} & 0 \\ & & & & \dfrac{1-\nu}{2} \end{bmatrix} \tag{10}$$

The above description should suffice to build up the element's stiffness matrix. However, a problem originating by the generation of the strains using the above linear displacement interpolation is the so-called element *locking* (*i.e.* the calculated displacements are orders of magnitude smaller than what they expected to be) when the element is thin. This can be explained by the fact that when using linear interpolations it is impossible for the transverse shear strains to vanish at all points in the element, when the element is subjected to a constant bending moment.

To solve this deficiency, various approaches have been proposed, as for example the use of selective and reduced integration [9]. The approach used in the MITC4 element formulation is to introduce separate interpolations for the shear strain components. In the natural coordinate system of the element the strain tensor is written as [10]:

$$\boldsymbol{\varepsilon} = \tilde{\varepsilon}_{ij}\boldsymbol{g}^i \otimes \boldsymbol{g}^j \tag{11}$$

where $\tilde{\varepsilon}_{ij}$ is the covariant components of the strain tensor measured in the natural coordinate system and $\boldsymbol{g}^i$ the contravariant base vector. In the MITC4 formulation the following strain interpolations are selected:

- The "in-layer" strain components ($\tilde{\varepsilon}_{11}$, $\tilde{\varepsilon}_{22}$, $\tilde{\varepsilon}_{12}$) are directly calculated from the displacement/rotation interpolations.

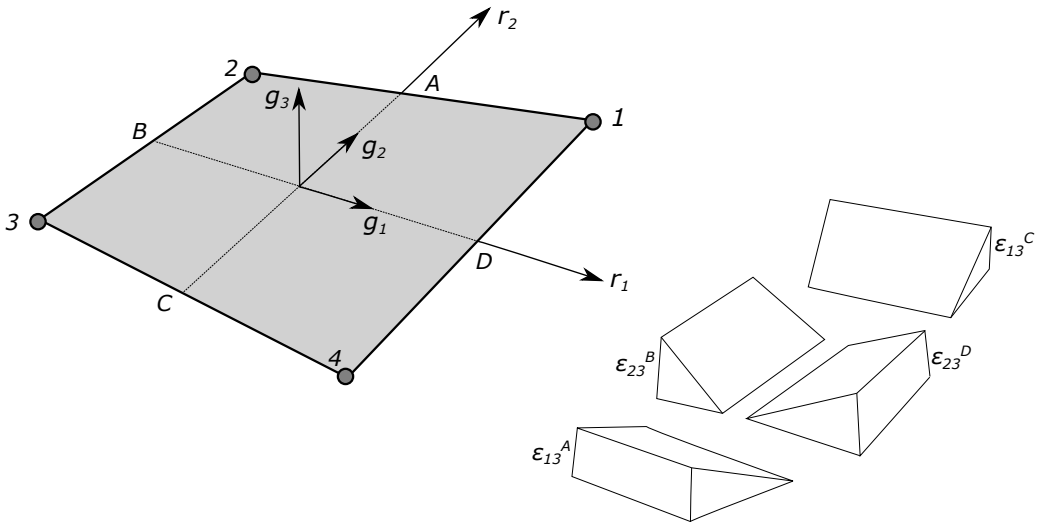

Figure 2: Strain interpolation

- The transverse shear strains ($\tilde{\varepsilon}_{13}$, $\tilde{\varepsilon}_{23}$) are interpolated using the following functions:

$$\tilde{\varepsilon}_{13}\frac{1}{2}(1+r_2)\tilde{\varepsilon}^A_{13}+\frac{1}{2}(1-r_2)\tilde{\varepsilon}^C_{13}, \quad \tilde{\varepsilon}_{23}\frac{1}{2}(1+r_1)\tilde{\varepsilon}^D_{13}+\frac{1}{2}(1-r_1)\tilde{\varepsilon}^B_{13} \tag{12}$$

  where $\tilde{\varepsilon}^A_{13}$, $\tilde{\varepsilon}^C_{13}$, $\tilde{\varepsilon}^D_{23}$ and $\tilde{\varepsilon}^B_{23}$, are the strain components at points A, C, B and D, evaluated from the displacement interpolations.

A lumped mass matrix based on the row summing approach of the consistent matrix [1] of the translational only masses is utilized within the context of this work. The consistent matrix is evaluated form the integral:

$$\mathbf{M}=\int_\Omega \mathbf{N}^T\rho\mathbf{N}d\Omega \tag{13}$$

where ρ the density and $\mathbf{N}$ the shape function matrix which follows directly from the kinematic assumptions defined above.

3 IMPLEMENTATION ASPECTS

The above formulation has been implemented in the Python programming language. Python's elegant syntax and dynamic typing, together with its interpreted nature, make it an ideal language for scripting and rapid application development [11].

An object oriented approach was followed, where five main classes have been defined:

- A `Node` class, which holds the coordinates and the local to global mapping vector of a finite element node and is responsible for storing the displacements, the reactions and the corresponding entries from the eigenvectors.

- A `Material` class, which is subclassed to `Isotropic` and `Orthotropic` classes, both of which hold the material properties and are responsible for the generation of the elasticity matrix $\mathbf{C}$.

- A `Section` class, which holds the `Material` and the thickness at a given point.

- A `GaussPoint` class, which holds a `Section`, the abscissae and the weights of the Gaussian quadrature and is responsible for updating the stresses, given a stress increment.

- The `MITC4` class, which contains the above and provides the functionality described in the previous section.

For the inclusion in the commercial code which is written in FORTRAN 2008, the above data structures will be ported as derived data types.

4 NUMERICAL VALIDATION

A cantilever beam serves as an initial validation example, which will be presented next. Assume a beam of length 10 (units: SI), defined by 1×1 uniform cross-section. The material is characterized by a Young's modulus $E = 3 \times 10^7$, a Poisson's ratio $\nu = 0.2$ and a density $\rho = 2500$. For the finite element model, the beam is divided into 100 elements.

The exact fundamental frequencies for the corresponding Euler-Bernoulli beam can be easily retrieved from literature as (see eg. [12])

$$\omega = (\beta l)^2 \sqrt{\frac{EI}{\rho A l^4}} \tag{14}$$

where I is the second moment of area and βl equals to 1.875104, 4.694091 and 7.854757 for the three first frequencies respectively.

The first eight eigenmodes and the corresponding eigenfrequencies are shown in Figure 3. A comparison between the numerical and the exact eigenfrequencies are given in the following table for the six (bending only) eigenmodes which the theory predicts. The difference in the two directions reflects the difference is the shell orientation: out-of-plane bending (first) *vs.* in-plane bending (second).

