SPH is a typical meshfree numerical method based on particles discretization, which mainly consists of two processes, kernel approximation and particles discretization. It has a great advantage in simulations with large deformation in dynamics. This section shows the implementation procedure of SPH method in elastic-plastic formulations.

2.1 SPH formulations

The first major process in SPH formulation is kernel approximation, which approximates the field variables and their derivatives by using the kernel function W. Therefore, kernel function in follow formulas is an important concept and its type has much weight for SPH performance. The kernel approximation can be shown by follow equations,

$$\langle f(x)\rangle = \int_{\Omega} f(x')W(x-x',h)\mathrm{d}x' \tag{1}$$

$$\langle \nabla\cdot f(x)\rangle = \int_{\Omega} f(x')\cdot\nabla W(x-x',h)\mathrm{d}x' \tag{2}$$

Where, h is the smooth length determining the size of nearby domain also called influence domain. Its value depends on the kernel function. Then, to discretize the above integral functions into the particles summations in its influence domain is called particles approximation.

$$\langle f(x_i)\rangle = \sum_{j=1}^{N}\frac{m_j}{\rho_j} f(x_j)W(x_i-x_j,h) \tag{3}$$

$$\langle \nabla\cdot f(x_i)\rangle = \rho_i\left[\sum_{j=1}^{N} m_j\left[\frac{f(x_i)}{\rho_i^2}+\frac{f(x_j)}{\rho_j^2}\right]\cdot\nabla W(x_i-x_j,h)\right] \tag{4}$$

2.2 Governing equations in solid elastic-plastic body and its SPH formulas

The conservation equations for solid mechanics are shown by

$$\frac{\mathrm{d}\rho_i}{\mathrm{d}t} = -\rho\frac{\partial v_i^{\alpha}}{\partial x_i^{\alpha}} = \sum_{j=1}^{N} m_j(v_i^{\alpha}-v_j^{\alpha})\cdot\frac{\partial W_{ij}}{\partial x_i^{\alpha}} \tag{5}$$

$$\frac{\mathrm{d}v_i^{\alpha}}{\mathrm{d}t} = \frac{1}{\rho}\frac{\partial\sigma_i^{\alpha\beta}}{\partial x_i^{\beta}} + f^{\alpha} = \sum_{j=1}^{N} m_j\left(\frac{\sigma_i^{\alpha\beta}}{\rho_i^2}+\frac{\sigma_j^{\alpha\beta}}{\rho_j^2}\right)\cdot\frac{\partial W_{ij}}{\partial x_i^{\beta}} + f^{\alpha} \tag{6}$$

$$\frac{\mathrm{d}e_i^{\alpha}}{\mathrm{d}t} = -\frac{\sigma_i^{\alpha\beta}}{\rho}\frac{\partial v_i^{\alpha}}{\partial x_i^{\beta}} = -\frac{1}{2}\sum_{j=1}^{N} m_j(v_i^{\alpha}-v_j^{\alpha})\left(\frac{\sigma_i^{\alpha\beta}}{\rho_i^2}+\frac{\sigma_j^{\alpha\beta}}{\rho_j^2}\right)\cdot\frac{\partial W_{ij}}{\partial x_i^{\beta}} \tag{7}$$

Where, for every particle i, the physical informations like mass m_i, density ρ_i, and internal energy e_i are carried. v_i is the component of the velocity vector and $\sigma_i^{\alpha\beta}$ is the stress tensor

and x_i is the Cartesian component of the position vector. The stress tensor in Eq.(6) and (7) can be written by

$$\sigma^{\alpha\beta} = P\delta^{\alpha\beta} - S^{\alpha\beta} \tag{8}$$

Where, P is pressure and $S^{\alpha\beta}$ is the deviatoric stress. In this paper, for elastic problem, calculating the pressure by a simple constitutive equation,

$$P = K(\frac{\rho}{\rho_0} - 1) \tag{9}$$

Where, K is the bulk modulus and ρ_0 is initial density. For the elastic-plastic problems, the Mie-Gruneisen equation is used,

$$P = (1 - \frac{1}{2}\Gamma\eta)P_H + \Gamma\rho e \tag{10}$$

Where,

$$P_H = \begin{cases} a_0\eta + b_0\eta^2 + c_0\eta^3 & \eta > 0 \\ a_0\eta^3 & \eta < 0 \end{cases} \tag{11}$$

$$\eta = \left(\frac{\rho}{\rho_0} \text{-} 1 \right) \tag{12}$$

$$a_0 = \rho_0 C^2,\ b_0 = a_0[1 + 2(S-1)],\ c_0 = a_0[2(S-1) + 3(S-1)^2] \tag{13}$$

Here, S and C, respectively, is the linear shock-velocity and the particle-velocity parameters to describe the Hugoniot fit and Γ is the Gruneisen parameter.

The deviatoric stress tensor $S^{\alpha\beta}$ can be calculated by its derivative,

$$\frac{\mathrm{d}S^{\alpha\beta}}{\mathrm{dt}} = 2\mu(\dot{\varepsilon}^{\alpha\beta} - \frac{1}{3}\delta^{\alpha\beta}\dot{\varepsilon}^{\gamma\gamma}) + S^{\alpha\gamma}R^{\beta\gamma} + S^{\beta\gamma}R^{\alpha\gamma} \tag{14}$$

$$\dot{\varepsilon}^{\alpha\beta} = \frac{1}{2}(\frac{\partial v^\alpha}{\partial x^\beta} + \frac{\partial v^\beta}{\partial x^\alpha}) \tag{15}$$

$$R^{\alpha\beta} = \frac{1}{2}(\frac{\partial v^\alpha}{\partial x^\beta} - \frac{\partial v^\beta}{\partial x^\alpha}) \tag{16}$$

Comined with the SPH formulations, the equations Eq.(14)-(16) can be described as summation forms of particles as follow,

$$\left(\frac{\partial v^\alpha}{\partial x^\beta}\right)_i = -\sum_{j=1}^{j=N} \frac{m_j}{\rho_j}(v_i^\alpha - v_j^\alpha)\frac{\partial W_{ij}}{\partial x_i^\beta} \tag{17}$$

In this paper, perfectly-plastic behaviors of the solid material are considered and Von Mises yield criterion is applied. The second stress invariant $J_2 = 0.5S^{\alpha\beta}S^{\alpha\beta}$ is checked and σ_y is the uniaxial yield stress. In every time step, if $\sqrt{J_2}$ exceeds the yield stress $\sigma_y/\sqrt{3}$, the individual stress components are given new values $S_{\text{new}}^{\alpha\beta} = fS^{\alpha\beta}$, where

$$f = \min\left\{\frac{\sigma_y}{\sqrt{3J_2}},\quad 1\right\} \tag{18}$$

The plastic strain $\varepsilon_p^{\alpha\beta}$ can be calculated by the increment form

$$\Delta\varepsilon_p^{\alpha\beta} = \frac{1-f}{2\mu} S^{\alpha\beta} \tag{19}$$

And here, the equivalent strain ε_e is defined as $\varepsilon_e = \sqrt{0.5\varepsilon^{\alpha\beta}\varepsilon^{\alpha\beta}}$, which includes both elastic and plastic deformation and it is an important variable to evaluate the material behavior and would be used in examples in this paper.

2.3 Time integration

In this paper, the predictor-corrector Leap-Frog (LF) scheme is applied in SPH time integration. Denoted the time step Δt, and the predictor step is

$$v_{n+1/2} = v_n + \Delta t \cdot \dot{v}_n \tag{20}$$

$$r_{n+1/2} = r_n + \Delta t \cdot v_n + 0.5\left(\Delta t\right)^2 \cdot \dot{v}_n \tag{21}$$

Where, r presents the value of particle's position which is not corrected. For the velocity v, the corrector step is shown by

$$v_{n+1} = v_{n+1/2} + 0.5 \cdot \Delta t \cdot (\dot{v}_{n+1/2} - \dot{v}_n) \tag{22}$$

Here, $\dot{v}_{n+1/2}$ is calculated using the predicted values. And the density ρ, energy e and deviatoric stress S are calculated by the same steps with velocity v. In that scheme, the time step is decided by below equation

$$\Delta t \approx 0.2\frac{h}{c_i + \left|v_i\right|_{\max}} \tag{23}$$

3 THE INSTABILITY PROBLEMS OF SPH FOR SOLID MECHANICS

In this section, standard SPH corrections are explained and implemented in our numerical code. Then, the discussion about the role of kernels in instability problems of SPH method is presented. Different kernels are also discussed and listed in table 3.1 for the investigation in mechanical tests in next section.

3.1 Artificial viscosity & Artificial stress

The artificial viscosity is widely used to remove the numerical oscillation in SPH method and it is also helpful to reduce the tensile instability when SPH simulates the solid problems. In this section, the basic form is introduced in Eq.(24).

$$\Pi_{ij} = \begin{cases} \dfrac{-\alpha_\Pi c_{ij}\phi_{ij} + \beta_\Pi \phi_{ij}^2}{\rho_{ij}}, & \vec{v}_{ij}\cdot\vec{x}_{ij} < 0 \\ 0, & \vec{v}_{ij}\cdot\vec{x}_{ij} < 0 \end{cases} \tag{24}$$

$$\phi_{ij} = \frac{h_{ij}\vec{v}_{ij} \cdot \vec{x}_{ij}}{\left|\vec{x}_{ij}\right|^2 + \left(\kappa h_{ij}\right)^2} \tag{25}$$

Where, $\vec{v}_{ij} = \vec{v}_i - \vec{v}_j$, $\vec{x}_{ij} = \vec{x}_i - \vec{x}_j$, $\rho_{ij} = \left(\rho_i + \rho_j\right)/2$, $h_{ij} = \left(h_i + h_j\right)/2$, $c_{ij} = \left(c_i + c_j\right)/2$ and c is the sound speed, which are explained well in [15]. κ is the constant and its value is 0.1 in this paper. And $\left(\alpha_\Pi,\ \beta_\Pi\right)$ is also a group of constant values. This term is added to momentum and energy conservations,

$$\frac{\mathrm{d}v_i^\alpha}{\mathrm{d}t} = \sum_{j=1}^{N} m_j \left(\frac{\sigma_i^{\alpha\beta}}{\rho_i^2} + \frac{\sigma_j^{\alpha\beta}}{\rho_j^2} - \Pi_{ij}\delta^{\alpha\beta} \right) \cdot \frac{\partial W_{ij}}{\partial x_i^\beta} + f^\alpha \tag{26}$$

However, the artificial viscosity adds an unphysical dissipation of energy into conservations. Then, choosing suitable parameters $\left(\alpha_\Pi,\ \beta_\Pi\right)$ is important to get satisfied results.

Artificial stress provides artificial repulsive forces to stress tensor specially in order to solve the tensile instability, adding the artificial stress terms $\mathbb{R}_{ij}^{\alpha\beta} = (R_i^{\alpha\beta} + R_j^{\alpha\beta}) \cdot f^n$ to the momentum and energy conservations as follow,

$$\frac{\mathrm{d}v_i^\alpha}{\mathrm{d}t} = \sum_{j=1}^{N} m_j \left(\frac{\sigma_i^{\alpha\beta}}{\rho_i^2} + \frac{\sigma_j^{\alpha\beta}}{\rho_j^2} - \Pi_{ij}\delta^{\alpha\beta} + \mathbb{R}_{ij}^{\alpha\beta} \right) \cdot \frac{\partial W_{ij}}{\partial x_i^\beta} + f^\alpha \tag{27}$$

Here, for 2-D problems just show the form of R_i^{xx} term when $\alpha = x$ and $\beta = x$,

$$R_i^{xx} = c^2 \bar{R}_i^{xx} + s^2 \bar{R}_i^{yy} \tag{28}$$

And, when the value of $\bar{\sigma}_i^{xx}$ is positive,

$$\bar{R}_i^{xx} = -\varsigma \frac{\bar{\sigma}_i^{xx}}{\rho^2} \tag{29}$$

Otherwise, $R_i^{xx} = 0$. In above equations, R_i^{xx} is the component of the artificial stress in the original coordinates and $\bar{R}_i^{xx}$ is new component of the stress tensor in a rotated frame and c denotes $\cos\theta_i$ and s denotes $\sin\theta_i$ (θ_i is the rotation angle which makes the stress tensor is diagonal). ς is a constant that controls the weight of artificial stress. f^n is defined as follow,

$$f_{ij}^n = \left(\frac{W(r_{ij})}{W(dx)} \right)^n \tag{30}$$

Where, r_{ij} is the distance of two particles and dx is the initial particle spacing. Constant value n is suggested as 4 in [22].

In this paper, XSPH correction is also used to update the velocity by an average of the particle velocities in every time step, like

$$\tilde{v}_i = v_i + \tilde{\varsigma} \sum_{j=1}^{N} \frac{m_j}{\bar{\rho}_{ij}} (v_j - v_i) W_{ij}, \qquad \bar{\rho}_{ij} = \frac{1}{2}(\rho_i + \rho_j) \tag{31}$$

It is suggested to be applied in tension problems simulated by SPH method in [9]. Corrected SPH (CSPH) proposed by Chen, Beraum and Jih [21] is also applied in our SPH code to simulate the examples in the section 4.

3.2 The role of kernel in SPH method

Illustrated in section 2, kernel function is an important concept in the SPH formulation, which directly determines the pattern to interpolate, and also defines the size of the influence area of a particle. As a kernel function, it needs satisfy three basic conditions like,

1. It must be normalized，

$$\int W(x-x',h)dx' = 1 \tag{32}$$

Obviously, kernel is the function with the distance between particles and h. h is the parameter called smoothing length determining the size of influence domain of a particle.

2. It has the characteristic of compact supportness, which means

$$if\ |x-x'| \le \kappa h,\ W(x-x') \ge 0\ \ else\ \ W(x-x') = 0 \tag{33}$$

Where, the combination between smoothing length h and a scale factor κ determines the spread of the specified smoothing function.

3. It should satisfy the Dirac delta function condition as $h \to 0$,

$$\lim_{h\to 0} W(x-x',h) = \delta(x-x') \tag{34}$$

Except for above three conditions, SPH kernel also should be an even function and need enough smooth. Otherwise, kernel function also can be written into the follow form,

$$W(x-x',h) = \alpha_d K(q),\ q = |x-x'|/h,\ d = 1,2,3 \tag{35}$$

Where, α_d is the dimension-dependent normalization constant for particular kernel functions.

Based on above conditions, one can construct any function as the kernel function in SPH algorithm, and M.B. Liu et. provide a systematic method to build kernels in [19]. However, specific kernel functions still have different performances for SPH instability and accuracy. Swegle et al. in [27] discussed the relation between SPH instability and kernel functions. They not only firstly proposed the concept of “tensile instability”, but also gives a conclusion about a sufficient condition for the unstable growth in SPH algorithm,

$$W''T > 0 \tag{36}$$

Where, W'' is the second derivative of the kernel W and determined by the slope of W'. T is stress state, which is negative in compression and positive in tension. According to this theory, some articles proposed new types of kernels for specific problems, for example Yang X et. in [29] introduced that using a hyperbolic shaped kernel function which possesses non-negative second derivatives can remove the tensile instability in viscous liquid drop problems. A new kernel called double cosine kernel function was also proposed in [30] which has smoother second derivative to obtain a better accuracy for SPH with applications in free surface flows.

Dehnen W et. in [28] proved that Wendland function is more effective to remove SPH clumping instability especially when increasing the number of neighbour particles. Besides, the kernel Fourier transform was found to have a strong relevance with SPH instability and an explanation in terms of the SPH density estimator was provided. K. Szewc et. used Wendland function as SPH kernel to simulate the incompressive flows and acquired better results compared with using traditional kernel functions based B-spline series [34].

Index	Name of Kernel	Function (α_d is the dimension-dependent)
Type-1	Cubic spline [35]	$W(r,h)=\alpha^d\begin{cases}1-\frac{3}{2}q^2+\frac{3}{4}q^3 & q<1\\ (2-q)^3 & 1\ll q<2\\ 0 & q\gg 2\end{cases}$
Type-2	Gauss [35]	$W(r,h)=\alpha^d e^{-q^2}\quad 0<q\ll 3$
Type-3	Quintic [35]	$W(r,h)=\alpha^d\begin{cases}(3-q)^5-6(2-q)^5+15(1-q)^5 & q<1\\ (3-q)^5-6(2-q)^5 & 1\ll q<2\\ (3-q)^5 & 2\ll q\ll 3\\ 0 & 3<d\end{cases}$
Type-4	Wendland [28]	$W(r,h)=\alpha^d\begin{cases}(1-0.5q)^4(2q+1) & 1\ll q<2\\ 0 & 2\ll q\end{cases}$
Type-5	Double cosine [30]	$W(r,h)=\alpha^d\begin{cases}4\cos\left(\frac{\pi}{k}q\right)+\cos\left(\frac{2\pi}{k}q\right)+3 & 0\ll q\ll k\\ 0 & k<q\end{cases}$
Type-6	Hyperbolic shaped [29]	$W(r,h)=\alpha^d\begin{cases}q^3-6q+6 & 0\ll q<1\\ (2-q)^3 & 1\ll q<2\\ 0 & 2\ll q\end{cases}$

Table 3.1 : A list for six types of kernel functions in SPH algorithm

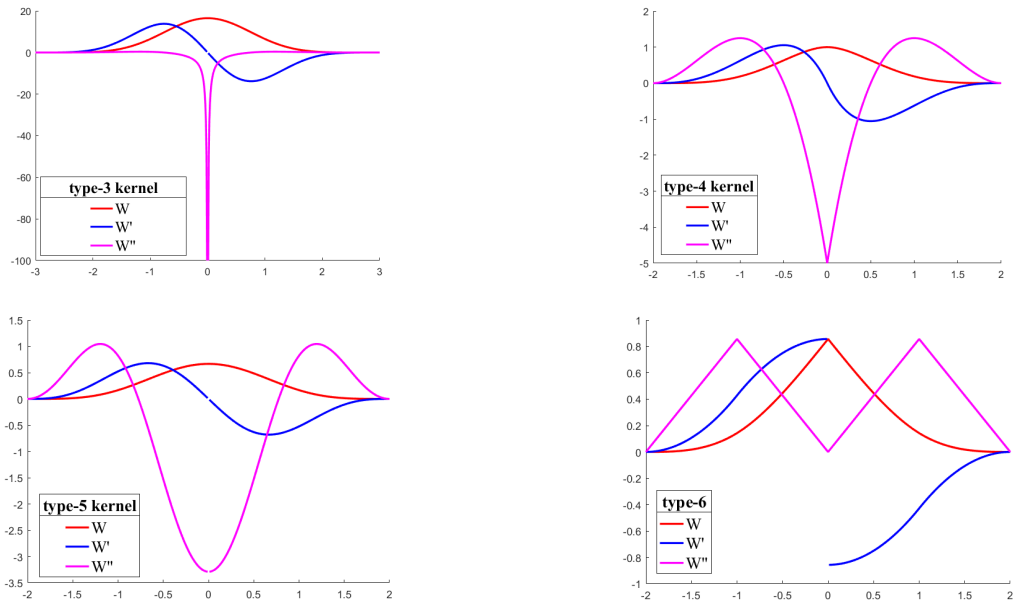

Figure 3.1 the curves of kernels in 1-D.

However, up to now, in the applications of SPH method simulating solid dynamics, the traditional kernels like the Gaussian function and B-spine functions are still mainly used. Table 3.1 lists six types of kernels including classic ones (type-1 to type-3) and some (type-4 to type-6) recently proposed for particular problems. Figure 3.1 shows four kernel curves including their

second derivatives. This paper aims to investigate the effect of these different kernel functions for dynamic problems with large deformations by the examples in next section.

4 EXAMPLES

This section shows two examples to investigate the different performances of different kernels listed in table 3.1. The first is the bending deformation of a cantilever beam with tip dynamic load simulated by CSPH method. It would demonstrate that different kernels have great influences on pairing instability and even unphysical cracks in elastic dynamics. The other is a 2-D Taylor rod impact problem which is considered frequently to investigate the performance of SPH in simulating material plastic behaviors.

4.1 Elastic bending beam

In this sample, the plane stress assumption is applied for the slender beam, therefore the physical three-dimensional solid problems can be degraded to two-dimensional problems. The geometrical dimensions of the beam structure are shown in figure 4.1, where the length $L=100\text{mm}$, the width $t=10\text{mm}$ and the beam thickness is fixed to 1mm. The left edge of the beam is fixed and the other edge is free and has a concentrated load given by acceleration a. The value of the load a is the quadratic function with time, starting from 0 to the maximum value a_{max} at time $T_1=1.5\text{ms}$ and after this time point keep the maximum load until the end of the simulation $T_{total}=3.0\text{ms}$. All the material parameters are shown in table 4.1 and the related parameters in CSPH are shown in table 4.2. The same tests are also studied by Liu Lin in his thesis [32].

Figure 4.1: the beam model and the left is fixed.

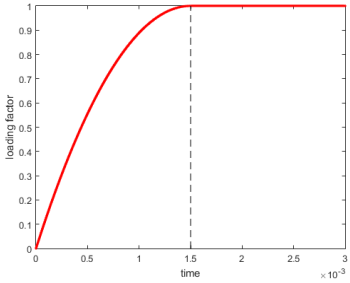

Figure 4.2: the dynamical loading.

Material	Young's modulus	Poisson's ratio	density	Sound speed
Steel	210 GPa	0.3	$7800\,\text{kg}/\text{m}^3$	5960 m/s

Table 4.1: material parameters.

Test	dx (mm)	Δt (s)	h	AV (α_Π, β_Π)	AS (ς)	XSPH $(\tilde{\varsigma})$
A	1	1.0e-7	$1.2\,dx$	0.1/0.1	0.5	0.5
B	1	1.0e-7	$1.4\,dx$	0.5/0.8	0.9	0.5

Table 4.2: the parameters in CSPH， AV is artificial viscosity and AS is artificial stress

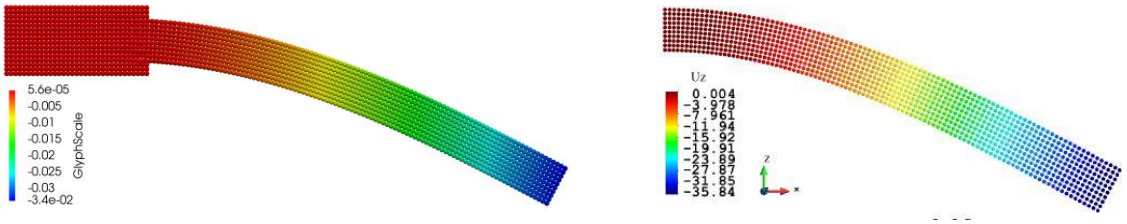
This example consists of two tests denoted "Test A" and "Test B" distinguished by maximum loading. In Test A, when the maximum loading force $F_{max}=1750\text{N}$, the beam deflec-

tion can be regarded as a linear change with load and can be estimated by the static solution reported by Timoshenko [33] with $W_{analytical} = FL^3/3EI + 6FL/5GA = 33.59\text{mm}$. The average errors e_{av} with different kernels are listed in table 4.3, ranging from 2.25% to 17.62%. This results demonstrate that the types of kernel have a large influence on SPH accuracy. Except for type-5 kernel, other several kernels all make the simulating accuracy lower that 10%. Figure 4.3 shows the distribution of beam deflection, in which the simulation (a) by our codes (CSPH with type-1 kernel) is very close to the one obtained by [32] using Total Lagrangian SPH in figure 4.3 (b).