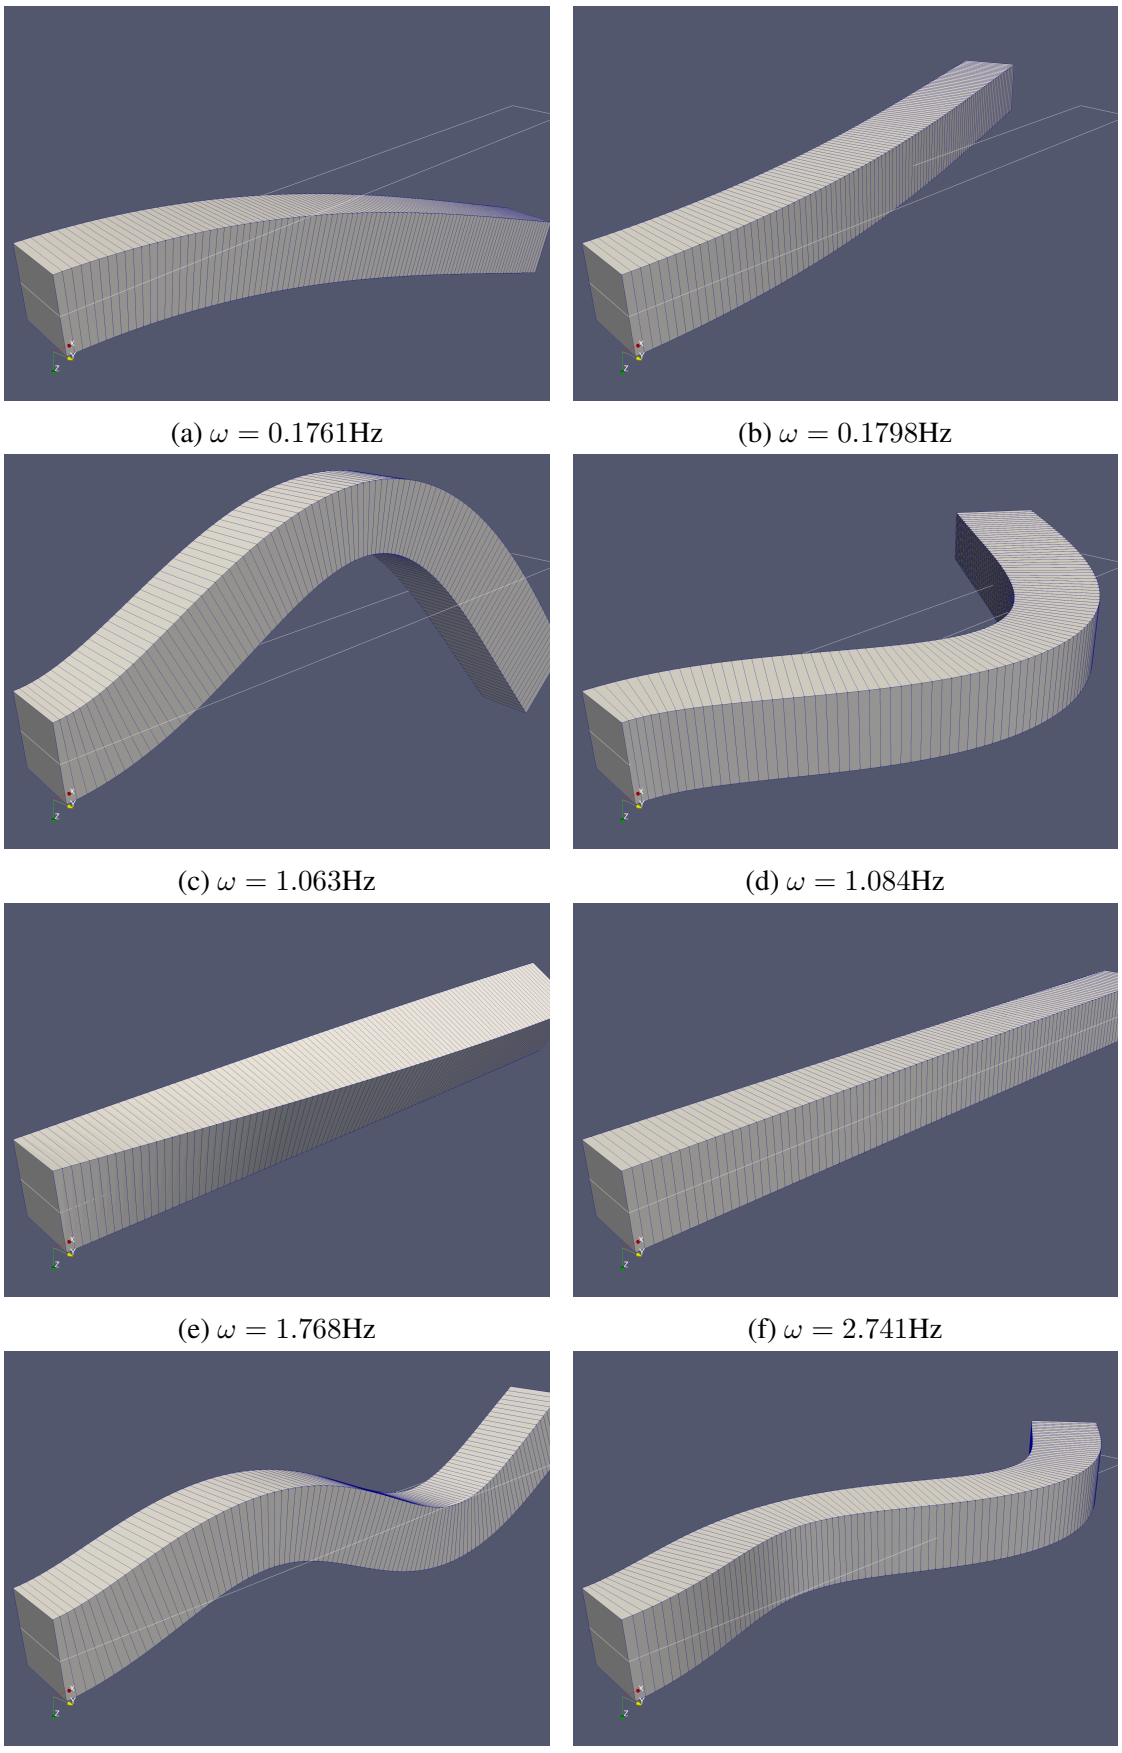
Exact (Euler-Bernoulli) [Hz]	MITC4 [Hz]	Difference [%]
0.1770	0.1761	-0.49
	0.1798	1.58
1.1090	1.0630	-4.33
	1.0840	-2.30
3.1052	2.7410	-13.29
	2.8240	-9.96

Table 1: Comparison between the exact (Euler-Bernoulli) and the MITC4 eigenfrequencies for the cantilever problem.

5 CONCLUSIONS

In the framework of a EU-funded research project for the enhancement of the cooperation between academic institutions and private firms, the research team is currently enhancing the capabilities of an existing commercial code for the seismic design of buildings. Among the various tasks, a major one is the implementation of shell finite elements in the existing code, to be used, among others, for linear and nonlinear dynamic analyses of structural systems.

The MITC4 shell element has been selected for this task. This element is based on the idea of degenerating a 3D solid finite element into a shell element by using special shape functions



(a) $\omega = 0.1761$Hz (b) $\omega = 0.1798$Hz

(c) $\omega = 1.063$Hz (d) $\omega = 1.084$Hz

(e) $\omega = 1.768$Hz (f) $\omega = 2.741$Hz

(g) $\omega = 2.824$Hz (h) $\omega = 2.876$Hz

Figure 3: The first eight eigenmodes and the corresponding eigenfrequencies

that are related to the Reissner-Mindlin kinematic assumption, and by introducing a zero stress assumption for the out of plane normal stress. To overcome the shear locking problem, a mixed interpolation of tensorial components is used resulting in an overall simple and transparent formulation, which gives the element a good predictive capability without containing spurious zero energy modes.

The formulation of the element is briefly presented in this work and then the element is validated using against a simple dynamical problem referring to a cantilever beam.

Abstract. *Most engineering applications involving solutions by numerical methods are dependent on several parameters, whose impact on the solution may significantly vary from one to the other. At times an evaluation of these multivariate solutions may be required at the expense of a prohibitively high computational cost. In the present work, a multivariate finite element approach is proposed, allowing for a fast evaluation of parametric responses. It is based on the construction of a reduced basis spanning a subspace able to capture rough variations of the response. The method consists in an extension of the Well-Conditioned Asymptotic Waveform Evaluation (WCAWE) to multivariate problems, by an appropriate choice of derivative sequences, and a selection of the most relevant basis components. It is validated and demonstrated for its potential on a semi-industrial sized 3D application involving coupled poroelastic and internal acoustic domains.*

1 INTRODUCTION

In order to limit the high computational burden associated with the evaluation of multivariate Finite Element (FE) solutions, an approach based on a Reduced-Order-Model (ROM), derived after a univariate moment-matching method, is proposed. This univariate method, namely the Well-Conditioned Asymptotic Waveform Evaluation (WCAWE) method, proposed by Slone *et al*. [1], is shown to allow for a robust generation of basis components with good convergence properties of the associated reduced systems [1–3]. It relies on a sequence of successive derivatives of the system of interest, leading to multiple Right-Hand-Side (RHS) problems to be solved sequentially, with intermediate orthonormalization steps and correction terms ensuring the robustness of the procedure and the good conditioning of the resulting transformation matrix. This univariate basis generation procedure may be extended to a multivariate procedure. However, the cost associated with the orthonormalization and correction steps, may lead to a computationally prohibitive cost, particularly as the dimension of the variable space increases [3]. Additionally, not all cross-derivative terms may contribute significantly to the convergence of the ROM, and it may be critical to be able to reduce them to a minimum. In this contribution, an effort is made to bring the WCAWE to multivariate problems, starting with a bivariate illustration, and attempting to limit the transformation bases to a minimum in view of higher dimensionality applications. The foundation for a multi-interval strategy is also presented in view of the reconstruction of wide parametric ranges. The approach is shown to benefit from the superior robustness of the WCAWE compared to the so-called component-wise Padé approximants [3–6], previously used to derive the Nested Padé approximant method [7, 8].

In the following Section, reminders are made about the WCAWE, the details of its procedure, and the proposed extension to multivariate problems. Then, the basis for a multi-interval strategy relying on error estimation following contours of convergence intervals is introduced. Finally, the accuracy and potential of the method are presented on a 3D poro-acoustic problem.

2 The WCAWE, a moment-matching, projection-based ROM

2.1 Generic multivariate problem and associated transformation

The starting point of the WCAWE-based parametric sweep is given by a linear system of the following form,

$$\mathbf{Z}(\mathbf{x})\mathbf{U}(\mathbf{x}) = \mathbf{F}(\mathbf{x}), \tag{1}$$

where $\mathbf{x}$ may be a vector of N_x independent variables corresponding to the parametric problem of interest, e.g. including the angular frequency ω, material parameters, ... For the original univariate case [1], the vector reduces to a scalar such that $\mathbf{x} = [x]$. In an FE problem, $\mathbf{Z}(\mathbf{x})$, $\mathbf{U}(\mathbf{x})$, and $\mathbf{F}(\mathbf{x})$ respectively represent the system matrix of the discretized problem, the solution vector and the vector of externally applied loads.

The projection-based approach, allowing to solve for a reduced set of equations associated with Eq. (1), relies on the construction of a transformation basis emerging from successive derivatives of the solution vector in Eq. (1) at a specific point $\mathbf{x}_0$ in the parameter space. The WCAWE algorithm provides a robust generation of this sequence of successive derivatives, overcoming the inherently ill-conditioned transformation matrix emerging from the direct approach used in the component-wise Padé approximants [3, 4], also used for the generation of Nested Padé approximants [7, 8]. The resulting well-conditioned transformation matrix $\mathbf{V}_\mathrm{N}$, consisting of N orthonormalized basis vectors, allows for a robust, non-stagnating convergence upon increasing the size of the subspace spanned. The associated approximation of the solution

in Eq. (1), to the order N, is such that

$$\widehat{\mathbf{U}}_{\mathrm{N}}(\mathbf{x}) = \mathbf{V}_{\mathrm{N}}\, \boldsymbol{\alpha}(\mathbf{x}) \approx \mathbf{U}(\mathbf{x}), \tag{2}$$

$\boldsymbol{\alpha}$ being a vector of N generalized coordinates. This transformation leads to a reduced system corresponding to Eq. (1), solving for the generalized coordinates in $\boldsymbol{\alpha}(\mathbf{x})$,

$$\mathbf{V}_{\mathrm{N}}{}^{T}\mathbf{Z}(\mathbf{x})\mathbf{V}_{\mathrm{N}}\boldsymbol{\alpha}(\mathbf{x}) = \mathbf{V}_{\mathrm{N}}{}^{T}\mathbf{F}(\mathbf{x}). \tag{3}$$

2.2 A multivariate WCAWE basis generation procedure

A generic expression of the multivariate WCAWE algorithm, as proposed in this contribution, may be given in $\mathbf{x} = \mathbf{x}_0$ by the following multiple right-hand-side procedure,

$$\begin{cases}
\mathbf{Z}^{(0)}\overline{\mathbf{v}}_1 = \mathbf{F}^{(0)} \\
\qquad Normalization\ \ \overline{\mathbf{v}}_1 \longrightarrow \mathbf{v}_1 \\
\mathbf{Z}^{(0)}\overline{\mathbf{v}}_2 = \mathbf{F}^{(1)}\mathbf{e}_1^T\mathbf{P}_{\mathbf{Q_1}}(2,1)\mathbf{e}_1 - \mathbf{Z}^{(1)}\mathbf{v}_1 \\
\qquad Othonormalization\ \ \overline{\mathbf{v}}_2 \longrightarrow \mathbf{v}_2 \\
\qquad \vdots \\
\mathbf{Z}^{(0)}\overline{\mathbf{v}}_n = \left(\displaystyle\sum_{j=1}^{(n-1)} \left(\mathbf{F}^{(n)}\mathbf{e}_1^T\mathbf{P}_{\mathbf{Q_1}}(n,j)\mathbf{e}_{n-j} \right) - \mathbf{Z}^{(1)}\mathbf{v}_{n-1} \right. \\
\qquad\qquad \left. - \displaystyle\sum_{j=2}^{(n-1)} \left(\mathbf{Z}^{(j)}\mathbf{v}_{n-j}\mathbf{P}_{\mathbf{Q_2}}(n,j)\mathbf{e}_{n-j} \right) \right) \\
\qquad Othonormalization\ \ \overline{\mathbf{v}}_n \longrightarrow \mathbf{v}_n \\
\qquad \vdots \\
\mathbf{Z}^{(0)}\overline{\mathbf{v}}_{\mathrm{N}} = \left(\displaystyle\sum_{j=1}^{(\mathrm{N}-1)} \left(\mathbf{F}^{(\mathrm{N})}\mathbf{e}_1^T\mathbf{P}_{\mathbf{Q_1}}(\mathrm{N},j)\mathbf{e}_{\mathrm{N}-j} \right) - \mathbf{Z}^{(1)}\mathbf{v}_{\mathrm{N}-1} \right. \\
\qquad\qquad \left. - \displaystyle\sum_{j=2}^{(\mathrm{N}-1)} \left(\mathbf{Z}^{(j)}\mathbf{v}_{\mathrm{N}-j}\mathbf{P}_{\mathbf{Q_2}}(\mathrm{N},j)\mathbf{e}_{\mathrm{N}-j} \right) \right) \\
\qquad Othonormalization\ \ \overline{\mathbf{v}}_{\mathrm{N}} \longrightarrow \mathbf{v}_{\mathrm{N}}
\end{cases} \tag{4}$$

where a modified Gram-Schmidt orthonormalization step is performed between each vector generation by the multiple RHS systems in Eq. (4), and where