Types of kernel	Type-1	Type-2	Type-3	Type-4	Type-5	Type-6
Errors (e_{av})	2.55%	8.11%	7.96%	9.58%	17.62%	8.86%

Table 4.3: Errors in test A and e_{av} is calculated by $e_{av} = \frac{1}{T}\sum_{t=1.5\text{ms}}^{t=3.0\text{ms}} \frac{|W_t - W_{analytical}|}{W_{analytical}}$,

T is the number of time steps from $t = 1.5\text{ms}$ to $t = 3.0\text{ms}$.



(a) (b)

Figure 4.3 the deflection distributions: (a) is simulated result by our code with type-1 kernel and (b) is simulated by Total Lagrangian SPH in [32]. the unity is mm in (b) and the unity is m in (a).

Test B gives a_{max} a larger value to make loading force $F_{max} = 17.5\text{kN}$ (the same loading process in figure 4.2), and in this case, the beam deflection W_c is non-linear related with loading force, and its analysical deflection is $W_{analysical} = 81.1\text{mm}$ according to Timoshenko [33] and Liu [32].

When the beam bends to nearly maximum deflection $W_{\max}$, different numerical instabilities happen when using different kernels as shown in figure 4.4. Obviously, when using the type-2 and type-3 kernel, the non-physical cracks emerge, which directly lead to wrong simulations. When applying type-5 kernel, the particles clump severely and cause the pairing instability in compressive part of the beam. The pairing instability also occurs in the case with type-1 kernel. Although the slightly tensile instability still exists in the fixed end of the beam with type-4 and type-6 kernel, it is not very severe especially using type-4 kernel and its average errors e_{av} is 4.89%. It is also observed that in figure 4.5, the simulation by SPH with type-4 kernel is in accordance with the results of both SPH code in [32] and FEM method in [32].

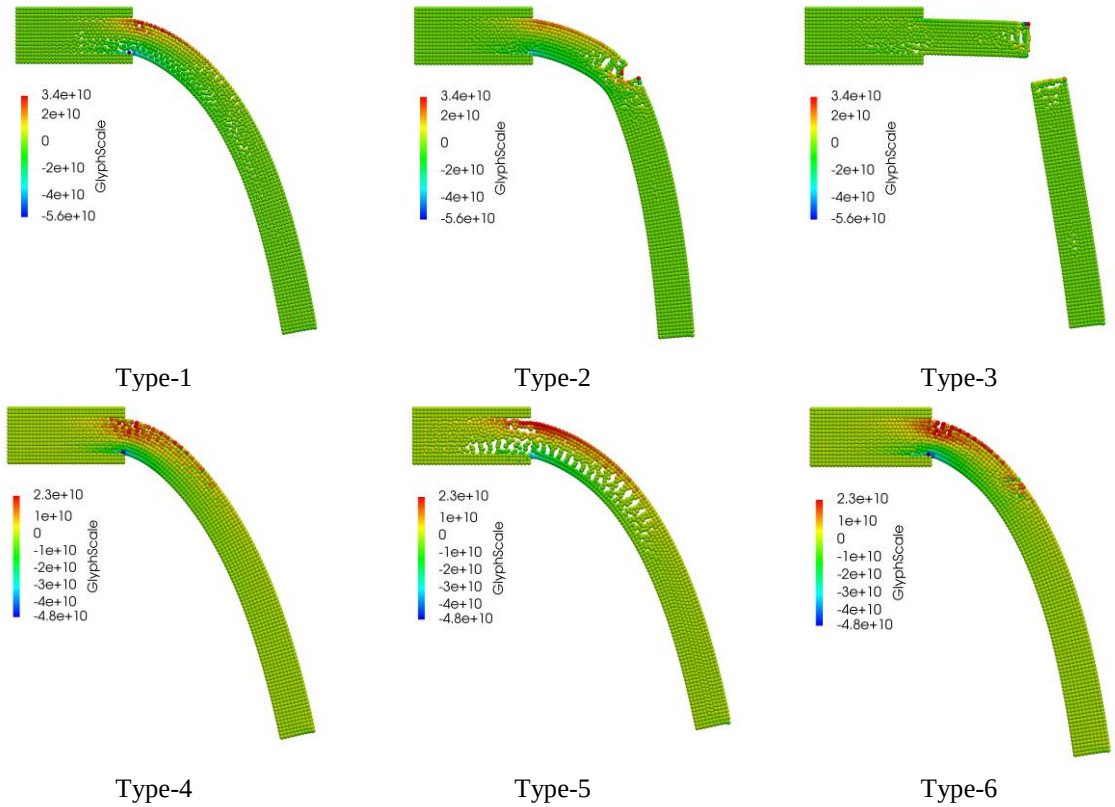


Figure 4.4: Distributions of σ_{xx} at the maximum deflection with 6 kernels.

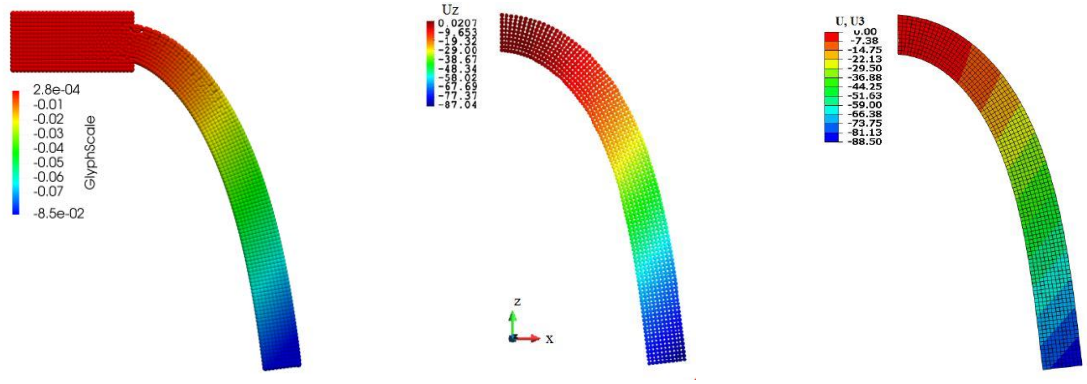

Figure 4.5 the distributions of deflections: (a) is simulated result by our code with type-4 kernel, (b) is simulated by Total Lagrangian SPH and (c) is FEM simulating in [32]. the unity is mm in both (b) and (c), the unity is m in (a).

Therefore, in this bending test, the conclusion is that types of kernel don't have much influences on clumping instability for small bending deflections but for large deflection problems they have obviously different performances. For the bending problem, the materials will experience both compression and stretch at the same time and both the tensile instability in large stress domain and paring instability in compressive domain are possible to occur. This test also shows that type-4 kernel has a more satisfied simulation compared with other kernels.

4.2 Plastic compressive

As a second test, a 2-D Taylor rod impact problem is simulated by standard SPH with artificial viscosity aiming to investigate the influences of different kernels. Figure 4.6 shows the 2D model of an iron rod which impacts a rigid surface. The values of all the parameters are set equal to those used by Libersky and Petschek [31]. The results can be compared with simulations conducted with the EPIC-2 code provided in [31]. For impact problem, Mie-Gruneisen EOS is used and its parameters are shown in table 4.4.

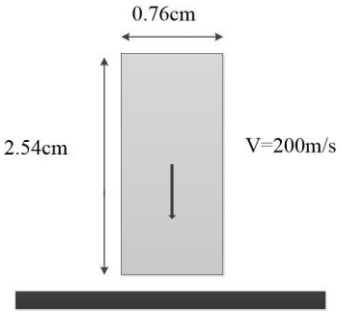

Figure 4.6: Model geometric of rob

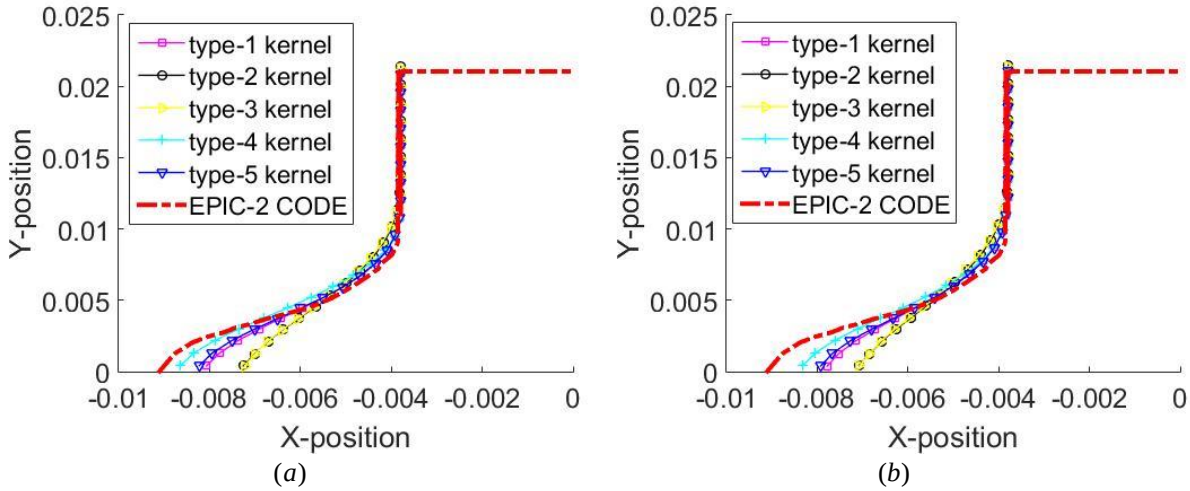
Parameter	Values
Young's modulus	208GPa
Shear modulus	80GPa
Yield stress	600MPa
C	3630m/s
S	1.80
Γ	1.80

Table 4.4: Parameters in rob impact

In this simulation, the rod is discretized by $25\times81=2025$ particles. The initial space dx of particles is 1.058mm and the smoothing length $h=1.5dx$. The computational time is 50μm from the beginning of the contact between the rod and the rigid surface.



(*a*) (*b*)

Figure 4.7: the shapes of rod at the impact end.
The artificial viscosity coefficient $(\alpha_{\Pi},\ \beta_{\Pi})$=(0.05, 0.05) in (*a*) and $(\alpha_{\Pi},\ \beta_{\Pi})$=(0.5, 0.5) in (*b*).

Figure 4.7 compares the rod shapes at the end impact at $50\mu m$ by SPH with different kernels, in which (*a*) and (*b*) used two different group coefficients in artificial viscosity. From these results, it is observed obviously that the simulation using kernel type-4 is the closest to the result provided by EPIC-2 code, which is taken as a reference [31]. The result obtained with the type-6 kernel is obviously wrong because of severe numerical instability, showing that type-6 kernel is not smooth enough to provide correct results. Figure 4.8 illustrates the

bad distribution of the equivalent strain of the structure using type-6 kernel. By contrast, Figure 4.9 presents a very smooth distribution of equivalent strain in 2-D rod using type-4 kernel , which is also in agreement with the physical phenomenon.

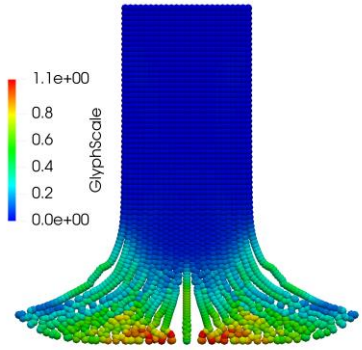


Figure 4.8: the distribution of equivalent strain with type-6 kernel

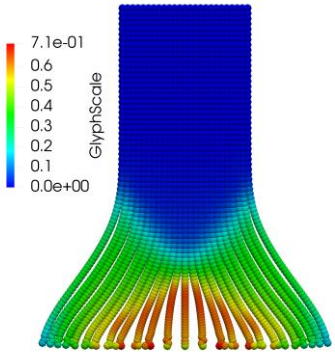

Figure 4.9: the distribution of equivalent strain with type-4 kernel

5 CONCLUSION

In this paper, the implementation of SPH method in dynamics is introduced and two examples including elastic and plastic dynamical deformations are tested to observe the influences of different types of kernels on instability of SPH simulations. The first example by a cantilever beam with tip dynamic load demonstrates that the different types of kernel directly affect the instability especially the tensile and pairing instability. The second test about rod impact with severe plastic deformations also shows that choosing the suitable kernels can improve effectively the accuracy of SPH simulations.

Kernel type-1 to type-3 are widely used in the scientific literature and they are also regarded as traditional kernels in SPH method. Type-4 to type-6 are proposed recently and applied in SPH in order to simulate different problems like flows or soils. But from our investigations, types-5 and type-6 do not have good performance in elastic-plastic problem. So, aiming to different fields, the kernel also has different suitability. Finally, the paper provides interesting step for the choice of a suitable kernel function to be used in SPH formulation for solid dynamic problems.

Abstract

This study presents a new reduction process where the proper orthogonal decomposition method is applied to the dual formulation of dynamic substructuring. Dual formulation is significant as it is effectively solving problems and solving ill-conditioned problems on parallel processing computers. Dual formulation uses the Lagrange multiplier method to couple substructures. In the proposed approach, substructures are reduced under constraint conditions with the Lagrange multiplier method. Each domain is divided into internal and interface parts, and the two parts are treated separately during the reduction process. The interface part is preserved without further reduction (i.e., the internal reduction method) or reduced to a different ratio from the internal part (i.e., the internal and interface reduction method). After the substructures are reduced, the Lagrange multipliers are applied to the preserved or reduced interface parts. Because the Boolean matrices that preserve the constraint conditions are not reduced but newly constructed, the stability and accuracy of the reduced system are guaranteed. The proposed methods are verified for a large-scale linear structure and a hyperelastic structure considering material and geometrical nonlinearities.

Keywords: Dynamic substructuring, Lagrange multiplier method, reduced-order model, Proper orthogonal decomposition (POD), Internal and interface reduction method (IIRM), Internal reduction method (IRM).

1 INTRODUCTION

Domain decomposition method has been studied to solve large-scale problems that cannot be solved by the limits of computational resources. Dynamic substructuring, a kind of domain decomposition technique, divides a dynamic system into several subdomains and shares only interface to solve the subpart level. Depending on how substructures are assembled, dynamic substructures are expressed in a primal or dual manner. Dual formulation of dynamic substructures employs Lagrange multipliers and Boolean matrices to impose constraint conditions on subdomain interfaces.

Large-scale model can be solved by domain decomposition, but there is still a problem that requires a lot of time to analyze especially the dynamic problems. So, the proper orthogonal decomposition (POD) method has been used to reduce the dynamic substructuring. Conventional methods of POD application to dual formulation of dynamic substructuring do not consider interfacial degrees of freedom or constraint conditions. In conventional approaches, the Lagrange multiplier method is first applied to substructures, and the coupled system is subsequently reduced. Reduction bases are constructed for each subdomain. However, this reduced order model (ROM) sometimes diverges. This is because the internal and interface parts are reduced as a single unit, and Boolean matrices that connect the interfaces are also reduced during the reduction process.

This study proposes reversal of the order of reduction processes. In the proposed method, the reduction bases of each domain is divided into internal and interface parts. Then, the two part can be handled separately in ROM. The interface part can be preserved without reduction or reduced to a different ratio than the internal part. After reducing the substructures, the Lagrange multipliers are applied to the preserved or reduced interface parts. This means that the Boolean matrices are not reduced but are newly constructed.

2 DUAL FORMULATION OF DYNAMIC SUBSTRUCTURING

There are two type of formulations in dynamic substructuring depending on how the set of interface degrees of freedom is defined. A primal formulation defines the interface degrees of freedom only once. On the other hand, a dual formulation presents the interface degrees of freedom multiple times, as many as the number of substructures connected to the interface. For example, if an interface with degrees of freedom is connected to n number of substructures, the total degrees of freedom are retained in the primal formulation, but the total degrees of freedom are increased by $n\times(m-1)$ in the dual formulation.

Another difference between the primal formulation and the dual formulation is that the primal formulation selects the displacements at the interface as unknown while the dual formulation selects the force at the interface as unknown. The dual formulation uses the Lagrange multiplier method for assembling structures. Boolean matrices giving compatibility conditions and Lagrange multiplier vectors corresponding unknown interface forces are included in the system matrix.

Dual formulation of dynamic substructuring is expressed in matrix notations as follows:

$$\begin{bmatrix} \mathbf{M} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} \end{bmatrix} \begin{bmatrix} \ddot{\mathbf{u}} \\ \boldsymbol{\lambda} \end{bmatrix} + \begin{bmatrix} \mathbf{K} & \mathbf{B}^{\mathrm{T}} \\ \mathbf{B} & \mathbf{0} \end{bmatrix} \begin{bmatrix} \mathbf{u} \\ \boldsymbol{\lambda} \end{bmatrix} = \begin{bmatrix} \mathbf{f} \\ \mathbf{0} \end{bmatrix} \tag{1}$$

where

$$\mathbf{M}=\begin{bmatrix}\mathbf{M}_1 & \mathbf{0} & \mathbf{0}\\ \mathbf{0} & \ddots & \mathbf{0}\\ \mathbf{0} & \mathbf{0} & \mathbf{M}_S\end{bmatrix},\quad \mathbf{K}=\begin{bmatrix}\mathbf{K}_1 & \mathbf{0} & \mathbf{0}\\ \mathbf{0} & \ddots & \mathbf{0}\\ \mathbf{0} & \mathbf{0} & \mathbf{K}_S\end{bmatrix}$$

$$\mathbf{u}=\begin{bmatrix}\mathbf{u}_1\\ \vdots\\ \mathbf{u}_S\end{bmatrix},\quad \ddot{\mathbf{u}}=\begin{bmatrix}\ddot{\mathbf{u}}_1\\ \vdots\\ \ddot{\mathbf{u}}_S\end{bmatrix},\quad \mathbf{f}=\begin{bmatrix}\mathbf{f}_1\\ \vdots\\ \mathbf{f}_S\end{bmatrix}$$

B is a signed Boolean matrix operating on the interface degrees of freedom. Let $u^{(a)}$ and $u^{(b)}$ refer to the same interface degrees of freedom, but belong to different substructure. This expression states any coupled interface degrees of freedom $u^{(a)}$ and $u^{(b)}$ must have the same displacement, i.e., $u^{(a)}-u^{(b)}=0$.

3 PROPER ORTHOGONAL DECOMPOSITION-BASED REDUCTION OF DYNAMIC SUBSTRUCTURING

While the modal reduction method obtains the reduction mode from the system matrix, Proper orthogonal decomposition (POD) method extracts the reduction mode by singular value decomposition of response data. In dynamic systems, large singular values give major characteristics of the system, while small singular values correspond to small perturbations to the overall system dynamics. Transformation matrix is constructed by choosing r dominant proper orthogonal modes corresponding large singular values. Using the transformation matrix, the original coordinates $\mathbf{X}$ can be reduced to the generalized coordinates $\mathbf{X}^{\mathbf{R}}$.

$$\mathbf{X}\approx\mathbf{T}\mathbf{X}^{\mathrm{R}} \tag{2}$$

Where $\mathbf{X}\in\mathbb{R}^{n\times1}, \mathbf{X}^{\mathrm{R}}\in\mathbb{R}^{r\times1}$ and $\mathbf{T}\in\mathbb{R}^{n\times r}\left(n\gg r\right)$.

First, the conventional method that reduces the dynamic substructures using POD is explained in Section 3.1. Then, the proposed method that considering interface degrees of freedom is introduced in Section 3.2 and Section 3.3.

3.1 Conventional method : One-unit Reduction

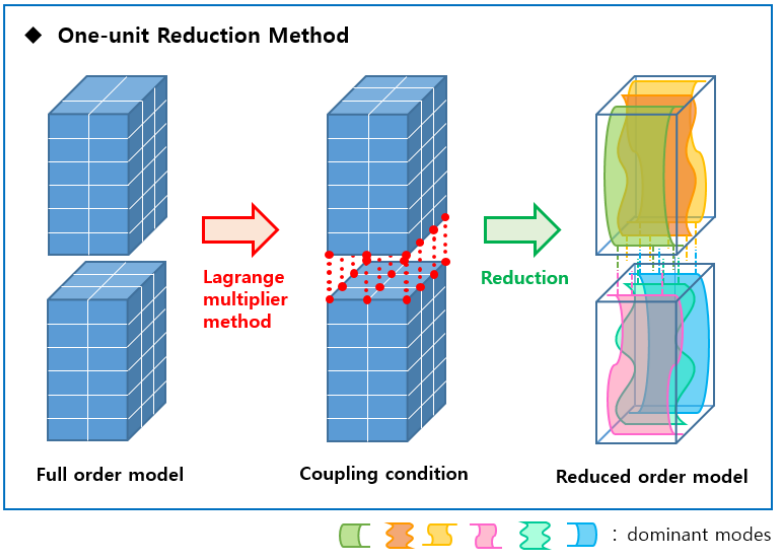

Figure 1: Conventional one-unit reduction method.

Figure.1 shows the conventional method to reduce the substructures in dual formulation. The two separated subdomains are first coupled by the Lagrange multiplier method and then reduced. Each subdomain is reduced by different modes. The interfaces and Boolean matrices for Lagrange multiplier method are also reduced by different modes, so the coupling condition cannot but be weakened.

3.2 Proposed method 1: Internal reduction

Internal reduction method reduces only internal degrees of freedom of substructures. In the subsystem equation, it is necessary to distinguish between the internal degrees of freedom and the interface degrees of freedom.

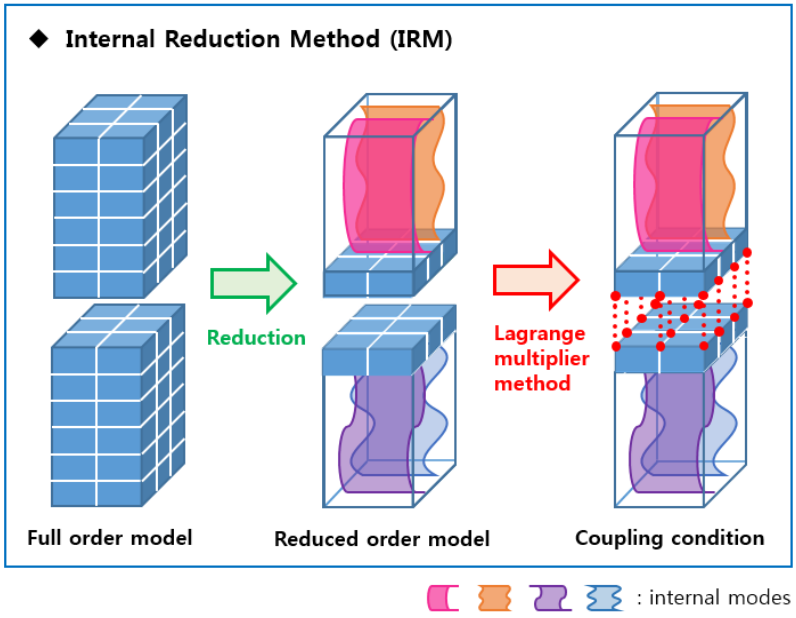

Figure 2: Proposed internal reduction method.

Figure. 2 shows the process of the proposed internal reduction method (IRM). In this method, only the internal part of each subdomain is reduced each different plane, and the Lagrange multiplier method is applied to the remaining interface part. In ROM, the coupling condition is highly robust and the interface responses can be considered well. However, since the interface degrees of freedom is not reduced, the overall calculation efficiency is lowered.

3.3 Proposed method 2: Internal and interface reduction

Internal & interface reduction method (IIRM) has been studied to overcome the limitation of internal reduction while maintaining constraint condition strong. IIRM also imposes constraint condition after reducing the subsystem. IIRM differs from IRM in that it reduces the interface degrees of freedom.