- $\mathbf{Z}^{(k)}$ stands for the differentiation of the system matrix $\mathbf{Z}$, in $\mathbf{x} = \mathbf{x}_0$, to the "cumulative" order k, regardless of the distribution of the differentiation between the independent variables x_i. In other words, given the notation $\partial_{x_j}^{i_j}(\cdot)$ for the partial derivative with respect to x_j at order i_j, and the convention $\partial_{x_j}^{0}(\cdot) = (\cdot)$, then $\mathbf{Z}^{(k)}$ results from the partial derivative orders summation such that

$$\mathbf{Z}^{\left(\sum_{j=1}^{\mathrm{N}_x} i_j\right)} = \left(\prod_{j=1}^{\mathrm{N}_x} \partial_{x_j}^{i_j} \right) \mathbf{Z}, \tag{5}$$

  with the aforementioned convention implying that $\mathbf{Z}^{(0)} = \mathbf{Z}$.

- $\mathbf{e}_k$ is a unitary standard basis vector associated with the k^{th} component of the solution vector,
- $\overline{\mathbf{v}}_k$ is the non-orthonormalized vector generated in the k^{th} iteration of the procedure,
- $\mathbf{v}_k$ is the basis vector orthonormalized against $\mathbf{v}_{k-1}$, generated after the k^{th} iteration of the procedure,
- $\mathbf{P}_{\mathbf{Q}_\omega}(\alpha,\beta)$, $\omega = 1, 2$, corresponds to the RHS correction terms, chosen to be associated with the modified Gram-Schmidt orthonormalisation process [1].

The orthonormalized and non-orthonormalized bases, $\mathbf{V}_\text{N}$ and $\overline{\mathbf{V}}_\text{N}$ respectively, are related by

$$\mathbf{V}_\text{N} = \overline{\mathbf{V}}_\text{N}\mathbf{Q}^{-1}, \tag{6}$$

where $\mathbf{Q}$ is an N $\times$ N upper triangular, nonsingular matrix containing the modified Gram-Schmidt coefficients. More precisely, column k of $\mathbf{Q}$ contains the successive coefficients resulting from the projection of partially orthonormalized $\overline{\mathbf{v}}_k$ on the orthnormalized vectors $\mathbf{v}_j$, $j < k$, and Q_{kk} corresponds to the norm of $\mathbf{v}_k$ before its normalization. The correction terms $\mathbf{P}_{\mathbf{Q}_\omega}(\alpha,\beta)$, $\omega = 1, 2$, are given by the following product of block matrices extracted from $\mathbf{Q}$,

$$\mathbf{P}_{\mathbf{Q}_\omega}(\alpha,\beta) = \prod_{t=\omega}^{\beta} \mathbf{Q}^{-1}_{[t:\alpha-\beta+t-1,t:\alpha-\beta+t-1]} \tag{7}$$

Further discussions on the choice of the RHS correction coefficients other than associated with the Gram-Schmidt coefficients, may be found in Ref. [1].

The approximated solution is evaluated at all DOFs from the generalized coordinates vector $\boldsymbol{\alpha}$, after Eq. (2).

Adapting the WCAWE algorithm from univariate problems to multivariate ones lies in the generation of sequences of RHS vectors, emerging from sequences of iteratively differentiated matrices $\mathbf{Z}^{(k)}$. The choice adopted here is to generate such sequences independently, thus generating a set of N_V bases $\left\{\mathbf{V}_\text{N}^1, \cdots, \mathbf{V}_\text{N}^{\text{N}_\text{V}}\right\}$ associated with N_V sequences of iteratively differentiated matrices $\mathbf{Z}^{(k)}$. These bases, in principle all of the same size N, each consist of orthonormalized basis vectors, but these are naturally not mutually orthonormalized from one to the next basis. These are not even guaranteed to produce linearly independent subsets of vectors upon merging these bases. A simple way to ensure this, as well as to reduce the basis to a minimum number of basis vectors is to proceed to a compression, or a component selection, via a Singular Value Decomposition (SVD) of the merged set of bases. Either way, the initial step consists in an SVD of the merged basis after concatenation, $\mathbf{V}_\text{N}^\text{mer} = \left[\mathbf{V}_\text{N}^1 \cdots \mathbf{V}_\text{N}^{\text{N}_\text{V}}\right]$, resulting in

$$\mathbf{V}_\text{N}^\text{mer} = \sum_{i=1}^{\text{N}_\text{mer}} \sigma_i \mathbf{w}_i^\text{l} \mathbf{w}_i^{\text{r}T}, \tag{8}$$

where N_mer corresponds to the total number of basis vectors in $\mathbf{V}_\text{N}^\text{mer}$, *i.e.* $\text{N}_\text{mer} = \text{N} \cdot \text{N}_\text{V}$; σ_i, $\mathbf{w}_i^\text{l}$, and $\mathbf{w}_i^\text{r}$ correspond to the singular values, left and right singular vectors respectively.

From the SVD, either the (left) singular vectors associated with the highest singular values are selected as the components of the reduced merged basis, or the compression of the merged basis associated with the highest singular values is performed from the selected left singular vectors, right singular vectors and their corresponding singular values. Here the former approach

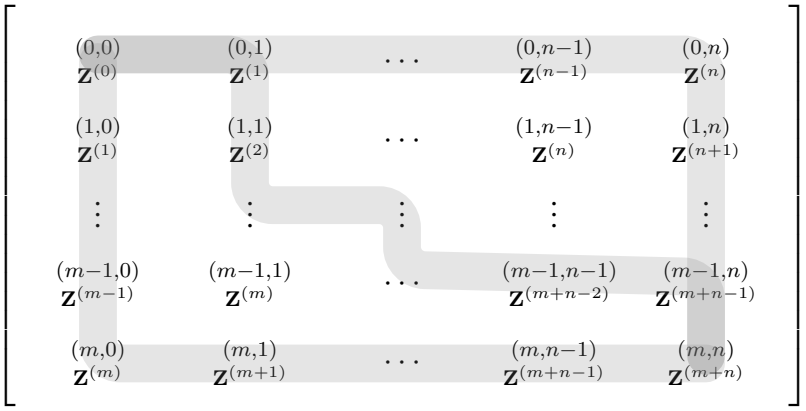

Figure 1: Illustration of three possible bivariate derivation paths for the system matrix $\mathbf{Z}$ up to the "cumulated order" $(m+n)$.

is used, such that assuming a descending-ordered sequence of singular values $(\sigma_1 \cdots \sigma_{\mathrm{N_{mer}}})$, the reduced, merged basis $\mathbf{V}^*$ is

$$\mathbf{V}^* = \left\{ \mathbf{w}_i^{\mathrm{l}} \mid i \in (1, \mathrm{N_{mer}}) \wedge \sigma_i \geq \sigma_{\mathrm{thresh}} \right\}, \tag{9}$$

where σ_{thresh} corresponds to the empirically chosen threshold value for the selection of the singular values resulting from the decomposition in Eq. (8).

The resulting reduced basis $\mathbf{V}^*$, consisting of $\mathrm{N_{V^*}}$ vectors, is then used in place of the univariate transformations corresponding to Eq. (2) and Eq. (3), in order to solve a reduced set of equations at most involving $\mathrm{N_{mer}}$ DOFs.

2.3 Sequences of multivariate differentiation

The sequential WCAWE procedure above depends on the generation of sequences of differentiated system matrices to successive "cumulated multivariate orders" k, i.e. $\mathbf{Z}^{(k)}$. The choice of these sequences is addressed empirically in this contribution, and illustrated for the case of bivariate problems. For the bivariate case, the cumulated differentiation orders and the associated differentiation paths may be represented in a matrix form, see Fig. 1.

The matrix sequences obtained from these differentiation paths of the system matrix subsequently feed the procedure presented in Eq. (4).

The rationale behind choosing a limited number of derivation paths is connected to the potential inefficiency resulting from the attempt to calculate all multivariate derivatives for a given set of maximum orders. Preliminary tests based on the methodology introduced in the previous section rapidly confirm the emergence of quasi-linearly dependent basis vectors associated with different differentiation orders from distinct sequences. In practice, it is estimated that a number of sequences of the order of the dimensionality of the multivariate problem may be sufficient in order to provide good convergence properties of the ROM. For instance, 2 sequences may be sufficient for a bivariate problem. Note that this observation addresses in part the issue of dimensionality and the associated efficiency of the approach: the number of successive derivatives necessary grows linearly with the dimensionality as opposed to an exponential growth if all cross-derivatives are calculated in a fully multivariate approach.

3 Multi-interval, multivariate WCAWE approach

In practice, the size of the reduction basis may be limited due to the increase of the computational cost of the procedure in Eq. (4) [3]. This implies that there may be a tradeoff between increasing the order of approximation, reflected in the size of the basis for a given reference point, and a multi-interval strategy. In order to proceed with an approximation based on multiple intervals, an error estimator is first necessary.

3.1 Error estimation

A Cauchy-type of convergence test is chosen in order to estimate the accuracy of the approximation without having to calculate the full solution. Provided an approximated output (scalar) quantity of interest, to the order N, in point $\mathbf{x}$, of the form

$$\widehat{S}_{\mathrm{N}}(\mathbf{x}) = 10\ \log\left(\frac{\widehat{U}_{\mathrm{N}}(\mathbf{x})^2}{U_{\mathrm{ref}}(\mathbf{x})^2}\right), \tag{10}$$

the convergence is estimated in a given point $\mathbf{x}$ with the Cauchy convergence test associated with the relative error $\epsilon^{(\mathrm{N})}(\mathbf{x}) = \widehat{S}_{(\mathrm{N}+2)}(\mathbf{x}) - \widehat{S}_{(\mathrm{N})}(\mathbf{x})$, such that

$$\epsilon^{(\mathrm{N})}(\mathbf{x}) \leq \epsilon_{\max}, \quad \forall \mathbf{x} \in [\mathbf{x}_{\min}, \mathbf{x}_{\max}]\,. \tag{11}$$

Note that the convergence test involves the solutions associated with several orders of difference. Two orders of difference is suggested here for examples associated with bivariate problems; more may be required for higher dimensionality. Despite a slight reduction of the convergence range achieved, a sufficiently enriched basis reduces the possibility of an erroneous estimate to occur, and leads to a conservative measure of the actual approximation error.

A Cauchy-type of convergence test however requires an evaluation of two solutions in each point of interest. It is consequently necessary to limit the number of evaluations of the relative error for each interval in order to limit the extra cost associated with the error estimation.

3.2 Contour-following and multi-interval strategy

In order to reduce the number of points at which the error estimation needs to be made, a contour-following strategy is implemented. Starting from the reference point for each interval, an isocontour is determined (Moore-Neighbour Tracing algorithm), associated with the max error $\epsilon_{\max}$ in Eq. (11). This contour subsequently allows to fit a regular shape (e.g. a rectangle for a bivariate problem) providing a simplified measure of the interval of convergence. The successive dimensions of the intervals of convergence may further be used in order to anticipate the choice of subsequent reference points for approximation of the solution on neighbour intervals.

There are several simple strategies possible in order to fill an entire parametric solution space with smaller intervals of convergence. One may iteratively choose reference points in direct connection with the range of convergence of the previously calculated intervals, as adopted for instance in Ref. [8]. Another possibility is to successively choose the reference points such that they are the furthest away from any boundary of the parametric space or the converged contours.

4 Application: poro-acoustic parametric sweep

The proposed multivariate approach is tested on an average-sized problem consisting of the interior cavity of a passenger train, treated with a 15-cm layer of sound absorbing porous material on the top surface. A time-harmonic point source is defined at a corner of the cavity, and

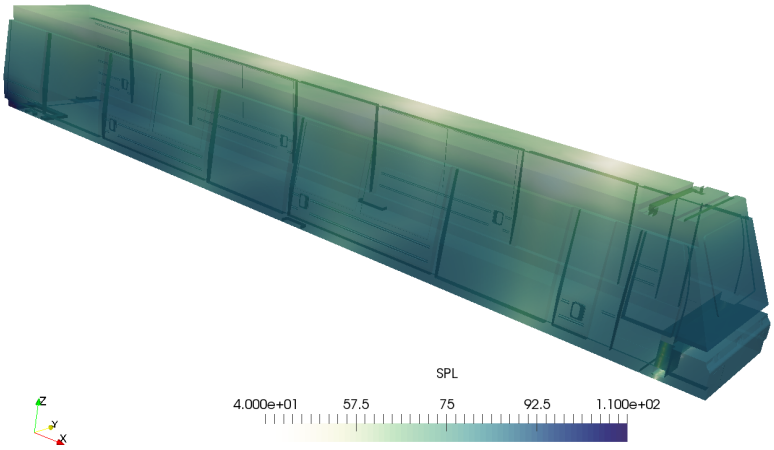

Figure 2: Sound pressure level of the damped solution at 63 Hz, $\Phi = 25000$ N.s.m^{-4}, scale $40 - 110$ dB.

parametric sweeps with respect to both the frequency and the static airflow resistivity of the porous layer are performed. All boundary walls are considered as rigid walls, except from the porous boundary. The porous boundary is modelled by an equivalent fluid formulation, consisting of a modified Helmholtz equation where the equivalent speed of sound is complex and frequency-dependent, given by

$$\tilde{c_{\mathrm{p}}} = \frac{c_0}{\sqrt{\dfrac{1 - i\Phi}{\rho_0 \omega}}}, \tag{12}$$

where $\tilde{(\cdot)}$ denotes a complex-valued quantity, $\rho_0 = 1.21$ kg.m^{-3} is the ambient density of the air saturating the pores and $c_0 = 343$ m.s^{-1} the speed of sound in the air. $\omega = 2\pi f$ is the angular frequency associated with the time-harmonic excitation, and Φ is the static flow resistivity, associated with the viscous dissipation in the porous material.

After a standard expression of the problem in its weak form and subsequent discretization by a Galerkin method, the finite element problem has the general form

$$\left(\mathbf{K_a} - \frac{\omega^2}{c_0^2} \mathbf{M_a} + \mathbf{K_p} - \frac{\omega^2}{\tilde{c_{\mathrm{p}}}^2} \mathbf{M_p} \right) \tilde{\mathbf{U}} = \mathbf{F}, \tag{13}$$

where $\square_{\mathbf{a}}$ correspond to air cavity global matrices, and $\square_{\mathbf{p}}$ to porous global matrices. $\tilde{\mathbf{U}}$ is the vector of nodal unknowns (acoustic pressure fluctuation here). The right-hand-side vector $\mathbf{F}$, associated with the time-harmonic acoustic excitation is in practice only non-zero at a few DOFs. The FE problem in Eq. (13) is evidently of the form of the generic problem in Eq. (1), thus suitable for the multivariate approach proposed. The discretized problem consists of around 300000 acoustic pressure DOFs.