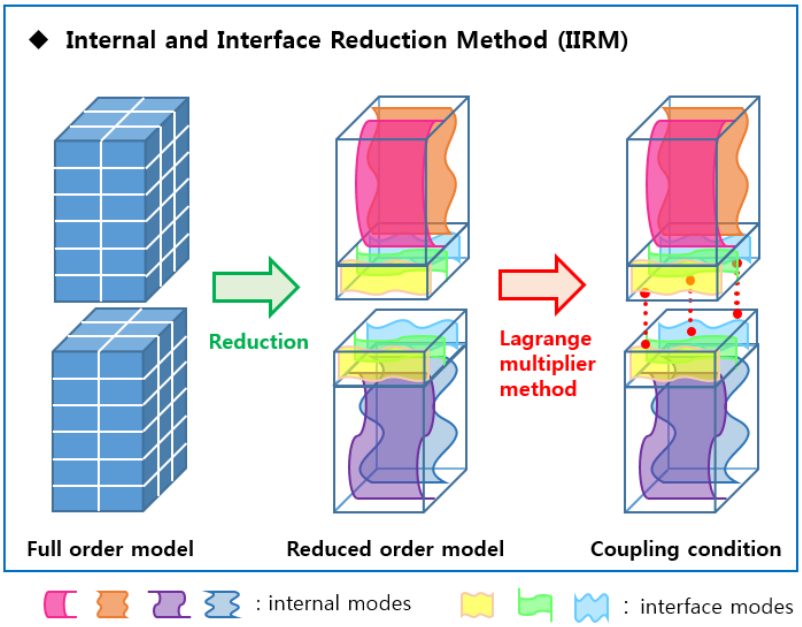

Figure 3: Proposed internal and interface reduction method.

Figure. 3 shows the process of the proposed IIRM. In this method, the internal part of each subdomain is reduced by different modes. Note that the interfaces of the subdomain are reduced by same dominant modes. By adjusting the reduction ratio differently from the internals, the interface degrees of freedom can be reduced in consideration of the interface response sufficiently. Coupling condition is imposed by applying the Lagrange multiplier method to the reduced interface. This method enables efficient computation while maintaining a strong constraint condition like internal reduction method.

4 NUMERICAL EXAMPLES

4.1 Wing model

A 3D wing model consisting of 6 substructures is dynamically analyzed with the three reduction methods in Fig. 4. The undivided wing model is a large scale structure with 72,438 degrees of freedom. The number of degrees of freedom corresponding to each subdomain listed in Table. 1. One interface consists of 678 degrees of freedom. Subdomain 1 and 6 have one interface while the other subdomains have two interface corresponding to 1356 degrees of freedom. As it is calculated in the dual formulation, the sum of the degrees of freedom of the subdomains is 678×5 more than the original degrees of freedom.

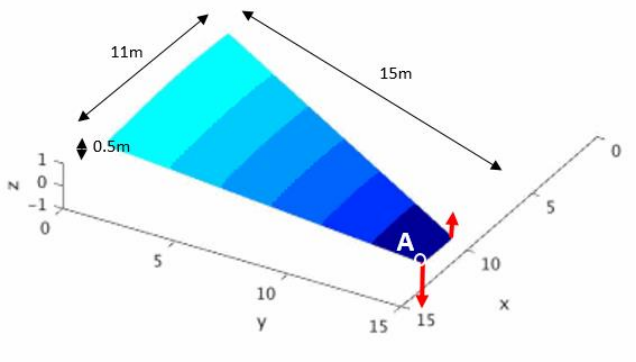

Figure 4: Wing model

The two concentrated forces are applied in opposite directions at different magnitudes, the wing model becomes not only up and down but also twisted. The thickness of the design variable is divided into 4 zones. With the thickness variation of both side skins and spars as 0.01/0.02/0.03/0.04 and of rips as 0.005/0.01/0.015/0.02, sampling analyses are performed 256 times. The sampling data set is subjected to singular value decomposition to construct the transformation matrix reducing full system matrix. The analysis results of ROM are compared to that of FOM with the randomly selected thickness.

(i : internal / b : interface)

Subdomain	1		2		3		4		5		6	
DOFs	14238		12318		12318		12318		12318		12318	
Internal/interface	i	b	i	b	i	b	i	b	i	b	i	b
DOFs	13560	678	10962	1356	10962	1356	10962	1356	10962	1356	11640	678

Table 1: Number of degrees of freedom corresponding to each subdomain

1) Conventional method : One-unit Reduction

Subdomain	1	2	3	4	5	6
POMs	400	500	500	500	500	400

2) Proposed method 1 : Internal Reduction

Subdomain	1		2		3		4		5		6	
POMs	978		1656		1656		1656		1656		978	
Internal/interface	i	b	i	b	i	b	i	b	i	b	i	b
POMs	300	678	300	1356	300	1356	300	1356	300	1356	300	678

3) Proposed method 2 : Internal & Interface Reduction

Subdomain	1		2		3		4		5		6	
POMs	400		500		500		500		500		400	
Internal/interface	i	b	i	b	i	b	i	b	i	b	i	b
POMs	300	100	300	200	300	200	300	200	300	200	300	100

Table 2: Number of used proper orthogonal modes corresponding to each subdomain

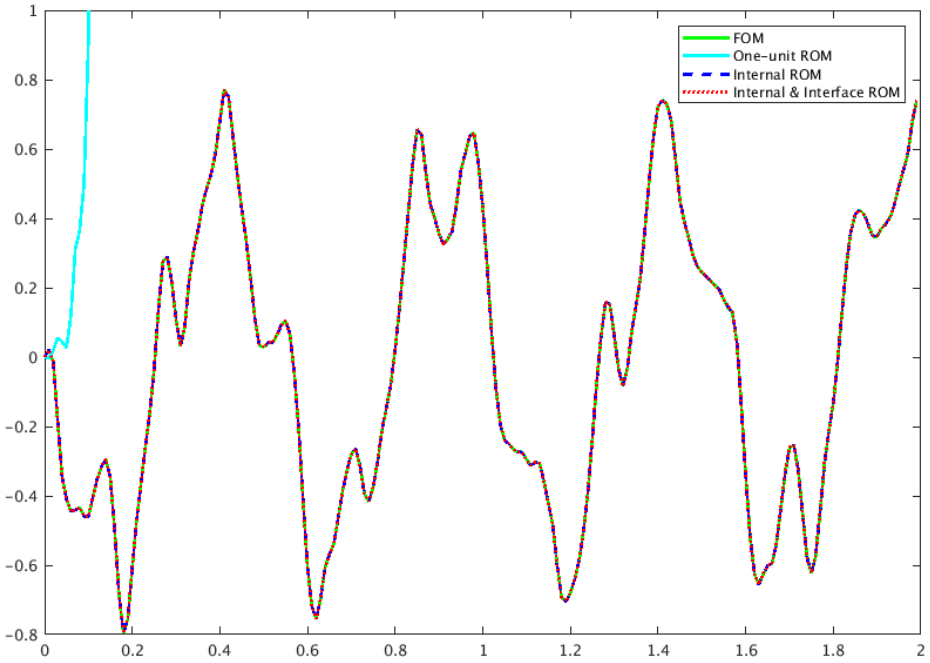

Figure 5: Z-direction displacement of point A

Figure. 5 shows that the analysis results of internal ROM and internal & interface ROM are accurate, whereas the analysis results of one-unit ROM are divergent. Even though the size of the internal & interface ROM is the same as the size of the one-unit ROM, it can be seen that IIROM is more stable than one-unit reduction method. In the case of IMR, there is a limit to reducing the ROM size as it does not reduce the interface.

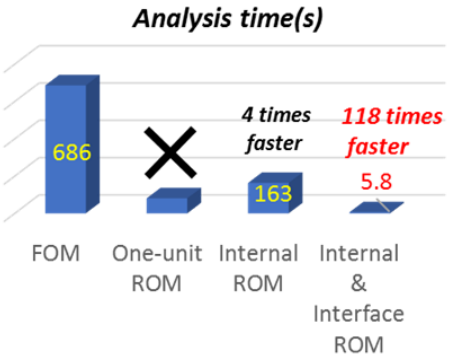

Figure 6: Analysis time

Figure. 6 shows the analysis time of full order model (FOM), one-unit ROM, internal ROM and internal & interface ROM. The time it takes to calculate the FOM is 11.4 minutes (686 seconds). It takes about 77 seconds to calculate the one-unit ROM, but it does not make sense because the result does not converge. The calculation time of the internal ROM and the internal & interface ROM takes about 163 seconds and about 5.8 seconds, respectively. Compared to the computing speed of FOM, it is 118 times faster to calculate the internal & interface ROM, while the internal ROM is 4 times faster.

4.2 Hyperelastic cubic with hole model

A hyperelastic cubic model with hole is dynamically analyzed with the two proposed reduction methods in Fig. 8. As this cubic model is Noe-Hookean model, the material nonlinearity and geometric nonlinearity are considered during the analysis. The undivided cubic model has 3,729 degrees of freedom. This model is divided two substructures which have 1,947 and 2,112 degrees of freedom. The interface consists of 380 degrees of freedom.

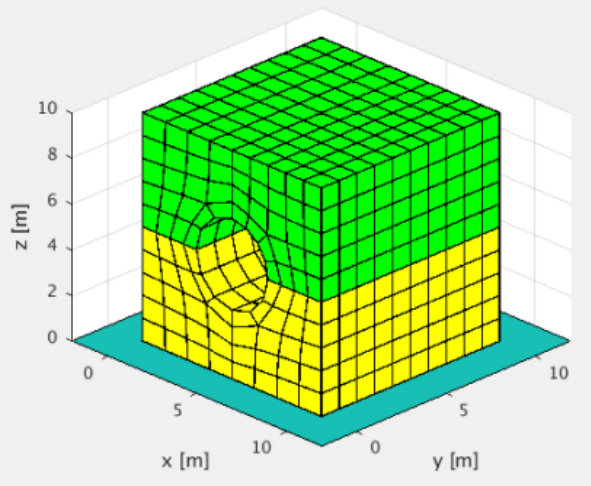

Figure 8: Hyperelastic cubic with hole model

Dynamic analysis is performed with the distributed load which pull up the cubic. Sampling analyzes were performed with the Neo-Hookean's material constants (λ, μ) set to values of (1e9, 5e8), (1e9, 1e9), (2e9, 5e8), and (2e9, 1e9) as design variables.

1) Proposed method 1 : IRM

Subdomain	1		2	
POMs	360		360	
Internal/interface	i	b	i	B
POMs /DOFs	30	330	30	330

2) Proposed method 2 : IIRM

Subdomain	1		2	
POMs	90		90	
Internal/interface	i	b	i	b
POMs	30	60	30	60

Table 3: Number of used proper orthogonal modes corresponding to each subdomain

This hyperelastic cubic model is reduced by IRM and IIRM as described in Table 3. ROMs of IRM and IIROM are computed in the error range of 1e-8. Comparing the results of two ROM, the size of the IIROM is one fourth of the size of the IROM, whereas the analysis time of the IIRM is almost the same as that of the IRM. IIRM took about 49.6 seconds to compute and about 50.6 seconds to IRM. This is because the time taken to construct the tangent stiffness during each iteration, which is a feature of the nonlinear analysis, is a large part. From this Neo-Hookean example, we can confirm that the two proposed reduction methods are convergent and robust in the nonlinear problem. However, in order to obtain the efficiency of the analysis time, the proposed method is not sufficient and it seems necessary to link it with other methods to reduce the time required to construct the system matrix.

5 CONCLUSIONS

This study suggests to impose the constraint conditions using the Lagrange multiplier method after reducing the dynamic substructures by POD method. This is the reversed order of general approaches. A substructure consists of the constrained interface part and the other internal part. By dividing the coordinate in the reduced system into internal part and interface part, the interface part can be fully preserved (proposed method 1) or reduced to a different ratio from the internal part (proposed method 2). Then, the Lagrange multiplier method can be directly applied the interface part of ROM. As Boolean matrices and the Lagrange multipliers are created for ROM without being reduced, the stability and accuracy of the analysis of the ROM is enhanced.

Abstract

These simulations deal with the application of LiABlock_3D, a rapid computational tool developed by the Authors [1], for limit analysis of masonry structures subjected to point live loads, seismic induced lateral loads and moving supports. The software was previously validated against several experimental tests available in the scientific literature mainly concerning small scale specimens of masonry walls subjected to lateral loads and settlement. The three-leaf masonry walls of the numerical contest will be represented as 3D assemblages of rigid blocks interacting at no-tension, frictional contact interfaces. LiABlock_3D will provide as outputs the computed collapse load and the plot of the corresponding failure mechanism.

Keywords: Micro-modeling approach; rigid block limit analysis; blind-test numerical prediction; collapse mechanism analysis.

1 INTRODUCTION

The seismic assessment of masonry structures has been receiving much attention in literature [2-5]. How to model the stone assemblage is a still open challenge. Several modeling approaches are available in literature in order to assess the seismic behavior of masonry structures [6]. Among these, simplified micro-modeling approach is one of the most used, thanks to the simplicity of the procedure compared to more complex approaches. According to this approach, the masonry brickwork is arranged as an assemblage of rigid blocks, considering a homogeneous material with no mechanical distinction between mortar and bricks. Failure gains through the contact interfaces.

In this framework, the paper is devoted to the application of "simplified micro-modeling" approach for the seismic-analysis of masonry structures. The proposed method starts with the generation of the geometrical model using simple CAD tools and continues with the analysis implemented in a novel software developed at the University of Naples "Federico II". The software, named LiABlock_3D, allows to analyze collections of polyhedral rigid blocks in contact via frictional surfaces, under the assumptions of infinite compressive strength and zero tensile strength. The formulation is part of the limit equilibrium analysis with the goal to predict the local and global failure modes of blocky structures. This kind of numerical formulation has the benefits of very quick calculation, without the need of a lot of input data. The high flexibility of the proposed formulation concerns also the loading conditions, where different loading axes and distributions can be assigned to the model. LiABlock_3D involves opening and sliding failure conditions under the assumptions of zero tension strength and frictional contact interfaces with infinite compressive strength.

In this study, LiaBlock_3D is applied to the blind-test prediction of experimental shake-table tests on a small-scale masonry walls in order to evaluate the software reliability in the prediction of seismic-induced collapse mechanisms.

The paper is organized as follows. Sections 2 deals with the micro-modeling approach and the numerical formulation for the rigid block limit analysis in LiABlock_3D. In Section 3 the application to two shake-table tests on three-leaf masonry walls is discussed in terms of failure modes and load factors promoting collapse.

2 MICRO-MODELING APPROACH AND NUMERICAL FORMULATION

2.1 Micro-modeling approach

The masonry structure performance under lateral seismic load can be assess according to three modeling approaches at least.

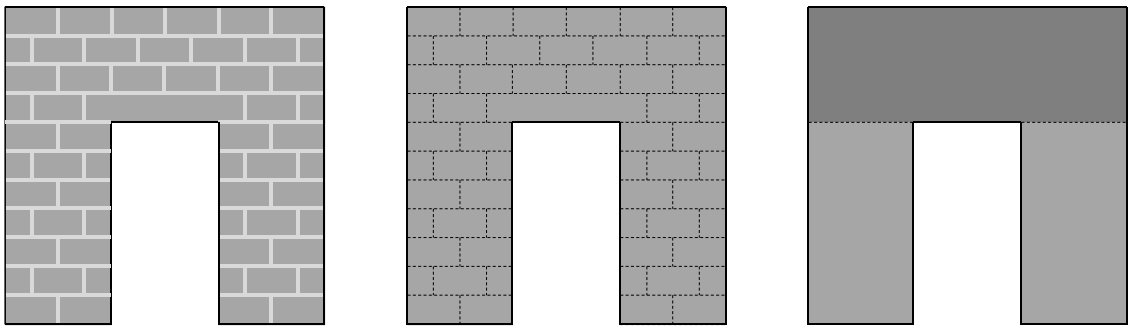

Figure 1: Modeling approaches for masonry structures: a) detailed micro-modeling; b) simplified micro-modeling; c) macro-modeling.

The most complex approach is a "detailed micro-model": this approach, particularly suitable for the finite element analysis, considers the separation between the mortar and bricks and requires two different constitutive laws. It is closer to the real masonry behavior but has the disadvantage of the slowness of calculation [7,8]. The "simplified micro-modeling" approach represents a good alternative where the mortar contribution is neglected, and the contact interfaces play an essential role in the failure modes definition. This approach perfectly commits to the rigid block model analysis [9]. Finally, the "macro-modeling" approach does not consider the real masonry texture but makes use of homogenization criteria for the material, considering average properties [10,11].

In this paper a simplified micro-modeling approach is used to create the geometry. According to the proposed approach the geometrical model is made of a collection of rigid block types generated in AutoCAD through the "Block Editor Menu". The block types are labeled with attributes which refer to the Cartesian coordinates of the vertexes of the block, its centroid and volume and the contact interfaces.

The full model is finally obtained by simply assembling the several block types in the CAD model space. The output of the modeling approach is represented by an Excel spreadsheet which contains the block type along the rows and the attributes in the columns. More details about the block generation and the output data extraction are provided in [1].

2.2 Numerical formulation implemented in LiABlock_3D

The modeling approach presented in the previous paragraph aims to the generation of a numerical model for the analysis in LiABlock_3D. This is a new tool, developed in MATLAB® environment, for the rigid block limit equilibrium analysis of masonry block assemblage. LiABlock_3D is equipped with a simple Graphical User Interface (GUI) where is possible to set the mechanical properties of the masonry and the loading and boundary conditions. A concave contact formulation is adopted to simulate the interaction between the blocks along the contact interfaces. In such a formulation, the internal forces are associated to the contact points located in the corner of the surfaces. These forces are the normal force n_k and the shear forces t_{1k} and t_{2k}.

LiABlock_3D solves an optimization linear programming problem based on the lower bound theorem of the limit analysis. The problem is described by the following formulation:

$$\begin{aligned} &max \quad \alpha \\ &s.t. \quad A \cdot x = f_D + \alpha \cdot f_L, \\ &\quad -n_k \le 0, \\ &\quad \sqrt{t_{1k}^2 + t_{2k}^2} - \mu \cdot n_k \le 0, \\ &\quad \mathrm{k} = 1, 2, ..., \mathrm{c}. \end{aligned} \tag{1}$$

Where c is the number of contacts. This formulation aims to calculate the maximum value of the load factor α subject to three constraints. The first equation constraint states the equilibrium condition: A is the contact equilibrium matrix, x is the vector of the static variables at contact point (t_{1k}, t_{2k} and n_k). The second member of the equation introduces the loading conditions since each rigid block is loaded by an external load f_i applied to its centroid and expressed as the sum of the dead load f_{Di} and of the live load f_{Li}, increased by the scalar multiplier α. The two inequalities constraints describe the failure conditions, involving both opening and sliding at contact points. The activation of a failure mode closely depends on the value of the friction coefficient μ.

LiABlock_3D returns the collapse mechanism and the value of the load factor promoting failure. The software contemplates both associative and non-associative flow plasticity rules. For the non-associative solution, the software implements an iterative procedure where the cohesion values for each iteration is calculated based on the normal forces of the previous iteration, starting from the value obtained in the associative solution. In order to achieve a comprehensive result, crushing and cracking failure condition should be considered [12].

3 APPLICATION TO EXPERIMENTAL CASE STUDIES

3.1 Test set-up

The case studies comprise two experimental shake-table tests developed at the University of Chieti-Pescara "Gabriele D'Annunzio" on two small-scale masonry walls. This study presents a blind-test prediction on three-leaf masonry walls made of two panels outside and an internal filling. The panels are 140 mm width and are made of stone blocks with dimensions 350 x 140 x 140 mm and mortar joints of 15 mm thickness. The internal filling is 170 mm width. The first case study is a simple wall and the second is a T-wall (Figure 4). The specimen is provided of a steel frame on the top for the application of a 6 tons additional mass. In the case of the T-wall, only in-plane load was contemplated (Figure 4b). Figure 4 shows the geometry and loading condition for the two case studies.

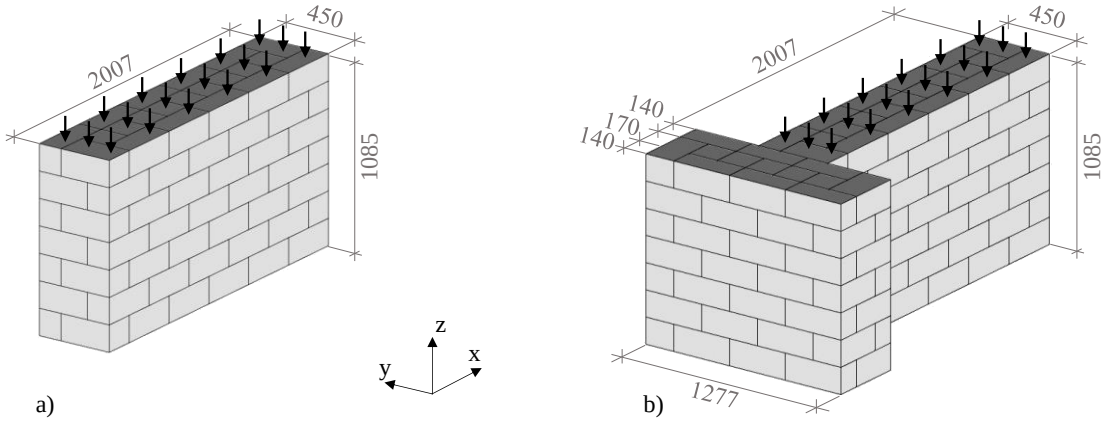

Figure 4: Experimental case studies geometry and loading condition: a) simple wall; b) T-wall.

Experimental campaign was carried on in order to obtain the mechanical properties of both mortar and stones. The shear tests return the value of the stone's properties involved in the sliding failure: the cohesion c, the friction coefficient μ and the sliding shear strength f_{vk0} was measured as 0.11 MPa, 0.21 and 0.091 MPa respectively. The Gazli earthquake record was selected as seismic input in the experimental tests. The Gazli earthquake dates to the 17th of May in 1976, with a magnitude equal to 6.8. Both horizontal and vertical acceleration component will be considered during the shake-table test.

3.2 Rigid block limit analysis using micro-modeling approach

The numerical models were generated through the proposed micro-modeling approach and then analyzed in LiABlock_3D. The block size follows the experimental data with a difference: seeing as how the formulation is not considering the mortar contribution, the brick size was increased in order to cover the mortar joints. Ad hoc blocks were generated to model the internal filling. The first case study (Figure 4a) is made of 150 rigid blocks (b) and 1812 contact points (c). The second case study (Figure 4b) is made of 241 rigid blocks and 2988 con-

tact points. With respect to mechanical parameters, the weight per unit volume was set equal to 24 kN/m^3 (average value for the selected stone type, *pietra di Pacentro*), the friction coefficient was set in the range between 0.4 (the value suggested by the Italian code [13]) and 0.6, and the cohesion was set equal to 0.00.

Both loading directions along the x-axis was analyzed in order to simulate the cyclic behavior of the seismic input considered in the experimental shake-table tests. Figure 5, Table 1 and Table 2 summarize the numerical outcomes obtained by LiABlock_3D software. Figure 5 shows the collapse mechanisms activated when a lateral live load is applied along the x-axis in both directions and a value of coefficient friction equal to 0.40 is used. The prevalent failure condition is the sliding at the contact points, except for the mechanism showed in figure 5b, where the model exhibits the overturning of the side wall. Table 1 and 2 contains the output of the analysis in LiaBlock_3D. The numerical analyses were carried out on a 3.50 GHz Intel Xeon Processor E5-1650 with 16.0 GB of RAM.