Fig. 2 illustrates the solution at a given point of the parametric sweep, for a frequency of 63 Hz, and a flow resistivity of 25000 N.s.m^{-4}.

The reference solution for the bivariate parametric sweep, where $f \in [50, 150]$ Hz and $\Phi \in [3000, 50000]$ N.s.m^{-4}, at a point in the cavity, is plotted in Fig. 3.

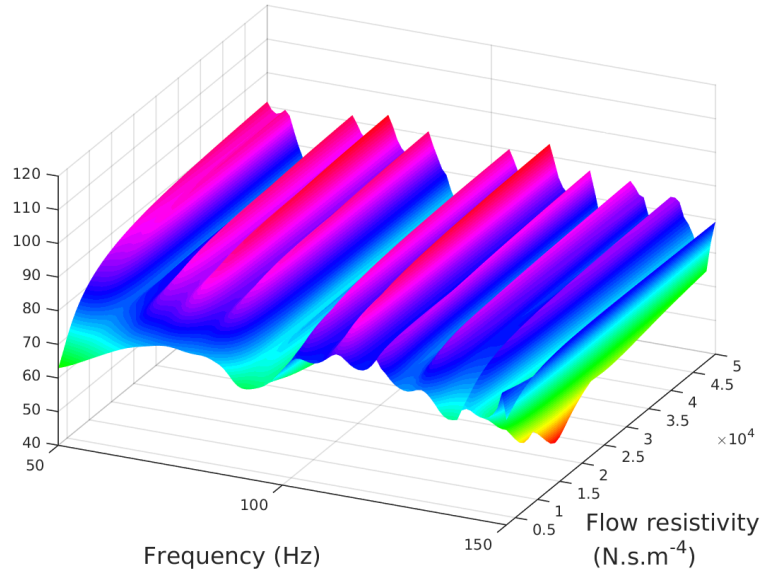

Figure 3: Reference solution. Sound pressure level at a point in the acoustic cavity, parametric solution, in dB.

The multivariate WCAWE procedure proposed here is applied for an approximated solution based on one reference point in the parametric space for the construction of the transformation basis.

Two configurations are tested regarding the number of sequences necessary in order to produce the reduced merged basis $\mathbf{V}^*$ of Eq. (9). The first configuration includes 3 sequences: the 2 ”outer” sequences, and one ”diagonal” sequence, as presented in Fig. 1. Given that in this configuration, some components added by the third sequence are not selected by the SVD, and that the increased size of the reduced basis $\mathbf{V}^*$ does not noticeably improve the accuracy of the approximation, the second configuration includes only the two ”outer” sequences. The singular value threshold σ_{thresh}, used for the selection of the main components for the reduced basis $\mathbf{V}^*$, is chosen to be such that $\sigma_{\text{thresh}} = \sigma_{\text{max}} \cdot 10^{-15}$, where σ_{max} corresponds to the largest singular value in the decomposition of Eq. (8).

In Fig. 4, the convergence of the approximated bivariate solution is illustrated for three different orders of approximation, for a reduced basis $\mathbf{V}^*$ based on the two ”outer” sequences.

Given the smooth variation of the solution with respect to the static flow resistivity, it is natural that a lower order of approximation is required than for the frequency. In this illustration, the order of differentiation for the static flow resistivity is set to 9. Three increasing orders of differentiation are plotted for the frequency, from order 19 to order 55. The degree of accuracy reached for the latter case, although using one point only at $f = 88$ Hz and $\Phi = 25000$ N.s.m^{-4} for the construction of the basis, highlights the potential of the method.

Table 1 provides a brief comparison of the size of the bases obtained from the proposed procedure when 2 or 3 sequences of differentiation are used prior to the SVD. A combination of the facts that some vectors added by the 3rd sequence are filtered out by the SVD, while all vectors emerging from the combination of the 2 ”outer” sequences are kept, indicates that a 2-sequence approach may be sufficient for the bivariate case. In particular, no improvement of