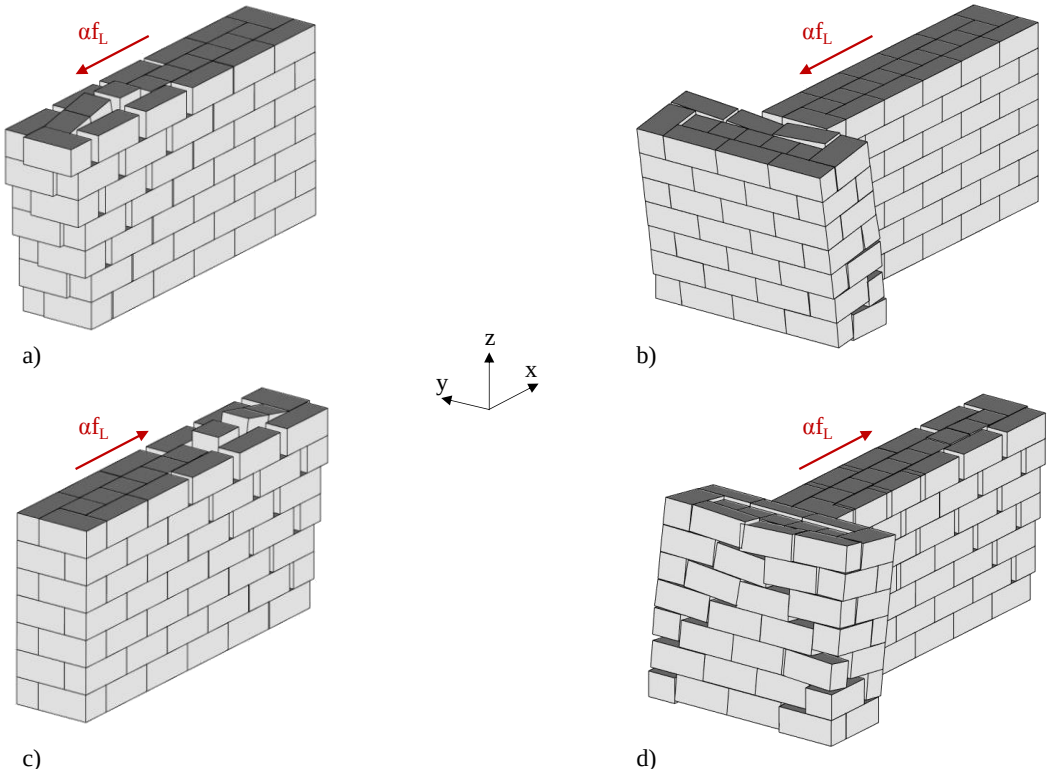

Figure 5: Collapse mechanism induced by live load applied along x-axis in both directions: (a)(c) simple wall; (b)(d) T-wall.

Model size (b x c)	ρ [kN/m^3]	c [N/mm^2]	Load directions	μ [-]	Numerical Solution		
					α [-]	αf$_L$ [N]	CPU Time [s]
150 x 1812	24	0.00	positive x-axis	0.40	0.38	31103.48	1.31
				0.50	0.45	37478.94	1.57
				0.60	0.56	46423.97	0.20
			negative x-axis	0.40	0.38	31068.96	1.36
				0.50	0.45	37478.94	1.58
				0.60	0.56	46423.97	0.30

Table 1: The case study of the simple wall: output by LiABlock_3D.

Model size (b x c)	ρ [kN/m^3]	c [N/mm^2]	Load directions	μ [-]	Numerical Solution		
					α [-]	αf_L [N]	CPU Time [s]
241 x 2988	24	0.00	positive x-axis	0.40	0.35	13522.47	2.83
				0.50	0.42	16405.84	2.76
				0.60	0.50	19229.06	1.92
			negative x-axis	0.40	0.27	10504.92	2.15
				0.50	0.29	11270.83	2.61
				0.60	0.31	12027.33	1.63

Table 2: The case study of the T-wall: output by LiABlock_3D.

Figure 6 shows the sensitivity analysis to the friction coefficient for both simple wall and T-wall specimens in terms of collapse load factor versus iteration number. As above mentioned, three values of friction coefficient were selected. Higher values of friction coefficient return higher value of the load factor and of the corresponding shear force at collapse.

The numerical analysis showed that the collapse could be expected for a load applied along both directions of the x-axis based on the shake-table shaking and the failure could occur with the overturning of the side wall along the negative direction or with the sliding in the opposite directions. The value of the acceleration promoting collapse in the experimental test should be derived by the value of the collapse load factor and the value of the behavior factor. Following the assessment method of force-based approach, the estimated peak ground acceleration (PGA) at collapse should be in the range between 0.8g and 1.0g, considering a behavior factor equal to 2.

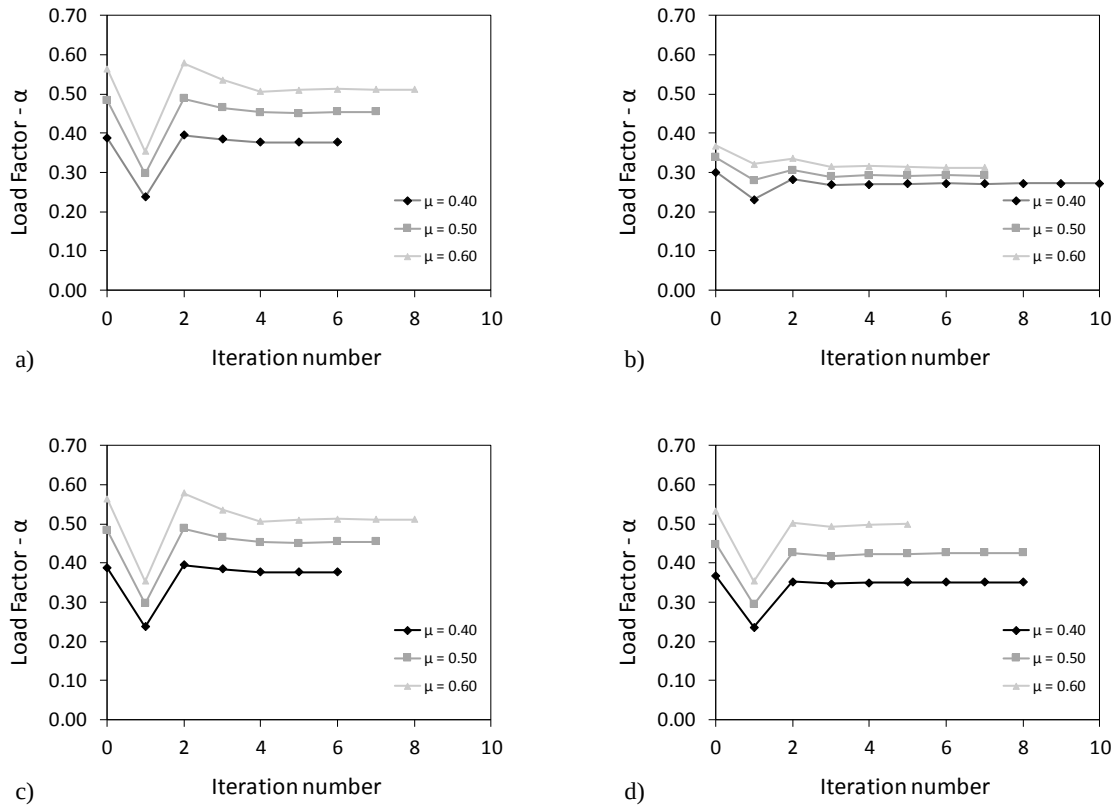

Figure 6: Collapse load factor vs iteration number for both simple wall (a)(c) and T-wall (b)(d) numerical simulation considering live loads applied along both negative (a)(b) and positive (c)(d) x-axis.

4 CONCLUSIONS

A procedure based on micro-modeling approach for the assessment of collapse mechanisms induced by seismic load was presented in this study. The approach is applied to the field of the blind-test numerical prediction. The numerical model is generated in AutoCAD model space, where each block is drawn and labeled with the attributes required for the numerical analysis. The software LiABlock_3D is used for the numerical analysis. It is a novel tool developed at the University of Naples "Federico II" based on the limit equilibrium analysis formulation and mathematical linear programming. LiABlock_3D can predict the local and global failure mechanisms and the value of the load factor for the mechanism activation considering different loading and boundary conditions.

Two blind shake-table tests on small-scale masonry walls represent the case studies with the goal of evaluating the ability of the proposed formulation in the failure mode prediction. The tests were designed by the University of Chieti-Pescara "Gabriele D'Annunzio".

The numerical simulations in LiABlock_3D tried to reproduce the shake-table loading condition. The software returned the failure modes and the load factor for the two case studies, proving the flexibility of the formulation and the high speed of calculation. The comparison between experimental and numerical outcomes is not yet available because the tests have not yet been carried out.

Keywords: geometrically exact beam theory, fiber elements, shear deformable beam , nonlinear programming, hybrid finite element

Abstract. *In the present work, a hybrid beam element based on exact kinematics is developed, accounting for arbitrarily large displacements and rotations, as well as shear deformable cross sections. At selected quadrature points, fiber discretization of the cross sections facilitates efficient computation of the stress resultants for any uniaxial material law. The numerical approximation is carried out through the lens of nonlinear programming, where the enengy functional of the system is treated as the objective function and the exact strain-displacement relations form the set of kinematic constraints. The only interpolated field is curvature, whereas the centerline axial and shear strains, along with the displacement measures at the element edges, are determined by enforcing compatibility through the use of any preferable constrained optimization algorithm. The solution satisfying the necessary optimality conditions is determined by the stationary point of the Lagrangian. A set of numerical examples demonstrates the accuracy and performance of the proposed element against analytical or approximate solutions available in the literature.*

1 INTRODUCTION

Problems frequently encountered by the engineering community over the last decades were concerned with structural systems whose response involved large displacements, rotations and strains on one hand, and inelastic behavior on the other. Such problems, in cases where the subject matter involved rod-like structures, necessitated the advancement of the classical Euler-Bernoulli theory, where displacements, rotations and strains were typically kept in the small range.

In the geometrically nonlinear case, the deformed geometry of the beam can be drastically different from the undeformed one, resulting in a rather involved description of beam kinematics. In general, there are two approaches in describing the kinematics of beams. The first one is the so-called continuum-based approach [1], which is employed for the derivation of the classical beam theory [2] and where all vectorial components are obtained from the three-dimensional theory of solids, with additional assumptions imposed on cross-section kinematics. The second approach, which is followed in this work, is concerned with the description of a material curve - an assemblage of material points representing the beam centroid - embedded in E^2 (or E^3 in the 3D case). The analysis of the curve by means of differential geometry of curves leads to the notion of intrinsic parameterization or one-dimensional formulation of beams, where spatial quantities can be expressed as functions of only one parameter. In the study of beams, this parameter is taken to be the arc-length of the beam. This in turn leads to the so-called arc-length parameterization of the beam with respect to a reference configuration. This approach was adopted in early works by Reissner [3, 4] and, next, Simo [5], Simo and Vu-Quoc [6] and can be traced back to Kirchhoff and his treatment of inextensible elastic rods. In these formulations, often termed as geometrically exact, the thickness of the rod is taken into consideration by attaching two vectors at each point on the material curve that would translate and rotate with the points, thus defining the properties of curvature and torsion at these points.

Approaches where strain measures are recast as primary field variables are often termed strain or deformation-based and were explored by Planinc et al. [7] for the planar case of the geometrically exact beam in order to properly account for the effect of local instabilites on the tangent stiffness matrix due to plastification, when global stability considerations are also present. It was later extended to the 2D dynamic case by Gams et al. [8] and to the three-dimensional case by Zupan and Saje [9] as a means to cope with the strain objectivity issue arising from the interpolation of the rotation vector [10]. Interpolation of strain measures is also encountered in mixed formulations, where more than one fields are interpolated and the underlying functional is augmented by additional terms to be satisfied in the weak sense [11]. Several other works with geometrically exact formulations in various settings can be found in the literature. Approaches based on mixed, hybrid, flexibility- and displacement-based considerations can be indicatively seen in [12, 13, 14, 15].

The present work is an extension of the geometrically exact hybrid formulation presented in [16] in order to account for the effect of shear deformation at the section level. As opposed to deriving the system equations from the Galerkin form after appropriate discretization, in the aforementioned work the problem is originally recast in a nonlinear programming framework, where the total potential energy functional (TPE) is augmented via Lagrange multipliers that enforce satisfaction of the exact kinematic conditions. The resulting functional is then approximated by employing a Gauss-Legendre quadrature rule, which yields the objective function to be minimized. Another interesting feature of this particular approach is that the primary variables in the element interior contributing to the elastic strain energy are the generalized

strain measures of the centroid, which are sought at quadrature points. Displacement measures, namely, the translations along the coordinate axes and the rotation of the cross sections, occur only at the nodes of the element and are associated with the external work. Kinematic consistency between the rotational measures of displacement and strain is enforced by using a Lagrange interpolation scheme to approximate the curvatures over the entire element domain. We should note that quadrature points coincide with the Lagrange interpolation points. In the remainder a succinct presentation of the formulation is presented, along with numerical investigations based on benchmark nonlinear problems studied in the literature, verifying the accuracy and efficiency of the suggested approach.

2 KINEMATICS AND TOTAL POTENTIAL ENERGY

We now proceed with the derivation of the kinematic equations that serve as constraints for the optimization problem. Let us consider two dimensional Euclidian space E^2 and a fixed Cartesian coordinate system $(X_1,\ X_2)$ with unit basis vectors $\{\mathbf{E_i}\}$, $i = 1,\ 2$ and a material curve of length L which represents the centroid of the beam embedded in that space. We will assume that the beam is initially straight, aligned with the coordinate axis X_1 and in an unstressed state. We also define the arc-length parameterization of the material curve $s \in I = [0,\ L] \rightarrow \mathbf{r} \in \mathbf{R}^2$, where s is the distance of a material point on the line of centroids in the reference configuration. The position vector of any material point on the centroid in any configuration can be written as:

$$\mathbf{r}(s) = (s + u(s))\mathbf{E}_1 + w(s)\mathbf{E}_2 \tag{1}$$

where u and w are the displacements of the material point along the coordinate axes X_1 and X_2 respectively.

Beam Kinematics

According to [3] the strain-displacement relations, assuming small axial strain of the beam centroid, are:

$$u' = (1+\epsilon)\cos\phi - \gamma\sin\phi - 1 \tag{2}$$

$$w' = (1+\epsilon)\sin\phi + \gamma\cos\phi \tag{3}$$

$$\phi' = \kappa \tag{4}$$

where $\epsilon,\ \gamma$ and κ are the axial, shear and bending strains of the line of centroids respectively, ϕ is the tangent angle to the material curve in the current configuration and derivatives with respect to the s are denoted by $(\,)'$. Integrating (2)-(4) over I yields:

$$\begin{aligned} u(L) - u(0) &= \int_0^L (1+\epsilon)\cos\phi - \gamma\sin\phi\, ds - L \\ w(L) - w(0) &= \int_0^L (1+\epsilon)\sin\phi + \gamma\cos\phi\, ds \\ \phi(L) - \phi(0) &= \int_0^L \kappa\, ds \end{aligned} \tag{5}$$

The integral form of the kinematic equations in (5) is utilized to impose the constraints on the nonlinear program.

Total Potential Energy

The total potential energy functional of the beam under a set of point loads $\mathbf{P} = [\,\mathbf{P}_1\ \mathbf{P}_2]^T$, with $\mathbf{P}_i$ the point loads at the element edge nodes, can be expressed in the reference configuration as:

$$\Pi(\epsilon,\ \gamma,\ \kappa,\ \mathbf{d}) = \int_0^L W(\epsilon,\ \gamma,\ \kappa)\ ds - \mathbf{P}^T\mathbf{d} \tag{6}$$

where W is the strain energy per unit length of the beam centroid. The displacement degrees of freedoms at the two edge nodes are collectively represented in vector $\mathbf{d}$ as:

$$\mathbf{d} = \begin{bmatrix} d_1 & d_2 & d_3 & d_4 & d_5 & d_6 \end{bmatrix}^T \tag{7}$$

with:

$$\begin{aligned} d_1 = u(0),\ d_2 = w(0),\ d_3 = \phi(0), \\ d_4 = u(L),\ d_5 = w(L),\ d_6 = \phi(L) \end{aligned}$$

The stress resultants on a section are associated with the strain energy as follows:

$$N = \frac{\partial W}{\partial \epsilon} \quad , \quad Q = \frac{\partial W}{\partial \gamma} \quad , \quad M = \frac{\partial W}{\partial \kappa} \tag{8}$$

The stress resultants defined in (8) can be numerically computed using appropriate fiber discretization at the cross section level. Thereby, any nonlinear constitutive law may be incorporated in beam element formulations to capture the effects of distributed elastoplastic behavior or damage [17, 18, 19].

3 NONLINEAR PROGRAMMING PROBLEM STATEMENT

In this section we formulate the equations pertaining to the description of our hybrid element as a nonlinear program.

Element Objective Function

The discrete form of the TPE in (6) is given by applying Gauss-Legendre quadrature to approximate the integral for one element:

$$f(\mathbf{x}) = \sum_{i=1}^{n} c_i W(\epsilon_i,\ \gamma_i,\ \kappa_i)\ - \mathbf{P}^T\mathbf{d} \tag{9}$$

where c_i are the weights of the quadrature, n the number of quadrature points and $\mathbf{x},\ \mathbf{d}$ and $\mathbf{y}_i$ are defined as:

$$\mathbf{x} = \begin{bmatrix} \mathbf{y}_1^T & \mathbf{y}_2^T & \dots & \mathbf{y}_n^T & \mathbf{d}^T \end{bmatrix}^T \tag{10}$$

with $\mathbf{y}_i = \begin{bmatrix} \epsilon_i & \gamma_i & \kappa_i \end{bmatrix}^T$

Element Constrains

The first set of constraints derived from the approximation of kinematic relations (5) is given as:

$$\mathbf{C}_{eq}^{A} = \begin{bmatrix} d_4 - d_1 - \sum_{i=1}^{n} c_i[(1+\epsilon_i)\cos\phi_i - \gamma_i \sin\phi_i] + L \\ d_5 - d_2 - \sum_{i=1}^{n} c_i[(1+\epsilon_i)\sin\phi_i + \gamma_i \cos\phi_i] \\ d_6 - d_3 - \sum_{i=1}^{n} c_i \kappa_i \end{bmatrix} = \mathbf{0} \tag{11}$$

In accordance with [16] we then interpolate the curvature field with Lagrange polynomials in order to obtain the rotations ϕ_i at the quadrature points:

$$\phi_i = d_3 + \sum_{j=1}^{n} \Theta_{ij} \kappa_j \tag{12}$$

$$\mathbf{\Theta} = L \begin{bmatrix} \xi_1 & \frac{\xi_1^2}{2} & \dots & \frac{\xi_1^n}{n} \\ \vdots & \vdots & \ddots & \vdots \\ \xi_n & \frac{\xi_n^2}{2} & \dots & \frac{\xi_n^n}{n} \end{bmatrix} \mathbf{G}^{-1}, \;\; \mathbf{G} = \begin{bmatrix} 1 & \xi_1 & \dots & \xi_1^{n-1} \\ \vdots & \vdots & \ddots & \vdots \\ 1 & \xi_n & \dots & \xi_n^{n-1} \end{bmatrix} \tag{13}$$

where $\xi = \frac{x}{L}$ and $\mathbf{G}$ is the Vandermonde matrix.

Notice that the first two equations of (11) are *nonlinear equality* constraints, while the third, along with the n equations of (12) are *linear equality* constraints. It is convenient to recast all constraints in one vector as follows:

$$\mathbf{C}_{eq} = \begin{bmatrix} \mathbf{C}_{eq}^{A} \\ \\ \mathbf{C}_{eq}^{B} \end{bmatrix} = \mathbf{0} \tag{14}$$

where

$$\mathbf{C}_{eq}^{B} = \begin{bmatrix} \phi_1 - d_3 - \sum_{j=1}^{n} \Theta_{1j} \kappa_j \\ \vdots \\ \phi_n - d_3 - \sum_{j=1}^{n} \Theta_{nj} \kappa_j \end{bmatrix} \tag{15}$$

Element Lagrangian Function

We now introduce a vector $\boldsymbol{\lambda}$ of the Lagrange multipliers and augment the TPE (6), constructing the Lagrangian of the optimization problem as:

$$f(\mathbf{x},\ \boldsymbol{\lambda}) = \sum_{i=1}^{n} c_i W(\epsilon_i,\ \gamma_i,\ \kappa_i)\ - \mathbf{P}^T \mathbf{d} + \boldsymbol{\lambda}^T \mathbf{C}_{eq} \tag{16}$$

Stationary points are provided by satisfying Karush-Kuhn-Tucker [20] optimality conditions for the Lagrangian function of (16).

4 NUMERICAL EXAMPLES

In the following examples we examine the performance of the proposed formulation and compare it with other well-known works in the literature. We first explore the accuracy when the shear stiffness is reduced and then we test against different loading cases. For each example, only one element with five quadrature points is used.

Table 1: Cantilever with constant transverse load at free end.

Problem data: $EA = 10^{21},\ EI = 10,\ L = 1$. Numerical data in [21], analytical in [22].

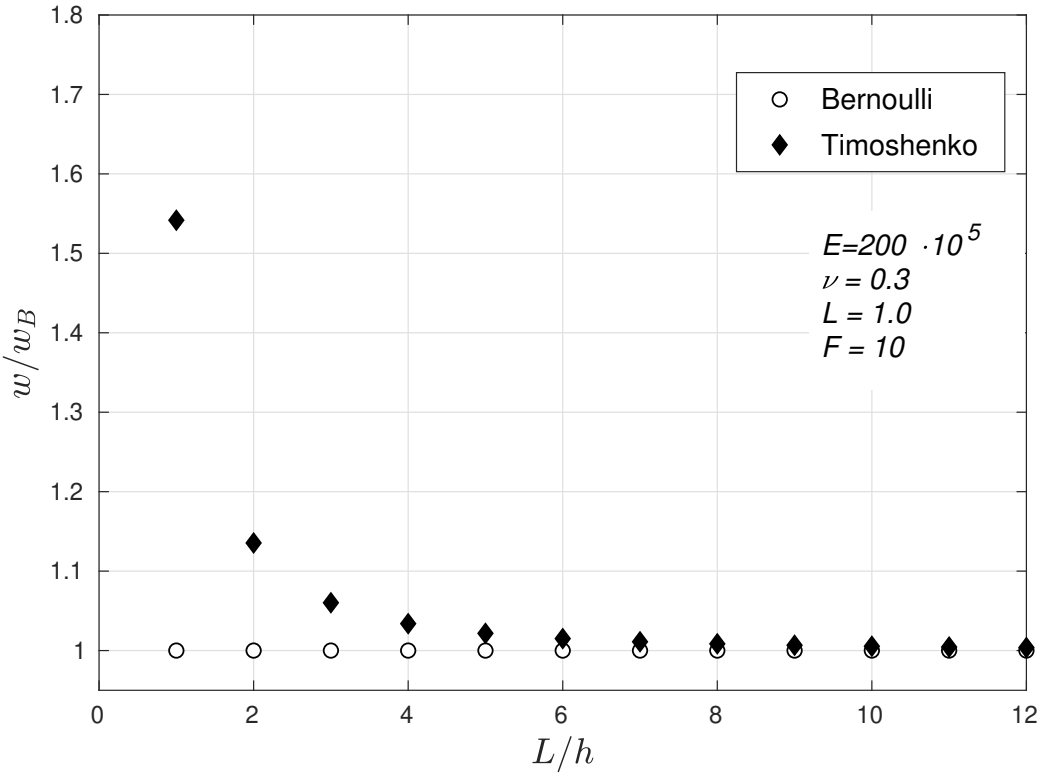

Figure 1: Timoshenko compared to Bernoulli solutions for different levels of slenderness.

Example 1 - Effect of shear deformation in cantilever deflection

In this example we explore the effect of shear flexibility on the tip deflection of a cantilever. A constant point transverse force $P = 10$ units is applied at the free end and, then, several analyses are performed by varying the shear stiffness coefficient, GA_s. Numerical and analytical results obtained by Batista in [21] and [22], respectively, are compared with the present formulation and are illustrated in Table 1.

Fig. 1 demonstrates the effect shear deformations have when not neglected, compared to the Bernoulli solutions, by varying the ratio L/h, with h being the height of the cross section and L the length of the beam. The applied load is F, ν is the Poisson's ratio and w_B is the deflection when shear flexibility is neglected. As can be seen from the results, when $L = 2h$, transverse

displacements due to shear deformation are increased by rougly 13%.

Example 2 - Cantilever with transverse point load at its tip

This problem has been analyzed in [23, 24], whereas Mattiasson [25] provided solutions by solving the elliptic integrals of the problem of large deflections of beams. Moreover, the problem was also examined in [26] using a co-rotational transformation for the Timoshenko beam, whereas Nanakorn [27] used 3 elements and a total tagrangian formulation.

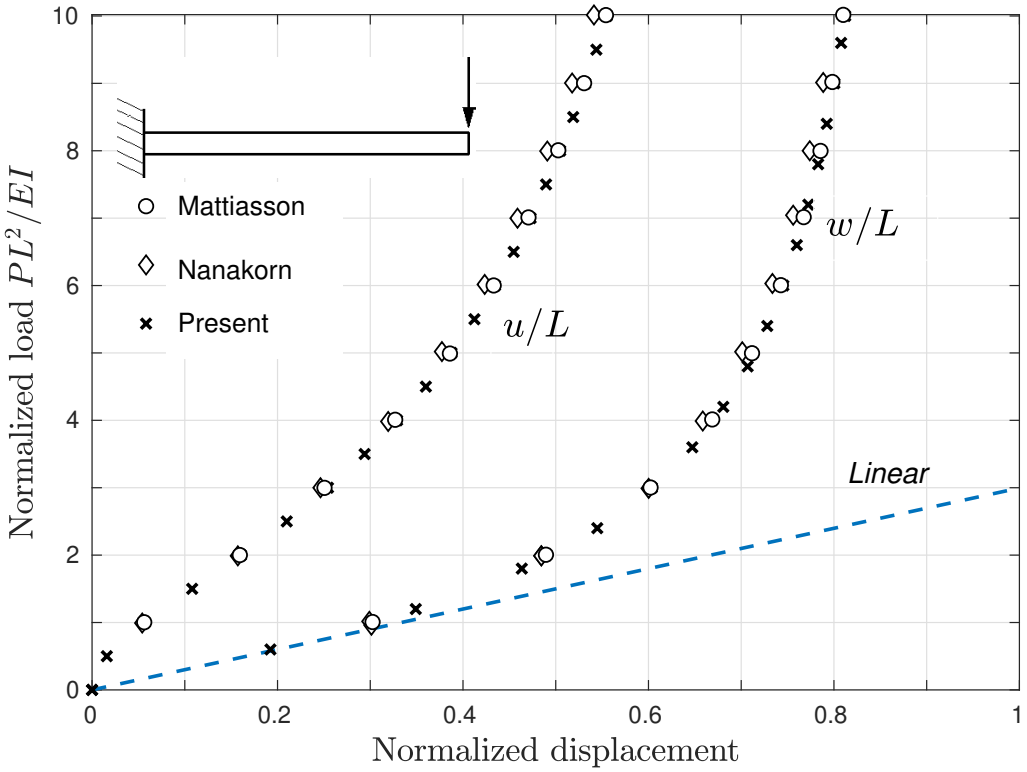

Figure 2: Cantilever with point transverse load at its free end.

Table 2: Cantilever with transverse load at its free end.

	w/L		u/L

10.0	0.81061	0.81073	0.55500	0.55498

Problem data: $EI = 1000$ lb/in^2, $L = 100$in, $P = 1$lb, $N = 20$ steps.
Results in Mattiasson [25].

Figure 2 illustrates the performance of the element when compared against the analytical and numerical solutions - mentioned above - and Table 2 demonstrates the accuracy up to six decimal points when compared to the analytical solutions for a sample of loading levels. The dotted line indicates the linear response.

Example 3 - Cantilever with point moment at its free end

This example tests the capabilities of our developed model capturing the response of an inextensional beam subjected to a point moment, forcing a curl into a complete circle. As mentioned previously, in all examples we only used one element with five quadrature points for our analysis. Bathe and Bolourchi [28] using five and twenty elements and an updated lagrangian procedure showed accuracy up to 90 degrees. In subsequent works, Simo & Vu-Quoc [6] (five elements), Rankin & Brogan [29] (ten elements) and Crisfield [30] (five elements) duplicated the exact solution. In the second and third works a corotational formulation was employed. The mechanical and geometric properties for this problem are $I = 0.01042\text{in}^4$, $L = 100\text{in}$, $A = 0.5\text{in}^2$, $E = 1.2 \times 10^4\text{psi}$.

In Fig. 3 our solution is compared with the one using twenty elements. As mentioned earlier, with the element proposed by Bathe & Bolourchi [28], which is based on large-displacement and large-rotation assumptions, the response starts to diverge from the exact solution at an angle of 90 degrees rotation, irrespectively of the mesh density. Our proposed formulation is instead able to capture the response for the whole loading scenario (360 degrees), as can be seen from the line that represents the normalized displacement $\phi/2\pi$.

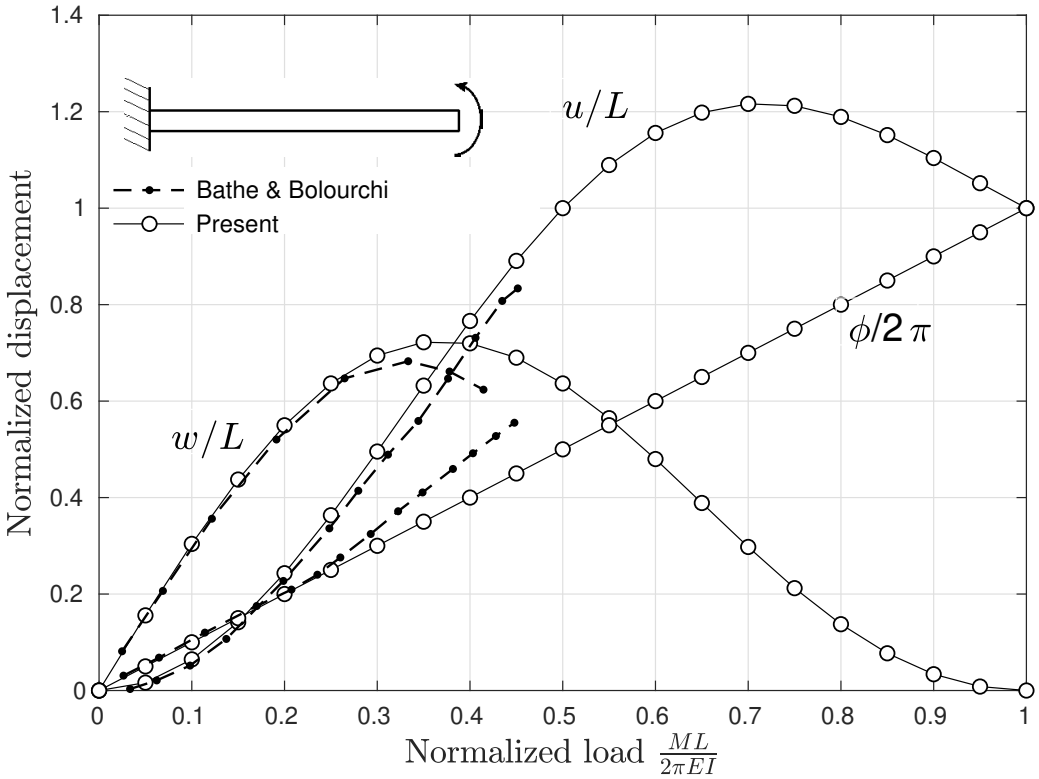

Figure 3: Cantilever with point moment at its free end.

Example 4 - Cantilever beam with eccentric compressive point load

We consider a cantilever beam of length $L = 100$, cross section thickness $b = 1$ and elastic modulus $E = 12$, with the load parameter $\lambda = P/P_{cr}$ is increased up to 4.0. The critical load for the cantilever is $P_{cr} = 0.25\pi^2 EI/L^2$. Wood & Zienkiewicz [31] used five continuum-based elements that allow for shear deformation and employed a total Lagrangian formulation. The results are illustrated in Fig. 4. Analytical solutions to the problem, provided in [23, 32] where it is assumed no axial or shear deformation occurs, show negligible discrepancy compared to the ones proposed here and in [31]. It should be noted that the eccentricity is $\epsilon = b/2$. The configurations for each load step for Examples 2,3 and 4 are depicted in Fig. 5, from left to right.

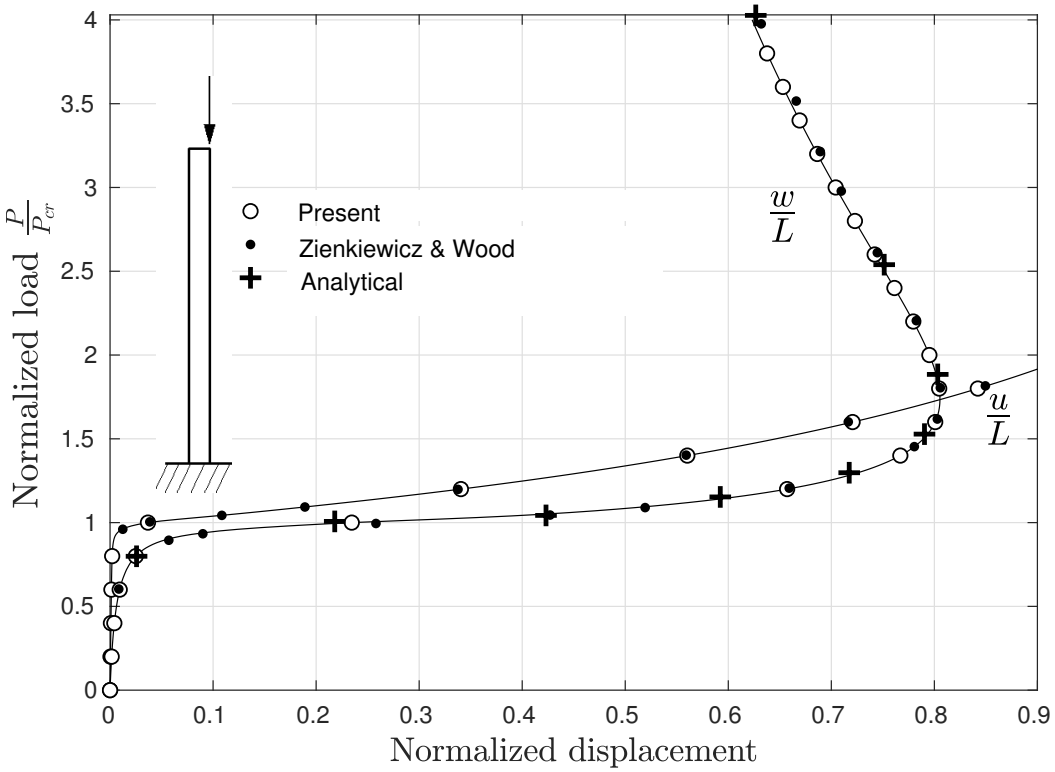

Figure 4: Cantilever with eccentric axial load at its free end.

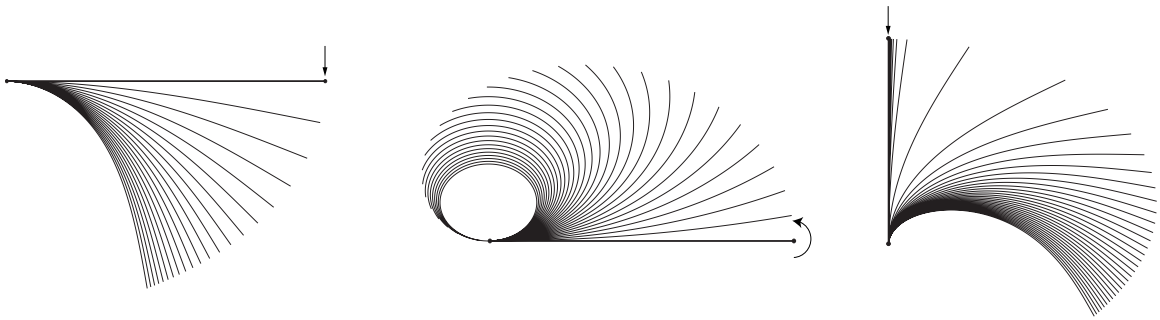

Figure 5: Configurations at each step for examples 2, 3 and 4 (left to right).

5 CONCLUSIONS

An extension to the geometrically exact hybrid element derived in [16] is presented herein that accounts for shear deformations. The system of equilibrium equations is originally derived within a nonlinear programming framework, where the total potential energy functional is discretized and then augmented by the exact kinematic constraints of the physical problem, also in discretized form, and solved by determining the stationary point of the Lagrangian. The suggested nonlinear programming hybrid formulation is capable of capturing the response of the benchmark problems with accuracy, using only one element, which is a desirable feature for framed structure applications. Ongoing work explores a variety of different approaches as far as the optimization algorithms are concerned, which is something the proposed formulation supports and enables, the extension of the material yield rule to account for the interaction of shear and axial stresses, as well as the extension to spatial and dynamic formulations.

Keywords: Rocking, Macro-element, Nonlinear analysis, Inelastic response, Resilient structures

Abstract. *In this paper, a macroelement for the prediction of the response of inelastic rocking bodies is proposed, which can be used in cyclic loading simulations. The ideas presented for the elastic rocking element formulation in previous works by the authors are extended here to the inelastic material case. Thus, apart from the deformability along the height of the body, the proposed macroelement also takes into account the inelastic deformations near the rocking interface, which is considered crucial for the accurate determination of the rocking response of deformable rocking bodies. Due to the partial loading of the rocking interface, nonlinear stress distributions develop across the rocking interface, which produce additional displacements to those predicted by the technical theory of bending. Taking these and the additional plastic displacements due to material nonlinearity into account, the correct stress distribution is determined based on the target displacements. The pushover curves derived with the proposed macroelement for characteristic problems are presented, while comparison is made against experimental results from the literature, showing satisfactory accuracy.*

1 INTRODUCTION

The complex mechanics of the motion of rocking bodies and structural members have attracted attention from the scientific community in recent years. The rocking motion occurs when a member is unrestrained or at least partially restrained at its base, so that tensile stresses cannot be transmitted, as considered in classical structural mechanics. Given that the imposed forces are large enough, the rocking body detaches from the ground and rotates about one of its corners. The vertical force acts as the restoring force that tends to bring the body back to its original equilibrium position.

Numerous studies have been presented regarding the analytical response of solitary rocking members or rocking members included in various configurations ([1], [2], [3], [4], [5], [6], [7], [8], among others). However, the base of the rocking body is assumed to be rigid in most of these studies, an assumption which does not hold for rocking members included in usual structural configurations, which experience large deformations.

Masonry and precast shear wall members, partially connected at their base, are also expected to rock during a strong seismic event. Analytical and experimental results, as well as design methodologies for such configurations have been presented by several authors ([9], [10], [11], [12], among others). The generalization of their application is difficult though, since such methodologies are usually based on several assumptions regarding the stress distributions and member deformations near the base and the interaction between rocking and deformability and, in many cases, the aforementioned elements of the proposed methodologies are calibrated using experimental or numerical results of specific examined configurations.

Few computational models have been proposed, which can be incorporated in a general finite element framework, in order to include rocking members in actual structural models ([13], [14], [15], [16], [17], [18], among others). The main drawback of such approaches is that either the interface between the rocking body and its base is considered rigid or that the deformability of the rocking body near the contact area is only approximately taken into account.

A macroelement formulation for elastic rocking members, addressing the previous remarks, has been proposed by the authors [19], which is able to take into account deformability both along the height of the members, as well as near the contact with the base. This macroelement is used for the ends of the rocking member, where nonlinear stress distributions are expected to develop (Fig. 1). The macroelement is based on the theory of elasticity, without making excess assumptions, and can be used to predict the static response of solitary rocking bodies, as well as rocking members included in structures (e.g. shear walls) in a consistent manner.

This formulation is extended in this paper in order to take material nonlinearity into account, since rocking members are expected to yield during strong seismic events. The monotonic case has been addressed in [20], but cyclic loading, which is examined herewith, is much more complex and needs a different treatment.

2 PROBLEM STATEMENT

The macroelement used for each rocking end of the column shown in Fig. 1 can be used in the context of any finite element framework. As described in [19], the use of a natural coordinate system of a simply supported beam, where the rigid body motion has been removed (Fig. 2b), is more convenient than the original local element configuration (Fig. 2a). The conversion between the two coordinate systems can be found e.g. in [19].

The material of the rocking body is assumed to be elastic-perfectly plastic with Young's modulus E, Poisson's ratio ν and yield stress σ_y, while the same modulus of elasticity is

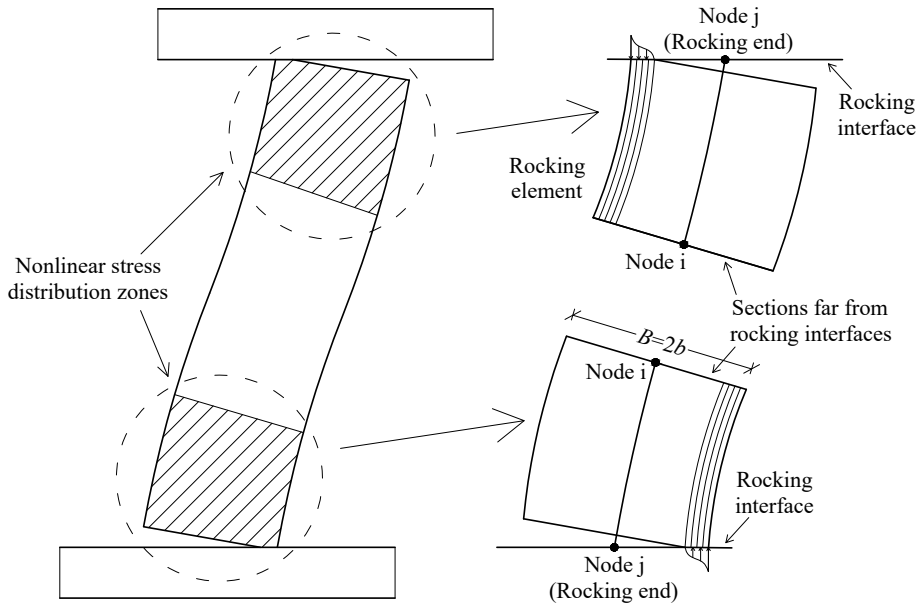

Figure 1: Use of the macroelement for the member segments near the rocking ends, where nonlinear stress distributions develop. Two rocking macroelements are used for the rocking column shown, one for each rocking end. Node j of each element refers to the corresponding rocking end. The fibers corresponding to the contact region of each element are shaded.

assumed during unloading. As usual practice in beam-column elements, material yielding is assumed only for the normal stresses, due to the increased difficulty of implementing another yielding criterion combining all stresses.

Due to the partial loading of the rocking interface, the stress distribution across this interface is nonlinear [21]. However, the technical theory of bending used in usual structural analyses cannot predict such response, meaning that this theory cannot be used for rocking members. As extensively described in [19], the following approach, based on the more general theory of elasticity, is used instead, which is considered an invaluable tool for the accurate prediction of deformable rocking bodies.

The displacements produced by the nonlinear stress distribution on the rocking interface can be examined by decomposing it into two distributions: (i) A stress distribution according to the technical theory of bending for the given rocking end resultant forces and (ii) Self-equilibrating distributions, which influence the local displacements but do not produce resultant forces and moments (Fig. 3).

The self-equilibrating stresses developing near the contact area have no resultant forces and moment, so according to the Saint-Venant principle their effect far from the contact area is negligible. This means that the displacement distribution across member sections far from the contact area is almost linear across the element, as predicted by the technical theory of bending (Fig 1). Furthermore, the additional displacements induced to the rocking body across the rocking interface by the self-equilibrating stresses can be calculated as those corresponding to a semi-infinite strip (Fig. 4), since this problem is much more easily solved. The semi-infinite strip examined is loaded with self-equilibrating normal and shear stresses across its end ($x = 0, -1 \leq y \leq 1$) and is stress-free at its sides ($y = \pm 1$). The results for the semi-infinite strip loaded with self-equilibrating normal and shear stresses can be easily translated into ones referring to the rocking body, as it will be shown in the ensuing.

Although the theory of elasticity used to solve the aforementioned semi-infinite strip problem

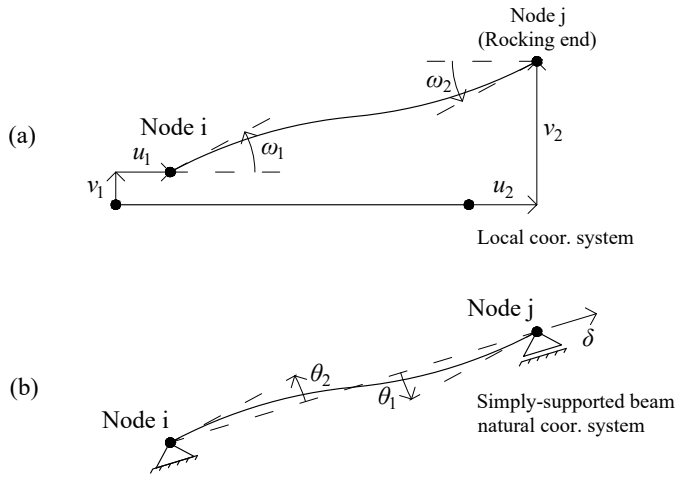

Figure 2: (a) Local member displacements, required by the general finite element framework and (b) Natural member displacements used by the element formulation

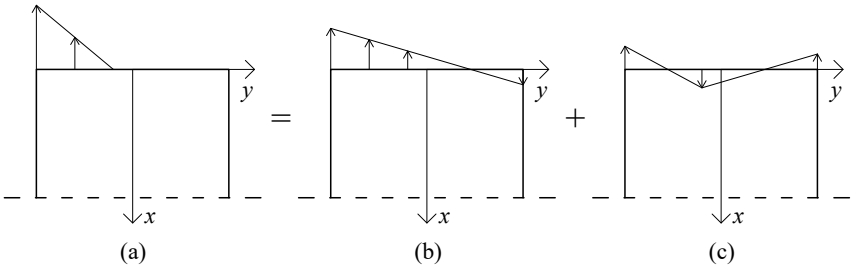

Figure 3: Decomposition of (a) the partial loading at the contact surface into (b) stresses according to the technical theory of bending and (c) self-equilibrating stresses

can only be rigorously applied to elastic bodies, it would be useful to use it appropriately also for inelastic ones. To this end, the following assumptions are made: (i) The inelastic behavior defined previously for the inelastic material is considered as is for the rocking interface. (ii) The stress distributions on the rocking interface produce elastic displacements, $[u_{\text{el}}]$, which are calculated according to the elastic theory of the semi-infinite strip. (iii) Fibers with inelastic behavior on the rocking interface are assumed to also develop plastic displacements, $[u_a]$, in addition to the aforementioned elastic ones, which are compressive ($u_a < 0$), while fibers that do not belong to the contact region develop gaps with the rocking interface, $[u_a]$, with $u_a > 0$ (Fig. 5).