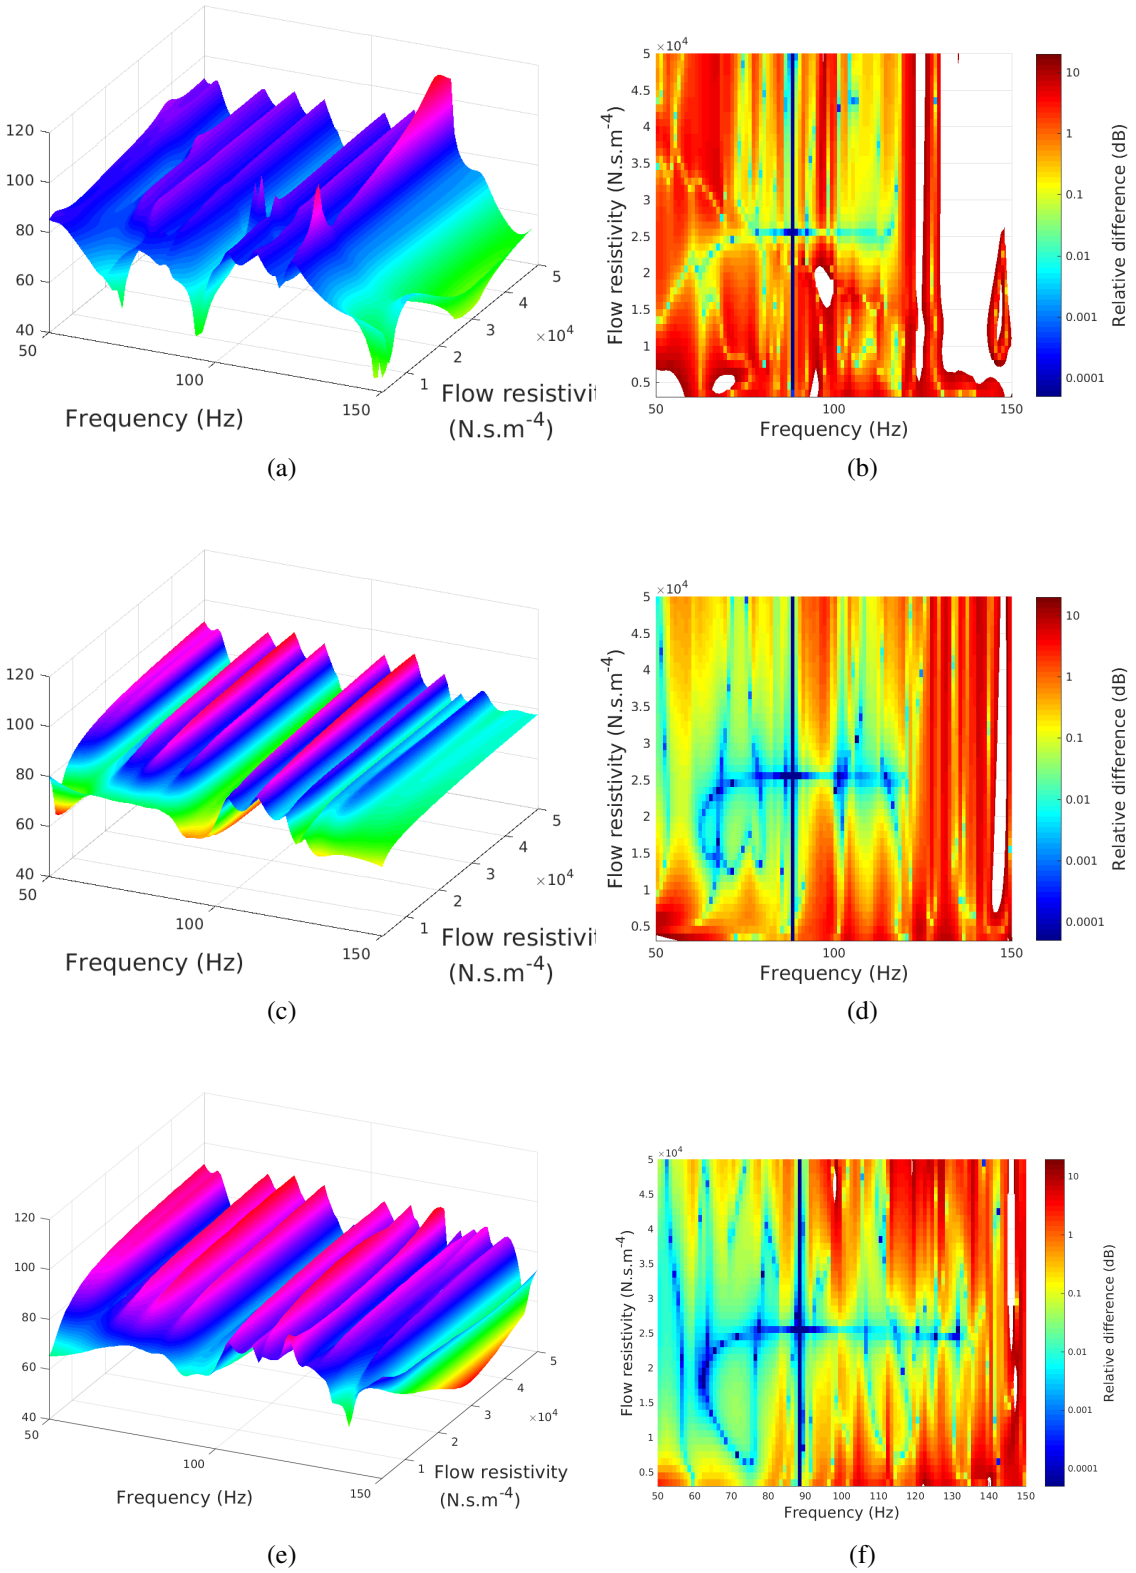

Figure 4: Convergence of the one-point WCAWE-approximated solution. SPL at a single point, in dB. Reference parametric point for the WCAWE basis procedure: $f = 88$ Hz and $\Phi = 25000$ N.s.m^{-4}. Approximation (left) and relative difference to the reference solution (right).

	N vec/basis	N_{mer}	N_{V^*}
2-sequence	29 (9+19+1)	56 (29+27)	56
3-sequence	29 (9+19+1)	83 (29+27+27)	79
2-sequence	41 (9+31+1)	80 (41+39)	80
3-sequence	41 (9+31+1)	119 (41+39+39)	112
2-sequence	65 (9+55+1)	128 (65+63)	128

Table 1: Overview of the size of the reduced basis $\mathbf{V}^*$ emerging from the 2- and 3-sequence procedure associated with the results in Fig.4.

convergence and accuracy was observed by adding the third sequence, thus indicating a minor contribution from the basis vectors emerging from this additional sequence. This also reflects a conservative threshold value for σ_{thresh}. Finally, the fact that no basis vector is filtered out by the SVD, when all vectors emerging from the combination of the 2 "outer" sequences are kept, implies that the SVD is in this case not associated with a selection of the basis components, but rather with a re-orthogonalization of the reduced basis $\mathbf{V}^*$.

Limiting the expansion to derivative orders 20/12 for the frequency and flow resistivity, respectively, Fig. 5 illustrates the contour-following, filling and shape-fitting approach in order to define sub-intervals of convergence. The error estimation is calculated along the contours only, in Figs. 5a and 5c, assuming a monotonous increase of the relative error inside the contours around the reference point of expansion, and a tolerance of $\epsilon_{\text{max}} = 0.02$ dB. These contours may subsequently be fitted, as plotted in grey in Figs. 5b and 5d, with a regular shape connected to the shape of the parametric space, i.e. a rectangle for this bivariate example.

A first attempt for a multi-interval approximation of the full bivariate parametric space is plotted in Figs. 6. This approach is based on a surface-fitting matching the surface area of the estimated contour, augmented by an overestimation factor, here set to 1.5. This over-estimation factor is justified by the slow increase of the error beyond the convergence contours, provided that the error tolerance is low enough (here 0.02 dB). The first reference point, associated with the first interval in Fig. 6a, is chosen following a preliminary step testing the convergence range associated with a reference point in the center of the parametric space. Then, subsequent intervals are chosen based on the dimensions of the last 2 calculated intervals, in the closest neighbourhood possible to the last calculated interval. When the parametric space has been entirely covered, the algorithm attempts to bridge the largest gaps, based on the dimension of the smallest interval of convergence. Fig. 6b shows in white the estimated range of convergence after 3 intervals (starting from the low frequency and low flow resistivity ranges). Fig. 6c shows the estimated range of convergence after 9 intervals, after which the entire parametric range is "covered". Finally, Fig. 6d plots the estimated range of convergence after the largest gaps have been added extra reference points, including 16 intervals in total. This implies the calculation of 16 multiple RHS problems consisting of 33 RHS vectors in order to build the complete set of reduced bases, to be contrasted with the full solution to be calculated at $101 \times 48 = 4848$ points for the reference solution.

The proposed approach is currently being tested for its robustness with respect to a wide range of problems, starting, as done here, with bi-parametric problems.

5 CONCLUSIONS

In this contribution, a multivariate approach based on the Well-Conditioned Asymptotic Waveform Evaluation algorithm is proposed. It relies on the generation of basis vectors emerging from sequences of incrementally differentiated system matrices at parametric points of expansion. These sequences, efficiently generated by a multiple right-hand-side type of problem, are subsequently merged and further reduced via a singular value decomposition.

The convergence of the approach is illustrated on a bivariate poro-acoustic application of about 300000 degrees of freedom. The limitation to a reduced set of sequences is promising in the scope of using the proposed approach for higher dimensionality. An extension to a multi-interval approximation strategy, based on the efficient use of error estimator is also tested and currently under further developments in connection with its robustness.

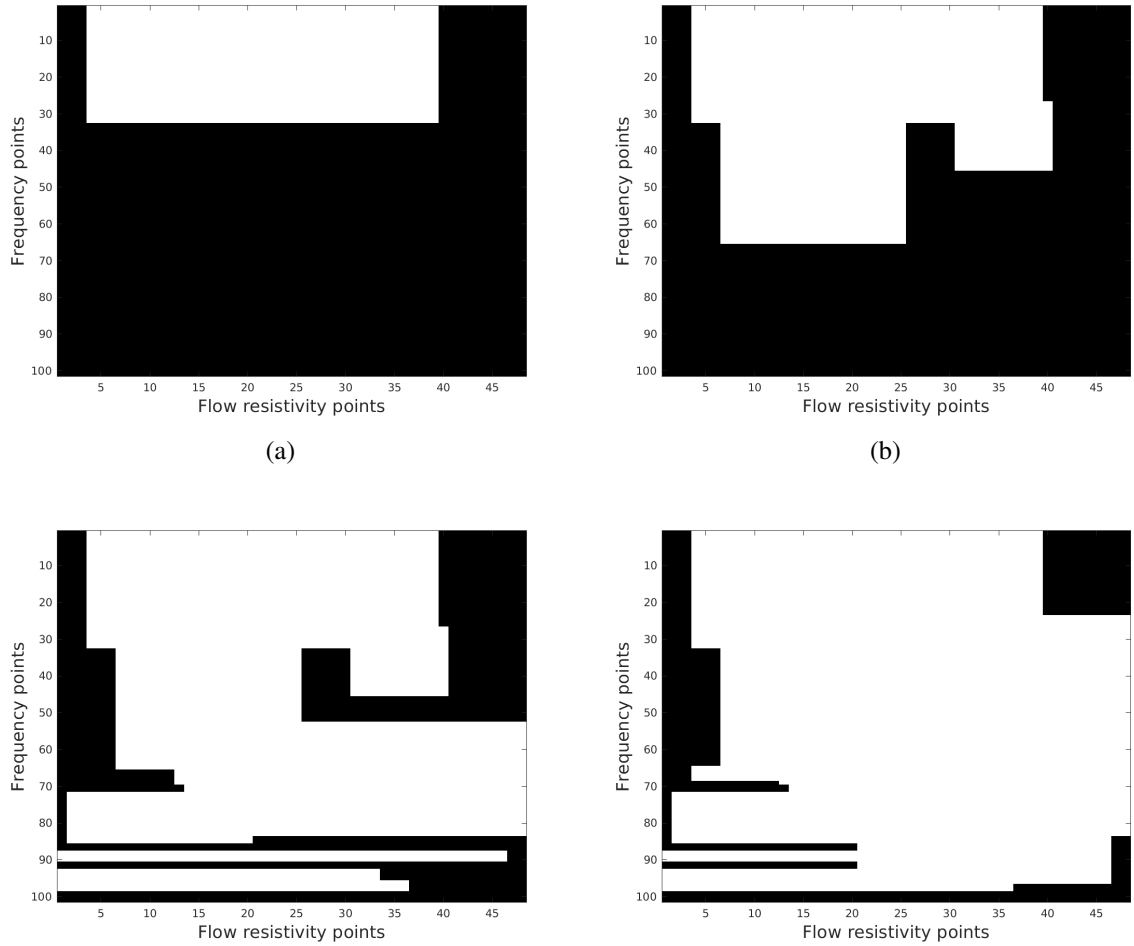

Figure 6: Convergence of a multi-interval approach for bases with fixed derivative orders 20/12, with a tolerance of $\epsilon_{\max} = 0.02$ dB. (a): 1 convergence interval, (b): 3 convergence intervals, (c): 9 convergence intervals, (d): 16 convergence intervals.

Abstract

As the earliest meshless method, Smoothed Particles Hydrodynamics (SPH) has been applied in solid dynamics because of its great potentials in simulating extremely large deformations. However, the numerical instability of SPH is still a severe problem, especially tensile instability and pairing instability can lead to some unphysical cracks when the solid material is stretched or compressed. At present, no method exists to completely avoid these instabilities, although a few corrections like Artificial Viscosity, Artificial Stress, CSPH or the Godunov-type SPH have been proposed. The base of SPH formulation uses a kernel function for numerical approximations. Some literatures demonstrate mathematically that the types of the kernel function directly influences the stability of SPH method. In this paper, we study the stability of SPH with the different kinds of kernel functions including traditional types and several new ones proposed recently. Combined with some corrected techniques, the suitability of these kernels in SPH method is discussed in solid dynamic problems like bending deformation in elastic beam and elastic-plastic deformation in impact problems.

Keywords: Smoothed particle Hydrodynamics, Tensile instability, Kernel functions, Elastic-plastic deformation

1 INTRODUCTION

Smoothed particle hydrodynamics (SPH) is a numerical method proposed initially by (Gingold &Monaghan 1977) [1], which discretizes a continuum and has been used to solve a wide array of partial differential equations [5][9]. As a typical meshfree method, it was initially used in simulating astrophysical and cosmological problems [2], and then was developed quickly to be applied in computational fluid dynamics [3-5], electromagnetics [6], explosive process[7]. Considering the characteristic of SPH which models the governing equations by a group of particles and is more flexible to simulate the material's large deformations, lots of researchers expanded its applications into solid dynamics [8][9]. It has been effectively applied in impact problems [10], metal forming [11] and biomechanics [12] in recent years.

Different versions and corrections of SPH method are still developed to reduce some numerical instabilities especially when simulating solid dynamics [13-14]. Artificial viscosity was proposed in [15] to mainly remove the numerical oscillation, which has been used in all the SPH versions. Because this technique can generate unphysical dissipation by adding an "artificial pressure" into the momentum and energy equations, it easily makes the system over-dissipative. Amit Shaw et. [16] discussed it detailly and introduced a modified method based on original artificial viscosity terms. Corrected SPH (CSPH) is developed to make the SPH procedure more stable and especially for boundary inconsistency [18] by corrected kernels. In the overview paper by M.Rothlin et. [9] in 2018, two kind of Corrected SPHs were discussed, the first was proposed by Randles and Libersky [20] which reproduces a linear function by a correction tensor for the kernel estimate. The other was based on Taylor expansion to correct kernel introduced by Chen, Beraum and Jih [21]. In this paper, the latter approach is used because it provides higher order derivatives in SPH formulation than the other. Artificial stress term was developed by Monaghan and Gray [22] to remove tensile instability in elastic dynamics. It is implemented by adding a strong repulsive force only when particles become too close to each other, resulting in a more stable simulation for elastic problems. These techniques based on standard SPH like Artificial viscosity, Corrected SPHs and Artificial stress all are developed to achieve more stability of SPH. New SPH versions are still being developed, with an aim of improving the stability like Godunov SPH [23-24] and Tatal Lagrangian SPH [25-26].

In spite of these modifications, SPH still shows the pairing instability when simulating extreme tensile and compressive behaviors [17-18], which are considered as a severe barrier to develop the SPH application in solid mechanics. J.W.Swegle et. [27] studied the stability analysis of standard SPH in 1994 and firstly proposed the important concept of "tensile instability" which means particles severe clumping phenomenon in stretch sections of material. The result of this study is that the instability of SPH method has close relevance with the second derivative of kernel function. In addition, Walter Dehnen and Hossam Aly [28] also investigated the relations between the instability of SPH method and kernel functions and it proposed that the pairing instability can emerge in both stretch and compressive parts of materials, not just tensile instability in solid dynamics. Besides, this study also concluded that the Wendland kernels are more effective than traditional B-splines, but just based on the mathematical deductions. Therefore, the type of kernel plays a significant role in SPH instability. The hyperbolic-shape kernel [29] and double-cosine kernel [30] were proposed by Xiufeng Yang et. and proved that these kernels are more suitable to remove the tensile instability. But these new types of kernel are just tested for flows and for the elastic-plastic problems, there are few research to discuss it. Therefore, a study is necessary to investigate the performances of SPH with different kernels.

The structure of this paper includes five sections. Section 2 introduces the SPH formulation

and its implementation in elastic-plastic problems. Then, some corrected techniques are demonstrated including the discussion between SPH kernels with numerical instabilities in section 3. After, two examples are provided to investigate the performances of SPH with different kernels in section 4 and the conclusion is in section 5.

2 SPH METHOD APPLIED IN SOLID MECHANICS