Since the assumption of the linear strain distribution across the contact area cannot be applied

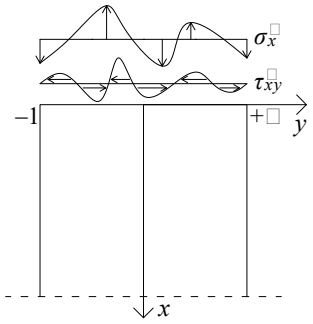

Figure 4: Semi-infinite strip

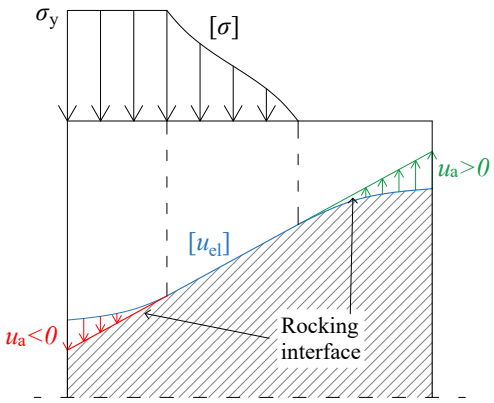

Figure 5: Normal stress distribution $[\sigma]$ acting on a rocking body. Elastic displacements due to this load, u_{el}, develop across the whole section (in blue), compressive additional displacements u_a develop across the yielded area (in red) and positive additional displacements u_a form between the rocking interface and the rocking body (in green). The shaded area corresponds to the deformed rocking body. Only deformations parallel to the loading are shown for clarity.

for cyclic loading due to arising inconsistencies between the plastic displacements and plastic strains, a different approach is presented in the following. For a given linear displacement distribution across the rocking end, $u_l(y)$, which corresponds to the planar rocking interface (Fig. 5), the real stress distribution at the rocking interface has to be determined, so that, for the produced elastic displacements, $u_{\text{el}}(y)$, the following conditions hold:

- $u_{\text{el}}(y) + u_{\text{pl}}(y) = u_l(y)$ for regions with $\sigma_y < \sigma(y) < 0$
- $u_{\text{el}}(y) + u_{\text{pl}}(y) \leq u_l(y)$ for regions with $\sigma(y) = 0$
- $u_{\text{el}}(y) + u_{\text{pl}}(y) \geq u_l(y)$ for regions with $\sigma(y) = \sigma_y$

where σ_y is the stress yield limit, $\sigma(y)$ is the normal stress at the fiber located at y and $u_{pl}(y)$ is the existing plastic displacement at this fiber, produced during previous cycles.

The additional displacements $u_a(y) = u_l(y) - u_{\text{el}}(y) - u_{\text{pl}}(y)$, needed in order the displacements match the given linear displacement distribution $[u_l]$, correspond to (i) the additional plastic elongations for the inelastic regions, where $u_a(y) < 0$, and (ii) the gap length between the body and the rocking base for the stress-free regions, where $u_a(y) > 0$ (Fig. 5). Therefore, for each fiber at location y, the unknown is either the normal stress, $\sigma(y)$ or the additional displacement, $u_a(y)$.

A number of control points, $\mathbf{Y}_w$, is chosen across the rocking interface, with normalized coordinates $-1 \leq y_w \leq 1$. Each of these points has an elastic stress, σ, or more conveniently an elastic strain, $\epsilon = \sigma/E$, and an additional displacement, u_a, normalized with respect to the semi-width of the member section, b. As previously described, these quantities are not independent of each other, since only one of them is unknown for each point y_w. Although quantities ϵ and u_a are not directly comparable with each other, a new dimensionless variable $w = \epsilon + u_a$ is introduced for algorithmic reasons, which is able to represent the whole allowable range of ϵ and u_a values at each fiber as follows:

$$\epsilon = \begin{cases} 0, \text{ if } w > 0 \\ w, \text{ if } \epsilon_y < w \leq 0 \\ \epsilon_y, \text{ if } w \leq \epsilon_y \end{cases} \tag{1}$$

and

$$u_a = \begin{cases} w, \text{ if } w > 0 \\ 0, \text{ if } \epsilon_y \leq w \leq 0 \\ w - \epsilon_y, \text{ if } w \leq \epsilon_y \end{cases} \tag{2}$$

where $\epsilon_y = \sigma_y / E$.

3 APPROXIMATE DETERMINATION OF REGION BOUNDARIES

By assigning a value of elastic strain, ϵ, or additional normalized displacement, u_a, at each control point across the rocking end, the corresponding strain and additional displacement distributions across the rocking end are created. However, by connecting the points of the aforementioned distribution with linear segments, regions are created that develop both elastic strains and additional displacements, which violates the assumptions taken into account, described above, unless specific points between the respective control points are chosen, corresponding to region boundaries with different behavior, where the additional displacements become zero and the elastic strains become either zero or equal to the yield strain.

This is why an approximate determination of the region boundaries is applied. Due to space reasons, the proof of the methodology is not given here, but can be found in [22]. The necessary region boundaries and correct strain and additional displacement distributions inside each interval are calculated as follows:

1. Calculate w' at the region boundaries:

$$w' = \begin{cases} w, \text{ if } w > 0 \\ w \dfrac{dy}{\pi}, \text{ if } \epsilon_y < w \leq 0 \\ w + \epsilon_y \left(\dfrac{dy}{\pi} - 1 \right), \text{ if } w \leq \epsilon_y \end{cases} \tag{3}$$

   where dy is the distance between the control points.

2. Draw the line connecting the aforementioned values.

3. Calculate the differences between all the linear segments of the plastic displacement distribution with the line connecting the plastic displacement values at the interval boundaries.

4. Add the opposite of the aforementioned deviant distribution to the line of step 2.

5. Determine the region boundaries from the points of the crossings of this curve with the horizontal lines corresponding to $w' = \epsilon'_y = \epsilon_y (dy/\pi)$ and $w' = 0$.

6. The regions between the aforementioned horizontal lines correspond to the correct modified strain or additional displacement distributions. The additional loads due to the nonlinearity of the strain distribution are calculated as the difference between the modified strain distribution, divided with (dy/π), from the line connecting the strain values at the interval boundaries.

4 CALCULATION OF DISPLACEMENTS

Convergence of the algorithm is achieved when the sum of the elastic, the additional and the plastic displacements equals the given target linear displacement distribution. This equality is checked explicitly only at the control points, $\mathbf{Y}_w$ and implicitly when region boundary points are formed between them, with the procedure described in the previous section.

Vector $\mathbf{U}_a$, calculated using Eq. (2), contains the additional displacements at the control points, while $\mathbf{U}_{pl}$ contains the plastic displacements induced at the control points from previous steps. The contribution of the elastic displacements induced by the loading is the most difficult to calculate and originates from three sources: The resultant forces at the rocking interface, the self-equilibrating normal stresses and the self-equilibrating shear stresses.

4.1 Displacements due to the resultant forces

Given the vectors $\mathbf{E}_s$ and $\mathbf{Y}_s$ of length n_s, containing the values of the elastic strain distribution at the respective coordinates, including those between the control points, the normalized axial force and the normalized moment at the rocking end are given by:

$$N_n = \frac{1}{2}\sum_{i=1}^{n_s-1}(y_{i+1}-y_i)(e_{i+1}-e_i) \tag{4}$$

$$M_n = \frac{1}{6}\sum_{i=1}^{n_s-1}(y_{i+1}-y_i)(2e_iy_i+e_iy_{i+1}+e_{i+1}y_i+2e_{i+1}y_{i+1}) \tag{5}$$

where e_i and y_i are the elements of vectors $\mathbf{E}_s$ and $\mathbf{Y}_s$ at entry i.

The displacement vector at the rocking end due to the resultant forces contribution, $\mathbf{u}_r = [\delta_r, \theta_{1r}]^T$, can be proven [22] that is given by the following equation:

$$\mathbf{u}_r = \begin{bmatrix} f_{r,11} & 0 \\ 0 & f_{r,22} - \dfrac{f_{r,23}\cdot f_{r,32}}{f_{r,33}} \end{bmatrix} \begin{Bmatrix} N_n \\ M_n \end{Bmatrix} + \begin{Bmatrix} 0 \\ \dfrac{f_{r,23}}{f_{r,33}}\theta_2 \end{Bmatrix} \tag{6}$$

where θ_2 is the given rotation at the end i of the element, $f_{r,11} = L/2$, $f_{r,22} = (3L)/(4b)$, $f_{r,23} = L^2/(4b^2) - a(1+\nu)$, $f_{r,32} = -(3L)/(4b)$ and $f_{r,33} = -L^2/(2b^2) - a(1+\nu)$.

4.2 Displacements due to the self-equilibrating shear stresses

If y_{cl} and y_{cr} are the boundaries of the compression zone, as determined by the approximate calculation of the region boundaries, since an equivalent parabolic shear stress distribution is considered between them, the maximum shear stress, normalized with respect to the modulus of elasticity, E, is:

$$t = \frac{3\,Q_n}{2\,(y_{cr}-y_{cl})} \tag{7}$$

where

$$Q_n = \frac{\theta_2 - f_{r,32}M_n}{f_{r,33}} \tag{8}$$

For given shear stress distribution boundaries, the displacements $\mathbf{u}_{tn} = [\delta_{tn}, \theta_{tn}]^T$ of the rocking end induced by a parabolic distribution with $t = 1$ can be calculated using the formulas

found in [22]. For the value of t calculated with Eq. (7), the respective vector containing the displacement parameters due to the self-equilibrating shear stresses is:

$$\mathbf{u}_t = t\ \mathbf{u}_{tn} \tag{9}$$

4.3 Displacements due to the self-equilibrating normal stresses

The contribution of the self-equilibrating normal stresses is the most cumbersome to calculate and is described in [22]. The procedure involves decomposing the normal stress distribution into triangular and trapezoidal normal loads. Afterwards, formulas for the calculation of the induced displacements due to these individual load shapes are employed, which result in a vector $\mathbf{U}_e$.

4.4 Target displacements

If $\mathbf{u}_n = [\delta, \theta_1, \theta_2]^T$ is the vector containing the element displacements in the natural coordinate system, namely the axial elongation, the chord rotation at the rocking end and the chord rotation at the other end, then a new vector $\mathbf{u}_{\text{tar}} = [\delta, \theta_1]^T$ is formed, which contains the two first elements of $\mathbf{u}_n$. These values describe the target linear displacement distribution of the rocking end, which must match the displacements produced by all the aforementioned contributions.

4.5 Combination of the control point displacements

The difference between the resultant and the target displacement vectors is finally defined as:

$$\mathbf{U}_d = \mathbf{U}_e + \mathbf{U}_a + \mathbf{U}_{pl} + \mathbf{C}\ \mathbf{u}_t + \mathbf{C}\ \mathbf{B}\ \mathbf{u}_r - \mathbf{C}\ \mathbf{B}\ \mathbf{u}_{\text{tar}} \tag{10}$$

with

$$\mathbf{C} = \begin{bmatrix} 1 & y_{w1} \\ 1 & y_{w2} \\ & \cdots \\ 1 & y_{w,n_w} \end{bmatrix} \tag{11}$$

and

$$\mathbf{B} = \begin{bmatrix} 1/b & 0 \\ 0 & 1 \end{bmatrix} \tag{12}$$

The algorithm converges if the norm of $\mathbf{U}_d$ is less than a convergence limit defined by the user. Usually, an iteration procedure is needed, in which a better estimation of $\mathbf{W}$ is derived in each step so that $\mathbf{U}_d$ fulfills the convergence criterion. After convergence is achieved, the forces and the respective stiffness matrix in the natural coordinate system are calculated as follows:

The produced forces in the natural coordinate system, $\mathbf{F}_n$, are calculated as:

$$\mathbf{F}_n = bdE \begin{bmatrix} 1 & 0 & 0 \\ 0 & b & 0 \\ 0 & -b & -L \end{bmatrix} \mathbf{F}_{nn} \tag{13}$$

where $\mathbf{F}_{nn} = [N_n, M_n, Q_n]^T$ is the vector containing the normalized rocking end forces.

The stiffness matrix in the natural coordinate system is derived as:

$$\mathbf{K}_n = \frac{D\mathbf{F}_n}{D\mathbf{u}_n} = \frac{\partial \mathbf{F}_n}{\partial \mathbf{u}_n} + \frac{\partial \mathbf{F}_n}{\partial \mathbf{W}} \frac{\partial \mathbf{W}}{\partial \mathbf{u}_n} \tag{14}$$

with

$$\frac{\partial \mathbf{W}}{\partial \mathbf{u}_n} = -\left(\frac{\partial \mathbf{U}_d}{\partial \mathbf{W}}\right)^{-1} \frac{\partial \mathbf{U}_d}{\partial \mathbf{u}_n} \tag{15}$$

5 EXAMPLES

5.1 Rocking body with constant vertical force

A free-standing rocking body with a constant vertical force on its top side (Fig. 6a) is examined first. The rocking body has height $H = 4$ m, width $B = 1$ m and thickness $d = 1$ m, modulus of elasticity $E = 30$ GPa and yield stress $\sigma_y = 20$ MPa and is loaded on its top with a vertical force $N = -2500$ kN. The whole body is modeled with one proposed macroelement with its rocking end at the bottom.

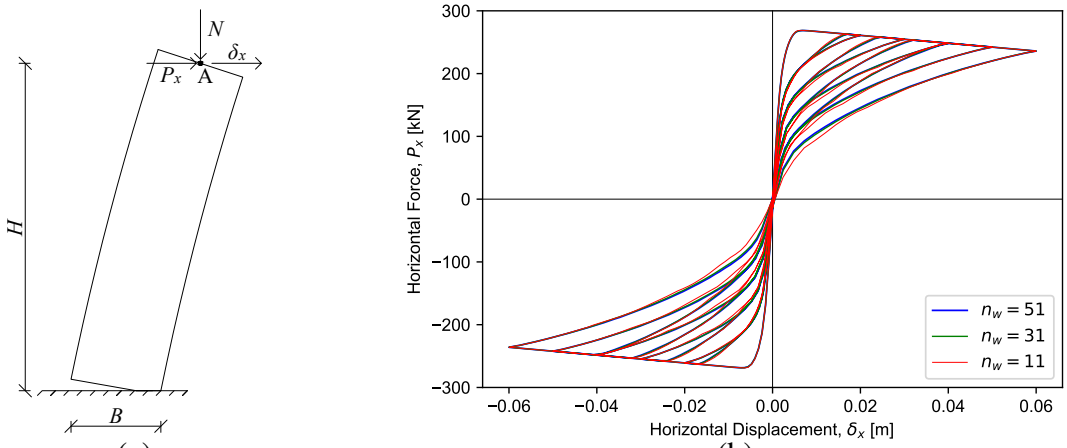

Figure 6: (a) Rocking body with constant vertical force model; (b) Rocking body with constant vertical force: Horizontal displacement versus applied horizontal force curves for various number of control points, n_w, used.

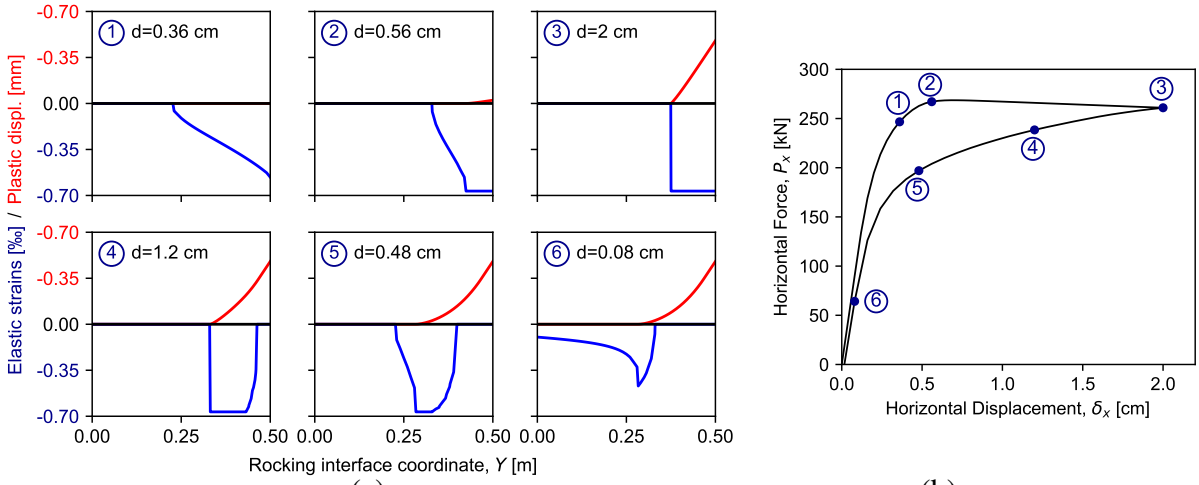
In Fig. 6b, the loading - unloading curves (applied horizontal force, P_x, versus horizontal displacement, δ_x) are shown for varying number of control points, n_w, used in the analysis. It can be seen that even the model with only 11 control points (red line) produces results that are very close to more dense control point configurations, meaning that the proposed algorithm can capture well the real deformation and stress distribution between control points.

In Fig. 7, the stress (blue curves) and plastic displacements (red curves) of the element at several steps during loading - unloading of the first half-cycle are presented. It can be seen that gradually the element yields, starting to develop plastic displacements, before reaching the maximum displacement of the quarter-cycle, where the stress distribution becomes almost rectangular.

It is interesting to note that the element continues to yield while returning to its original position, with the stresses gradually moving towards the center of the element, before becoming elastic again, i.e. the contact region does not decompress immediately during motion reversal. This means that the formation of plastic displacements does not stop at the maximum displacement, but continues during unloading at regions a little further from the base edge.

5.2 Restrained rocking concrete wall

A tendon restrained rocking concrete wall is discussed here and more specifically the model SRW_B examined in [23]. In brief, the rocking wall has height $H = 2.86$ m, width $B = 0.8$ m and thickness $d = 0.125$ m and is restrained with three prestressed tendons located at the center and about 0.2 m from the center. Regarding the material properties, concrete strength



(a) (b)

Figure 7: (a) Stresses (blue curves) and plastic displacements (red curves) developing on the rocking interface before the end of the first half-cycle, where yielding occurs. The right half of the element section is shown. (b) Corresponding points on the loading - unloading curve.

is f_c = 35.0 MPa, its modulus of elasticity is assumed $E_c = 4700\sqrt{f_c}$ = 27.8 GPa, while the tendons have stiffness EA_t = 28529.0 kN/m and initial prestress 96.1 kN, which is reduced to 89.1 kN due to prestress losses equal to 7.3%. As mentioned in the paper, the prestress is further reduced with respect to the expected value as the lateral displacement increases, approximately following the simplified analysis by [24]. For this reason, in the present analysis the tendon stiffness was calibrated so that the sum of the tendon forces at the maximum lateral displacement matches the one measured at the experiment (about 440 kN). Additional weight is added on top of the wall equal to 31.35 kN, while the self-weight of the wall equals 7.15 kN.

The loading - unloading curves produced by the macroelement model is shown in Fig. 8, while the red line shows the envelope of the experimental response at the last cycle [23]. It can be seen that the results obtained with the proposed algorithm match well the experimental backbone curve. Comparing the results with those in [23], a notable discrepancy between the results can be seen during unloading for large displacements, where the experimental curve does not pass close to (0,0) as in the numerical analysis and contrary to what one would expect for typical rocking systems. This can be attributed to several reasons according to [23], such as prestress loss, debris underneath the wall or damage near the wall toes.

Although the bilinear material model assumed for the macroelement cannot account for the precise material response, such as that of concrete, the main characteristics of the cyclic response can be adequately predicted. Thus, the proposed macroelement can be used for a quick and adequately accurate estimation of the response of structural systems with rocking members.

6 CONCLUSION

In this paper, a macroelement able to predict the rocking response of inelastic members under cyclic loading is formulated. The usual assumption of linear strain distributions according to the technical theory of bending does not hold, due to the nonlinearity created by the partial loading of the rocking interface. However, since the contact region of the rocking interface remains planar, the proposed formulation involves checking the displacements instead of the strains at the control points of the discretized rocking interface.

In the regions of the rocking interface that remain elastic, the aforementioned displacements

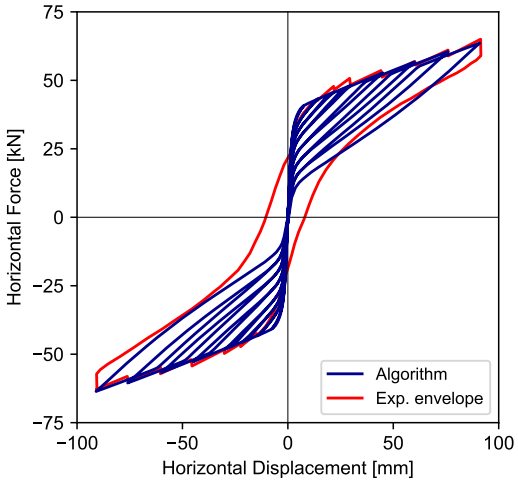


Figure 8: SRW_B response according to the proposed algorithm. The red line shows the envelope of the experimental response at the last cycle [23].

are caused by the contribution of the resultant forces, which is calculated according to the technical theory of bending, and the contribution of the self-equilibrating normal and shear stresses. Additionally, plastic displacements develop in inelastic regions, while the gap between the body and the rocking interface in non-contact regions is also taken into account.

The proposed macroelement formulation can be used to predict the response of rocking bodies included in structural configurations. The results show that the algorithm can predict the localization of the stress and plastic displacement distributions as the body rocks from one side to the other. In addition, comparison of the results produced for a typical rocking member configuration found in literature with the corresponding experimental data shows that the proposed algorithm can predict the cyclic response of yielding rocking bodies quite accurately, given the uncertainties of the experimental setups.

Keywords: Wind–Induced Vibration, Pseudo 3D Multi-Slice Algorithm, Partitioned Approach, Vortex Methods, Thin-walled Roof System.

Abstract. *The paper presents a partitioned extension of vortex particle methods (VPM) in the context of pseudo three-dimensional (3D) multi-slice model to simulate wind-induced vibration of thin structural elements like membrane roof system. The fluid dynamics is analysed by using a pseudo-3D VPM. The immersed boundary methods are used to simulate the complex flow around deformable boundaries. The structural analysis is carried out using the superposition of the linear uncoupled vibration modes because of its efficiency to handle small displacement problems. Finite element model is used to extract the natural vibration modes of the structure. The equation of motion is solved at the mid-surface of thin element. At each time step, the pressures on the surface panels on each slice are projected to the structural nodes. Once the structural analysis is performed for a time step, the new positions and velocity of the surface panels are calculated from the nodal structural solution to update the boundary conditions. For the validation of the coupled solver, it has been utilized here to identify the critical wind speed at which an inverted cantilever plate exhibits large amplitude flapping. In contrast to a conventional flag configuration, a flag with a free leading edge and clamped trailing edge, an inverted cantilever flag shows unstable large amplitude vibration in axial flow. The identified critical wind speed is found to be in very good range when compared with the literature. This mentioned benchmark case is analysed using the coupled solver considering different number of slices, and the identification of the critical wind speed is found satisfactory for all cases. The solver is used further to simulate a skewed inverted cantilever, which is modified over the reference system, in order to simulate the differential displacement along the slices since the vortex induced forces varies along the slices. Finally, the dynamic response of a cantilever roof system which is fixed at the base and hinged in two sides is analysed under different incoming wind speeds.*

1 INTRODUCTION

Fluid-structure interaction (FSI) problems are frequently encountered in many areas of civil, mechanical, aerospace and biomechanical engineering, such as the aeroelastic analysis of long-span bridges, tall buildings, and lightweight structures, the stability analysis of airplane wings, the flow-induced vibration of marine risers and floating platforms, the hemodynamics and blood vessel dynamics [1, 2, 3]. In recent years, the use of membrane and umbrella-type has gained increasing popularity [4]. They are extremely light-weight and the flexible nature makes them prone to destructive aeroelastic effects. The numerical methods to solve FSI problems can be classified as monolithic and partitioned. The monolithic method is the direct approach to solve the complete nonlinear algebraic equations, and hence, it is highly robust and unconditionally stable [5]. The partitioned approach, in contrast, offers software modularity and allows synthesizing independent computational schemes for fluid and structure subsystems. Moreover, the recent advancements and reduction in computational costs for modelling of both fluid and solid structures have made the partitioned schemes more popular for simulating FSI problems [6, 7]. The partitioned approaches can be classified into two types: the loose coupling approach and the strong coupling approach depending on the satisfaction of the coupling conditions. The Arbitrary Lagrangian Eulerian (ALE) approach and Immersed Boundary (IB) methods are two general approaches for simulating flow around deformable boundaries.

This paper presents a partitioned new extension of vortex particle methods (VPM) in the context of pseudo three-dimensional (3D) multi-slice numerical model to simulate FSI of thin structural elements such as the thin membrane type roofs. The partitioned methods are often used in FSI simulations for their flexibility of using different existing solvers for fluid and structure models. Here, the pseudo-3D vortex particle method (VPM) is used for analysing the fluid dynamics [8, 9, 10, 11, 12]. A two-dimensional (2D) fully coupled FSI model was presented in [13] for simulating non-linear aeroelastic instabilities. The presented method is a further extension in 3D. The difference between the existing and currently implemented pseudo-3D VPM is presented schematically in Fig. 1. The immersed boundary methods are used to simulate the complex flow around deformable boundaries. The structural analysis is carried out using the superposition of the linear uncoupled vibration modes because of its efficiency to handle small displacement problems of large system. A finite element solver is used to model and extract the natural vibration modes of the thin-walled structural systems. The equation of motion is formulated and solved at the mid-surface of the thin element. At each time step, the pressures on the surface panels on each slice are calculated in the flow solver. An in-house python code is developed to project the surface pressure to the structural nodes. The projected nodal forces from each slice are applied to the structural nodes in the global coordinate system. Once the structural analysis is performed for a time step using the Newmark-Beta method, the new positions of the surface panels are calculated from the nodal displacements. The panel velocities are calculated from the nodal velocities in order to update the velocity boundary conditions in the flow solver.

For the validation of the coupled solver, it has been utilized here to identify the critical wind speed at which an inverted cantilever plate exhibits large amplitude flapping [17, 18]. In contrast to a conventional flag configuration, a flag with a free leading edge and clamped trailing edge, an inverted cantilever flag shows unstable large amplitude vibration in axial flow. It has been observed as vortex-induced vibration (VIV) in literature. This mentioned benchmark case is analysed using the coupled solver considering different number of slices, and the identification of the critical wind speed is found satisfactory for all cases. The solver is used further to

Figure 1: Schematic representation of the difference between existing and new pseudo 3D VPM-based coupled solver: (a) existing pseudo 3D model analyses flexible line-like structures such as the long-span bridges. The structural dynamic calculations are performed by using the forces from 2D simulation slices with rigid cross sections. On the other hand, the newly extended VPM model (b) analyses thin-walled surface-type flexible element such as membrane roof systems considering the deformable geometry at the level of 2D simulation slices.

simulate a skewed inverted cantilever, which is modified over the reference system, in order to simulate the differential displacement along the slices since the vortex induces forces varies along the slices. Finally, the dynamic response of a cantilever roof system which is fixed at the base and hinged in two sides is analysed under different incoming wind speeds.

2 A PSEUDO-3D ALGORITHM FOR FLUID–STRUCTURE INTERACTION

2.1 Fluid solver

The flow solver uses simplified vorticity description of fundamental Navier–Stokes (NS) equations. For incompressible flow of a viscous fluid, the vorticity transport equation for 2D flow in a bounded domain $\mathcal{D}$ can be expressed as follows:

$$\frac{\partial \omega}{\partial t} + (\boldsymbol{u} \cdot \nabla)\,\omega = \nu \nabla^{\mathbf{2}} \omega. \tag{1}$$

where the vorticity $\boldsymbol{\omega}$ is the curl of velocity field $\boldsymbol{u}(\boldsymbol{x}, t)$ such that $\boldsymbol{\omega} = \nabla \times \boldsymbol{u}$, and ν is the kinematic viscosity. For inviscid flow Eq. (1) can be rewritten in substantial derivative notation such that $\mathrm{D}\omega/\mathrm{D}t = 0$. It allows the use of grid-less numerical scheme and discretization of particle elements in Lagrangian manner. The velocity field can be expressed in terms of stream function $\boldsymbol{\Psi}$ such that $\boldsymbol{u} = \nabla \times \boldsymbol{\Psi} + U_\infty$, and curl of it results in Poisson equation $\nabla^2 \boldsymbol{\Psi} = -\omega$. Greens functions are used to obtain the velocity distribution from vorticity field by solving the Poisson equation. By taking curl of $\boldsymbol{\Psi}$, the velocity field of a point in fluid domain $\mathcal{D}$ is computed using Biot-Savart relation

$$\boldsymbol{u}(\boldsymbol{x}_p) = \boldsymbol{U}_\infty - \frac{1}{2\pi} \int_{\mathcal{D}} \frac{\omega(\boldsymbol{x_0}) \times (\boldsymbol{x_0} - \boldsymbol{x_p})}{|\boldsymbol{x}_0 - \boldsymbol{x}_p|^2}\, \mathrm{d}\mathcal{D}_0. \tag{2}$$

The 2D vortex method is based on the discretization of the vorticity field by a finite sum of N_p Lagrangian particles located at $\boldsymbol{x}_p(t)$ as follows:

$$\omega(\boldsymbol{x}, t) = \sum_{p=1}^{N_p} \delta(\boldsymbol{x} - \boldsymbol{x}_p(t)) \Gamma_p, \tag{3}$$

where $\omega(\boldsymbol{x}, t)$ is the vorticity at position $\boldsymbol{x}$ and time t, δ is the Dirac delta function, Γ_p is the strength of pth particle, and $\boldsymbol{x}_p(t)$ is the position. The use of Eq. (3) in Eq. (2) yields

$$\boldsymbol{u}(\boldsymbol{x}_p) = \boldsymbol{U}_\infty - \frac{1}{2\pi}\sum_{p=1}^{N_p} \frac{e_z \times (\boldsymbol{x}_p - \boldsymbol{x})}{|\boldsymbol{x}_p - \boldsymbol{x}|^2}\Gamma_p = \boldsymbol{U}_\infty - \sum_{p=1}^{N_p} \boldsymbol{K}(\boldsymbol{x}_p - \boldsymbol{x})\Gamma_p, \tag{4}$$

where $\boldsymbol{K}$ is the velocity kernel. In the present implementation of the fluid solver, a hybrid particlemesh Vortex-In-Cell algorithm is used for smooth projection of the vorticity carried by the particles onto a regular mesh. The immersed interface techniques utilize fast Fourier transforms (FFT) on the regular mesh and enforce the appropriate boundary conditions on immersed interfaces to solve the Poisson equation efficiently. A Particle–Particle Particle–Mesh (P^3M) algorithm is employed to resolve sub-grid scales using an influence matrix technique in the presence of immersed interfaces. The solver uses the stochastic Random Walk Method for modelling the diffusion of the flow.

In order to perform pseudo-3D simulation with deformable bodies, the kinematic velocity boundary condition is enforced at each 2D simulation slice by applying boundary element technique. At the solid surface, the boundary condition $u\left(x_B\right) \cdot n_B = 0$ is enforced such that the surface is impermeable where n_B is the unit normal vector. The geometry of immersed bodies is discretized assuming piecewise linear panels of approximately uniform length. This creates a polygon of N_l panels of lengths Δ_{s_i}. The surface vorticity is discretized as sheets of linearly varying vorticity along the panels. The bound vortices are obtained from equation $M_i\gamma_0 = b$, in which M_i is the influence matrix that contains the influence coefficients in order to describe the mutual induction of the vortex sheets while the right-hand side (b) contains all external influences such as the induced velocities on the panels from the free stream contribution. The influence matrix is constant for non-deforming bodies undergoing solid body motion. However, the influence matrix for deforming bodies should be recalculated based on the updated surface geometry. The surface vorticity found by solving this system is assigned to the control points on the boundary and subsequently released into the flow. The section forces for aerodynamic analysis can be calculated by integrating pressures on the surface panels. More details about the solver can be found in [8, 9] while its specific implementations can be found in [10, 14, 15, 13, 16].

2.2 Structural equations

The superposition of generalized vibration modes is a powerful technique for performing dynamic response analyses of linear structures. It can reduce the computational time significantly. A system with few degrees of freedom (DOFs) can be solved using full system. However, for large systems, especially when the displacements are linear it is usually advantageous to transform the equation of motion to a smaller set of equations by expressing the displacements in terms of the first few natural vibration modes ϕ_n of the undamped system. The basic assumption in mode superposition is that the nodal displacements of the system are approximated by a linear combination of the first j eigenmodes such that

$$\boldsymbol{d}(t) = \sum_{n=1}^{j} \phi_n \boldsymbol{q}_n(t), \tag{5}$$

Here, $\boldsymbol{q}_n(t)$ are the modal amplitudes. The equation of motion related to time dependent forces can be expressed in modal coordinates as follows

$$\mathbf{M}\phi_j\ddot{d}_j + \mathbf{C}\phi_j\dot{d}_j + \mathbf{K}\phi_j d_j = f_{ext}\left(t\right), \tag{6}$$

pre-multiplying with ϕ_j^{T} gives

$$\phi_j^{\mathrm{T}}\mathbf{M}\phi_j\ddot{d}_j + \phi_j^{\mathrm{T}}C\phi_j\dot{d}_j + \phi_j^{\mathrm{T}}\mathbf{K}\phi_j d_j = \phi_j^{\mathrm{T}} f_{ext}\,(t)\,, \tag{7}$$

where ω_j is the modal circular natural frequency, ξ_j is the modal damping ratio, ϕ_j is the mode shape, the subscript j is the mode number and f_L is the lift force vector, respectively. The equation of motion can be written as following

$$\tilde{\mathbf{M}}\ddot{d} + \tilde{\mathbf{C}}\dot{d} + \tilde{\mathbf{K}}d = \tilde{\mathbf{P}}(t), \tag{8}$$

where

$$\tilde{\mathbf{M}} = \phi^{\mathrm{T}}\mathbf{M}\phi \qquad \tilde{\mathbf{C}} = \phi^{\mathrm{T}}\mathbf{C}\phi \qquad \tilde{\mathbf{K}} = \phi^{\mathrm{T}}\mathbf{K}\phi \qquad \tilde{\mathbf{P}(\mathbf{t})} = \phi^{\mathrm{T}} f_{ext}\,(t) \tag{9}$$

with $\tilde{\mathbf{M}}$, $\tilde{\mathbf{C}}$, and $\tilde{\mathbf{K}}$ being diagonal matrices. In dynamic analysis, it is a common choice to provide the relative damping for each mode directly since it allows the calculation of the response using the superposition of uncoupled modal responses. The use of modal damping ratios gives a more control to assign a higher damping value if, for physical reasons, they are expected to be strongly damped. The damping of a multi degrees of freedom (MDOF) system with N DOFs the damping matrix can be expressed in terms of the modal damping ratios ξ_n with $(n = 1, \ldots, N)$. In principle, the procedure can be explained by considering the complete diagonal matrix of generalized damping coefficients, given by pre- and post-multiplying the damping matrix by the mode shape matrix:

$$\tilde{\mathbf{C}} = \phi^{\mathrm{T}}\mathbf{C}\phi = diag(2\xi_1\omega_1 M_1, ..., 2\xi_n\omega_n M_n) \tag{10}$$

For classically damped systems, the square matrix $\tilde{\mathbf{C}}$ is diagonal. A numerical time integration scheme can be used to solve the system under external forces in the time domain. The implicit Newmark time integration with is used with the average acceleration method (γ = 0.5; β = 0.25), which is well known "unconditionally stable condition" irrespective of time step for linear problems. The structural element is considered linear according to the constitutive law.

2.3 Projection of the surface loads to the structural nodes at each 2D slice

The equation of motion of the 3D thin-walled system is formulated and solved at the mid-surface of the thin element. At each simulation slice of the multi-slice analysis, it is necessary to map the fluid pressure on the boundary panels to the structural nodes (Fig. 2). Moreover, to update the boundary conditions at the interface, it is also necessary to map the displacement and velocity of structural nodes from the mid-surface to boundary nodes. It is challenging to calculate the loads on the structure nodes imparted by fluid stresses at the fluid–structure interface. It is because at every point on the boundary panels there is a unique normal vector that points toward the fluid side of the interface, namely the positive wall normal vector. In other words, the fluid pressures acting toward the fluid side of the interface are positive. For such a case, it is readily apparent that at each FE node at the mid-surface in the local coordinate system (LCS) of the structure, it has both positive and negative wall normal vectors pointing toward the fluid side of the interface. Here, the FE nodes and elements are used to calculate and project the surface loads to the structural nodes. At first, the elements and the surface panels are defined as vectors as shown in Fig. 2. Importantly, the surface panels of each immersed body in presented VPM solver have always been defined in anticlockwise orientation. The definition of FE has no restriction about the direction. An iterative search is perform over the surface panels of an immersed body to find a corresponding element, at which the panel pressures of the interface

should be projected. The projection of the panel pressures on FE nodes is performed in LCS. The angle between the vectors of the surface panel and the corresponding element decides the position of the panel, which means above or below, corresponding to element in LCS. The same direction of the panel vector and element vector indicates the position of the panel below the element, and vice-versa. When the projection of the loads for each panel to the FE nodes are made, the force vector is transformed into the global coordinate system.

2.4 Fluid–structure coupling

The fluid and structural equations are coupled with each other through the coupling of boundary conditions at fluid–structure interface Σ to satisfy the continuity of displacement $\mathbf{d}$, velocity $\mathbf{v}$ and equilibrium of stresses such that

$$\mathbf{d}_\mathbf{s}^\mathbf{\Sigma} = \mathbf{d}_\mathbf{f}^\mathbf{\Sigma}, \quad \mathbf{v}_\mathbf{s}^\mathbf{\Sigma} = \mathbf{v}_\mathbf{f}^\mathbf{\Sigma}, \quad \mathbf{f}_\mathbf{s}^\mathbf{\Sigma} = \sigma_\mathbf{f}^\mathbf{\Sigma}.\mathbf{n}. \tag{11}$$

Here, no-penetration, velocity boundary condition, and traction condition are satisfied at the fluid–structure interface to couple VPM and nonlinear structural dynamics solver. The pressures on the solid bodies are computed from the vorticity flux. The presented partitioned solver is based on loosely coupled iteration which is displayed schematically in Fig. 3. For FSI problems of large mass ratio ($\rho_s \gg \rho_f$), the added mass effect of the fluid is not significant and the

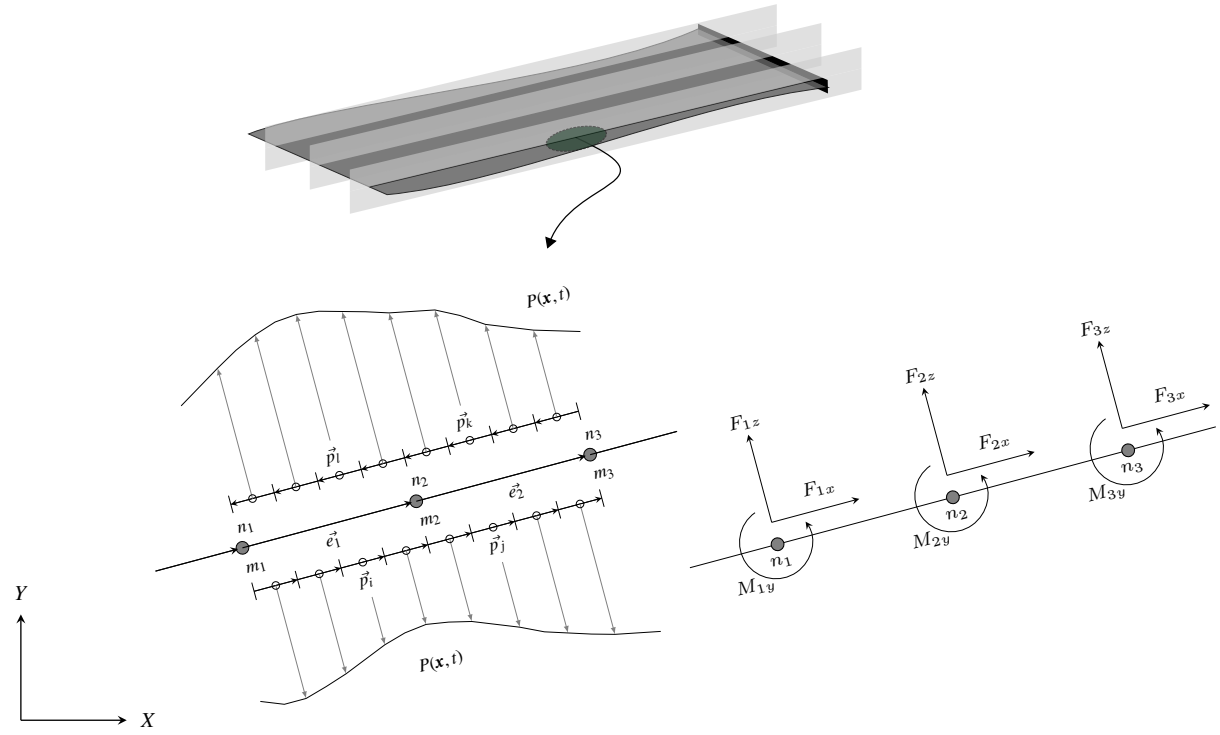

Figure 2: A partial and schematic presentation of thin-wall immersed body in fluid flow. The finite element (FE) formulation is used at the mid-surface to model the structural motion. The vectors of elements and the surface panels are presented as $\vec{e}$ and $\vec{p}$, respectively. Here, the filled circles (•) represents the FE nodes, numbered as n_i, at which the surface loads has to be projected. The unfilled circles (○) shows the nodes associated with the immersed boundary or surface panels. In local coordinate of an element at mid-surface, the direction or the angle between element and panel vectors are used to identify the position of the panel with respect to the element. The projection of the surface loads from the boundary panels is performed to the FE nodes in local coordinate (x-y) and then transformed into global coordinate (X-Y).

problem can be solved with staggered partitioned scheme such as in case of aeroelasticity. Assuming that the displacements and velocities of the solid structure $\mathbf{d_s}$, $\mathbf{v_s}$ are known at time step t_i, and the boundary conditions are projected accordingly. For time step t_{i+1}, the flow solver VPM recalculate and distribute the surface vorticity based on the updated boundary conditions. It computes the pressure distribution on the surface panels which are then interpolated at the FE nodes as nodal forces $\mathbf{f_s}$ for time step t_{i+1}. After achieving the nodal solution from the structure solver, the panel displacements and velocities are calculated and projected back to the interface for updating boundary conditions. This update of information to the flow solver is performed only at the global time step of the coupled simulation.

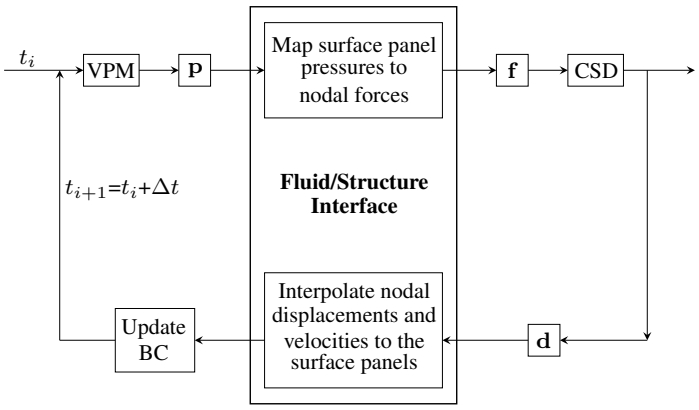

Figure 3: Schematic representation of the coupled numerical algorithm: At each time step, the pressure ($\mathbf{p}$) on the surface panels, which is calculated from the flow solver VPM, is mapped to the nodal force vector ($\mathbf{f}$) for finite element method (FEM) applied at the mid-surface. The panel displacements and velocities are calculated from the nodal displacements in order to update the boundary conditions.

3 FLAPPING MECHANISMS OF INVERTED CANTILEVER PLATES

In contrast to a cantilever plate in conventional flag configuration, the inverted flag or cantilever with a free leading edge and a clamped trailing edge displays large-amplitude flapping over a finite band of wind speeds [17]. Extensive studies on several influential parameters were performed in [18] to establish the flapping mechanism of an inverted cantilever plate. The schematic configuration of an inverted cantilever in axial flow is shown in Fig. 4(a). The typical flapping pattern is shown in Fig. 4(b). The simulation of the inverted cantilever in the context of multi-slice coupled model is shown schematically in Fig. 4(c). It is a non-linear large displacement problem. Though the presented model is based on linear analysis, the validation of the solver is performed in terms of identification of the wind speed at which large amplitude flapping initiates.

3.1 Validation of multi-slice model on a reference inverted cantilever

3.1.1 Flapping regions

The flow-induced vibration of elastic inverted cantilevers has drawn significant attention because of its complicated coupling mechanisms. The flapping of inverted cantilever was identified in [18] as two quasi-steady regimes, which are the straight mode and fully deflected mode, and a limit-cycle flapping mode with large amplitude that appears in between two quasi-steady regimes (Fig. 4(b)). The stability of inverted flags were explained in [18] in terms of two non-

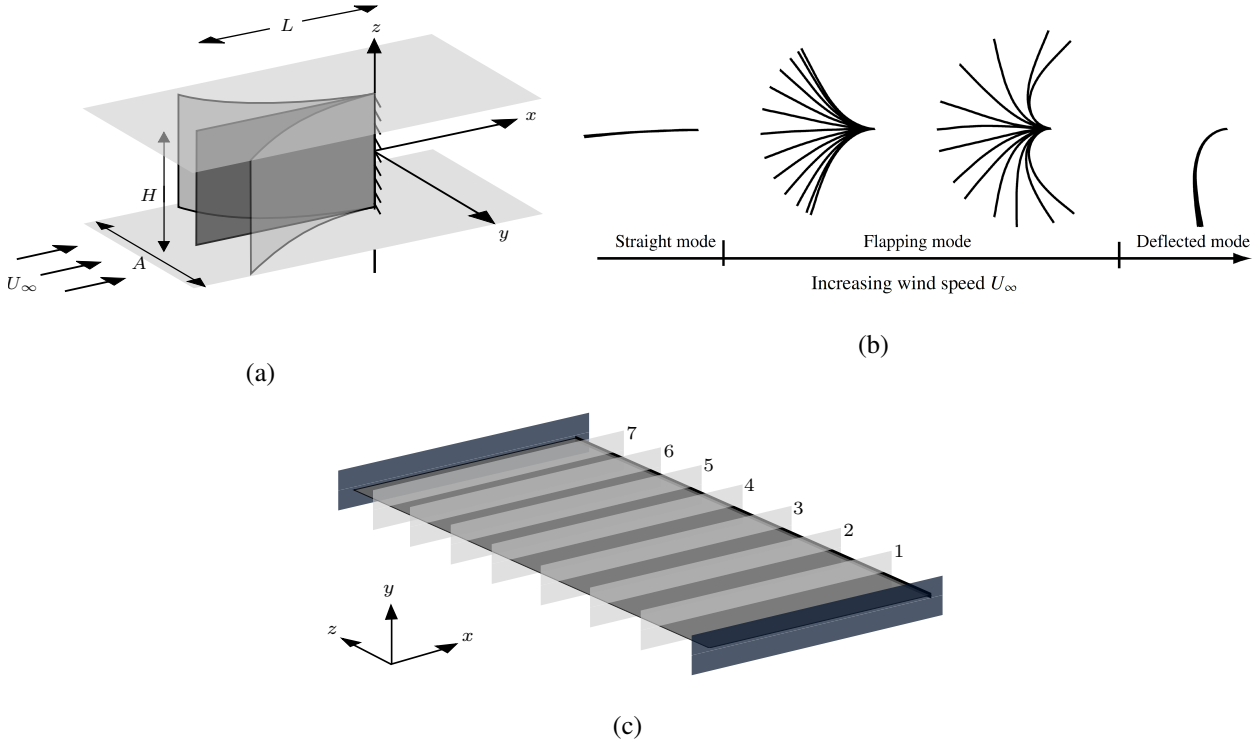

Figure 4: Pseudo 3D simulation of a cantilever plate in inverted flag configuration: (a) Schematic of an inverted cantilever plate (length L × height H). A is the peak-to-peak amplitude in y-direction. The presented coupled numerical model ignores the edge-effects of the cantilever plate, and it is visualized here by the confinement of the cantilever system in between the walls. The characteristic regions of dynamic motion of an inverted cantilever are shown in (b). The schematic multi-slice arrangement of the system for the coupled solver is shown in (c).

dimensional dynamic parameters:

$$\mu = \frac{\rho_f L}{\rho_s h}, \tag{12}$$

$$\kappa = \frac{\rho U_\infty^2 L^3}{D}, \tag{13}$$

where μ and κ specifies the mass ratio and dimensionless flow speed, respectively. The eigenvalue analysis was performed for infinite aspect ratio showed that the stability of an inverted cantilever is lost at zero frequency when $\kappa = 1.85$. The bifurcation of the inverted flag at zero frequency indicates its independence on μ. The flapping mechanism of the inverted flag was established as a vortex-induced vibration (VIV). The aspect ratio was shown to be an influential parameter. A plate with a small aspect ratio in a steady flow allows to generate edge vortices along and across the flow direction which reduces the overall lift. Therefore the bifurcation is primarily affected by the aspect ratio. However, the influences diminish with the increase in aspect ratio and converge to a bifurcation point $\kappa = 1.85$ for an infinite aspect ratio.

3.1.2 Pseudo 3D multi-slice simulation

Variations in cross section are common in civil structures. The fully coupled 3D simulations are computationally very expensive, in particular when it is necessary to resolve the flow around complex structural geometries with small details such as hand rails, guide vanes and wind shields in the case of bridges. The aerodynamic analysis of line-like thin-walled structure

is proposed to be represented as several 2D simulation slices along the structure. The in-plane forces and displacements are coupled to a 3D dynamic representation of the structure in terms of superposition of the natural vibration modes.

In the following, the dynamics of a reference inverted cantilever plate which was studied in [18] has been investigated numerically using the presented multi-slice coupled model. It is a very simple type of line-like thin-walled system. However, it is particularly chosen because of its complex aeroelastic interaction and large-amplitude flapping. The physical and geometrical properties of the plate are listed in Table 1. The coupled simulation is performed using 7 slices, as shown in Fig. 4(c). For the structural solver, the cantilever system is modelled first using a finite element solver in order to obtained the undamped natural vibration modes. The cantilever plate is discretized into 102 shell elements along the length while 8 elements along the width. The natural vibration modes and corresponding frequencies of the modelled system are shown in Fig. 5. Within the flow solver at each simulation slice, the non-dimensional size of the boundary elements is chosen such that $\Delta_s/h = 3.8462$ which results in 206 panels. The instantaneous number of particles in the flow domain for each slice is estimated approximately between 65,000 and 75,000. During the coupled analysis, at each simulation slice the panel pressures are integrated to the structural nodes. Each slice is assigned an effective width based on the selection of the slice locations. Finally, the inverted cantilever plate is simulated under different wind speeds. No edge-effects are considered in the analysis. Concerning edge-effects, the consideration of a 2D plate with infinite aspect ratio is analogous to the consideration of finite plate confined between the side walls (Fig. 4(a)).

The tip displacement of the cantilever at the middle slice (slice number 4) are displayed in Fig. 6 for both dimensional and non-dimensional incoming flow speeds. The time histories of the tip displacements for all the slices are found relatively same. There has been very negligible differential displacement in between the slices. The bifurcation is observed immediately after non-dimensional flow speed $\kappa = 1.85$. This is an agreement with the results from [18] since the present model doesn't consider the effect of vortices from the edges across the flow direction. This result indicates that the bifurcation of small aspect ratio is still possible at $\kappa = 1.85$ if the sides of the plates are perfectly isolated. The response frequencies of the cantilever for the periodic motion follows the frequency of the vortex shedding, which is found approximately to be 6.5 Hz. It is almost the half of the first natural frequency of the system. Similar fundamental behaviour was observed in [18]. The visualization of the vorticity field in all the slices for different vibration phases of the cantilever plate are shown in Fig. 7(a, b). This particular test case has been analysed considering different number of slices such as 1, 2, and 4. It requires the change of the effective width of the slices accordingly. Furthermore, several analyses are performed considering 2 to 4 number of vibration modes. The critical wind speed at which the large amplitude flapping initiates is always identified around 2.45 m/s for the studied case.

Table 1: The physical parameters of the reference inverted cantilever plate.

Solid	density	ρ_s	(kg m^{-3})	1200
	elastic modulus	E	(GPa)	2.4
	plate thickness	h	(mm)	0.13
	plate length	L	(cm)	5.1
	plate width	B	(cm)	6.4
	Poisson ratio	ν	(-)	0.38
Fluid	density	ρ_f	(kg m^{-3})	1.2
	kinematic viscosity	ν_f	(m^2 s^{-1})	1.54×10^{-5}

The model is presented for small displacement FSI problem, and therefore, it is not reliable to study the post-critical behaviour of the system using the present model. It requires a model that accounts the geometrical nonlinearity, such as in [13]. However, the presented model is very good regarding the identification of the critical flapping wind speed and shows its applicability for small displacement FSI problems. Moreover, the model is found computationally very efficient. Simulations are performed separately one after another using a computer having Linux

operating system, 32 open-MP multithread Cores, 3.5GHz processor, 64 GB RAM. The 7-slice simulation for 20,000 steps took approximately around 12 hours only.

3.2 Multi-slice simulation of a skewed inverted cantilever plate

In the following, a skewed inverted cantilever plate is simulated under the axial wind using the multi-slice numerical model. It is expected that a differential motion between the slices should occur. The physical properties of the skewed inverted cantilever plate are chosen according to Table 1. The length of the plate is changed at top and bottom in order to make it skewed (L_{top} = 4.284 cm, L_{bottom} = 5.916 cm). The dimensions and multi-slice representation of the skewed inverted are shown in Fig. 8. The coupled simulation is performed using 7 slices as before. The cantilever system is modelled again using 102 and 8 shell elements along the length and width, respectively. The natural vibration modes and corresponding frequencies of the modelled system are shown in Fig. 9. Within the flow solver at each simulation slice 206 panels are used which means the size of the boundary elements Δ_s is different in slices. In such case, the simulation time step is normally considered either equal to the minimum average panel length for a slice over free stream flow ($\overline{\Delta}_{s(min)}/U_\infty$) or smaller. The displacement time histories of the cantilever tip for different slices are compared in Fig. 10. The differential displacement is clearly observed at different slices. The critical wind speed for initiation of large amplitude is identified 2.45 m/s as before.

4 MULTI-SLICE SIMULATION OF A THIN ROOF SYSTEM

Membrane roof systems are a good example of extremely light-weight and highly optimized constructions. Due to the constant stress state over the thickness, the material strength is optimally used. In the last years, the use of membranes in structural engineering became more and more common such as the Allianz Arena in Munich. Structural umbrella-type roofs have become popular for providing shelter whilst maintaining the feeling of open air. Their lightweight and flexible nature makes them prone to destructive aeroelastic effects. In this section, a thin-walled roof system is modelled and the responses are analysed under laminar wind flows. A Schematic configuration of a roof system under free stream wind U_∞ is shown in Fig. 11. The roof is considered curved in a parabolic way. The physical properties those are considered in this study for the roof system are presented in Table 2.

The coupled simulation is performed using 19 slices. The roof system is modelled using 80 and 20 shell elements along the length and width, respectively. The beam elements are used

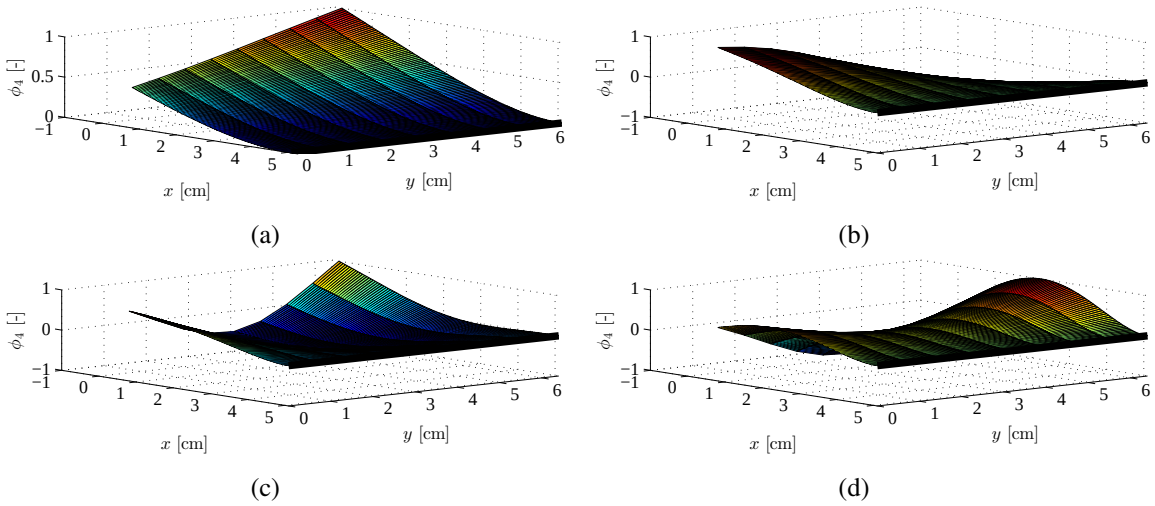

Figure 9: Normalized natural vibration modes and frequencies of the skewed inverted cantilever plate model: (a) f_1 = 11.12 Hz, (b) f_2 = 26.91 Hz, (c) f_3 = 62.21 Hz, and (d) f_4 = 66.69 Hz.

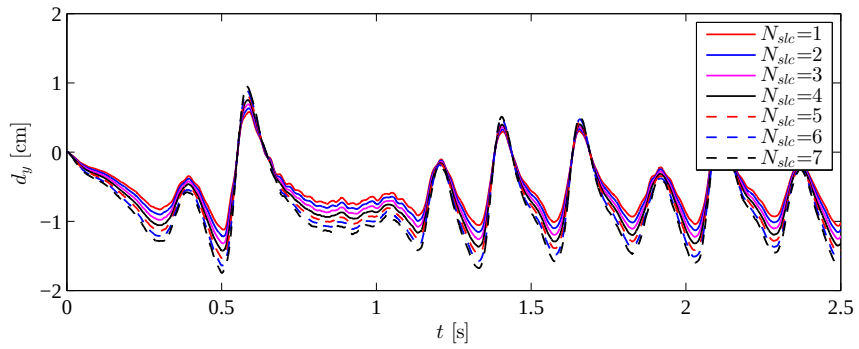

(a) U_∞ = 2.35 m/s

as stiffeners regularly along the length and width of the roof. The natural vibration modes and corresponding frequencies of the modelled system are shown in Fig. 12. Within the flow solver at each simulation slice 162 panels are used which means the size of the boundary elements Δ_s is different in slices. As mentioned earlier for such cases, the simulation time step is considered either equal to the minimum average panel length for a slice over free stream flow ($\overline{\Delta_s}_{(min)}/U_\infty$) or smaller. The simulation of the roof system is under wind speed of 30 and 50 m/s. The

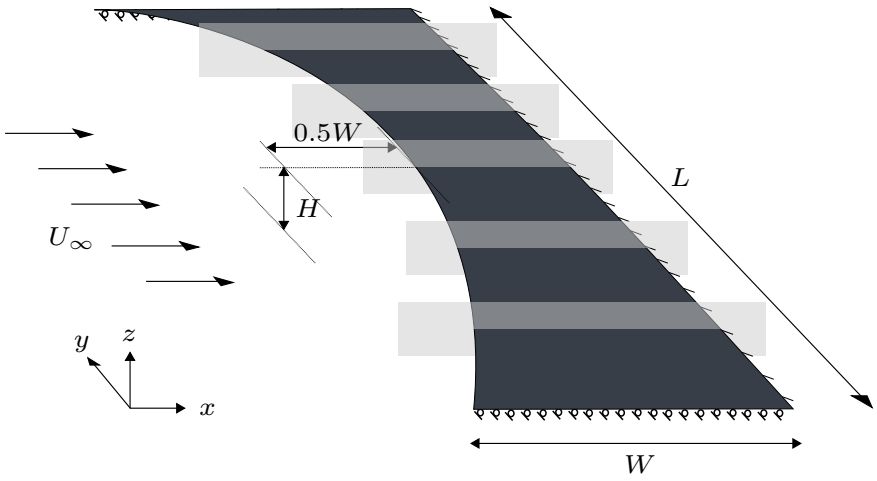

Figure 11: Schematic configuration of a roof system under free stream wind U_∞. The roof is considered curved in a parabolic way; the length, width and height are expressed as L, W, and H, respectively. The isometric view shows that the width of the system is reduced by half at the centre along the length. In this study, the fully coupled simulation of the system is performed in multi-slice sense which is by performing several 2D simulation slices that are interconnected by their natural vibration modes.

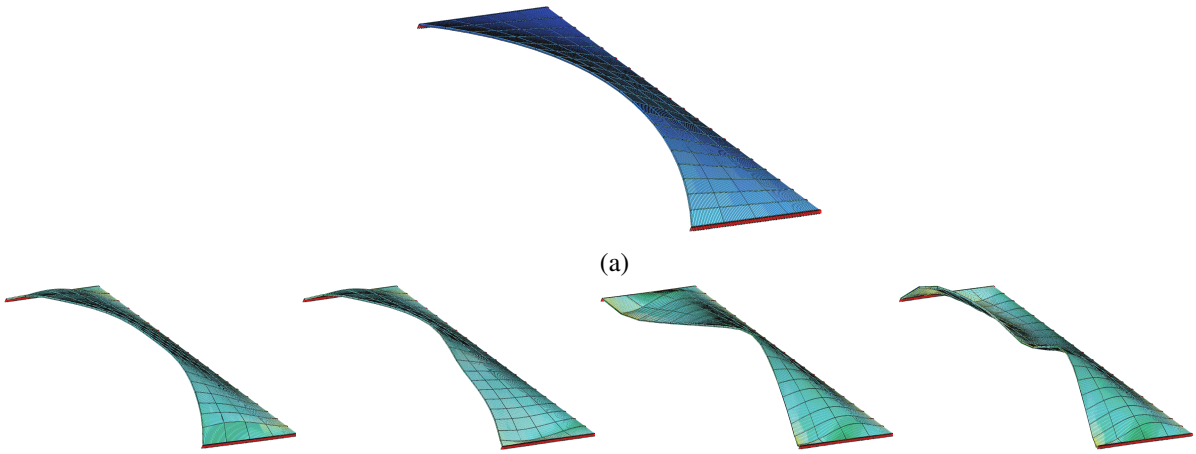

Figure 12: The modelled roof system and its natural vibration modes and frequencies: (a) the system, (b) f_1 = 8.97 Hz, (c) f_2 = 9.33 Hz, (d) f_3 = 15.21 Hz, and (e) f_4 = 16.44 Hz.

Solid	density	ρ_s	(kg m^{-3})	7950
	elastic modulus	E	(GPa)	180
	roof thickness	h	(mm)	4
	roof length	L	(m)	10
	roof width	W	(m)	2
	roof height	H	(m)	0.4
	Poisson ratio	ν	(-)	0.3
Fluid	air density	ρ_f	(kg m^{-3})	1.2
	kinematic viscosity	ν_f	(m^2 s^{-1})	1.5×10^{-5}

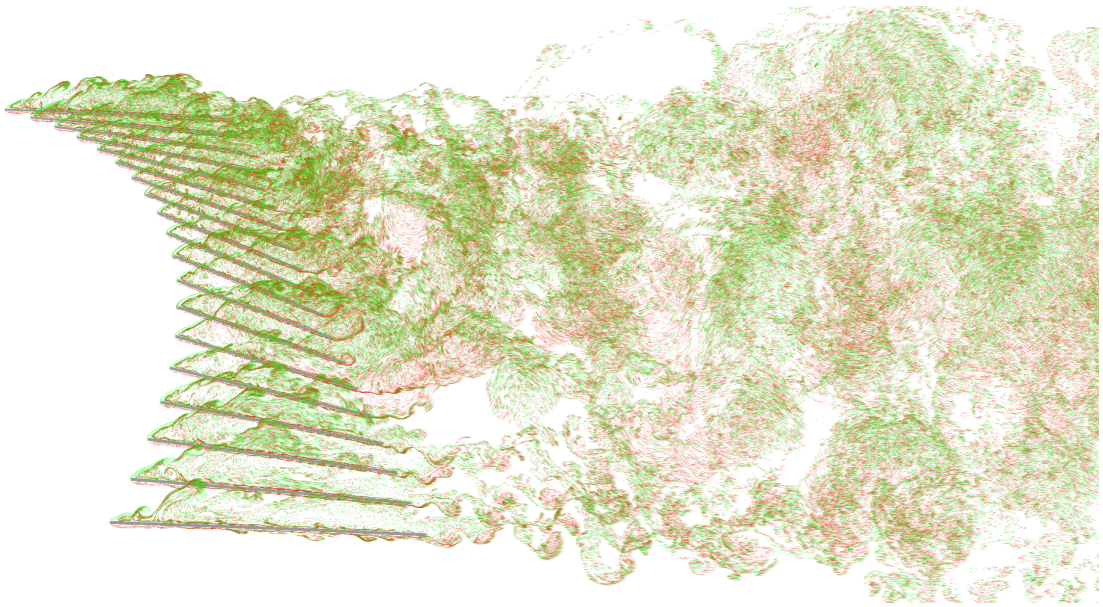

Figure 13: Instantaneous particle map for the Pseudo-3D roof system under laminar flow of 30 m/s.

corresponding simulation time steps are chosen 0.000754 s and 0.000452 s. The number of simulation time steps are 20,000 and 18,000, respectively. The instantaneous vorticity around the roof system at different simulation slices are shown in Fig. 13. The displacement time histories of the tip of the roof system at different slices are compared in Fig. 14 and Fig. 15, respectively under the wind speed of 30 and 50 m/s. The real time computation of such large scale analysis with the presented numerical model took only around 18 hours and 20 hours, respectively. As for future scope, the interest exists to study the influence of bluff vertical plate at the tip of the roof on aeroelastic response. The influence of incoming turbulence is also of particular study interest.

5 CONCLUSION

The paper has presented a partitioned extension of vortex particle methods (VPM) in the context of pseudo three-dimensional (3D) multi-slice numerical model which allows to simulate aeroelastic behaviour of thin structural elements, such as thin cantilevers and membrane roof system. A pseudo-3D VPM has been used to simulate the dynamics of the fluids. The complex flow around deformable boundaries has been analysed with the help of immersed boundary methods. The finite element model has been used to model the structural system. The linear uncoupled vibration modes are obtained for the structural dynamic solver because of its efficiency to handle small displacement problems. The equation of motion has been solved at the mid-surface of thin structural element. The projection of the surface pressures to the structural nodes at each 2D simulation slice has been explained. The validation of the solver has been performed by analysing the dynamics of an inverted cantilever in axial flow. The identified critical wind speed has been found to be in very good range when compared with the literature. A skewed inverted cantilever, which is modified over the reference system, has been analysed in order to simulate the differential displacement along the slices since the vortex induced forces varies along the slices. Finally, the dynamic response of a cantilever roof system which is fixed at the base and hinged in two sides has been analysed under incoming wind speeds of 30 and 50 m/s. The displacement time histories has been presented corresponding to the slices. The solver has been found computationally very efficient in terms of solving such large scale problem. The

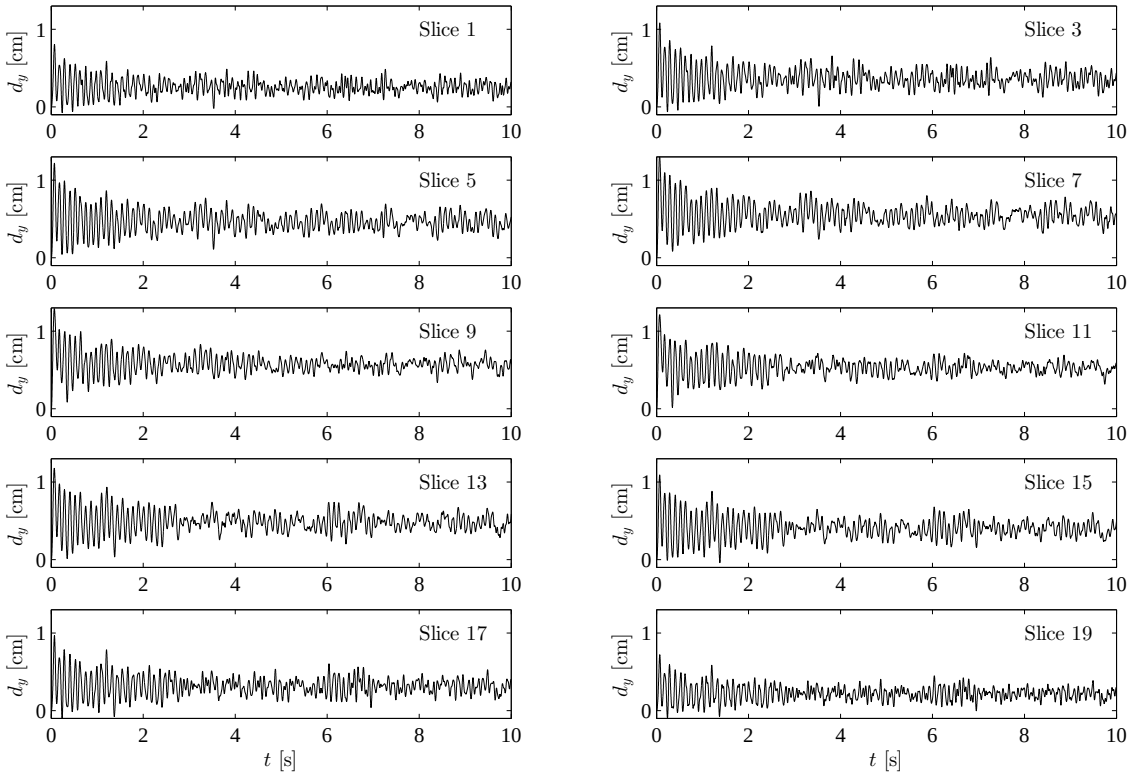

Figure 14: Tip displacement of the roof system at different slices under wind speed of 30 m/s.

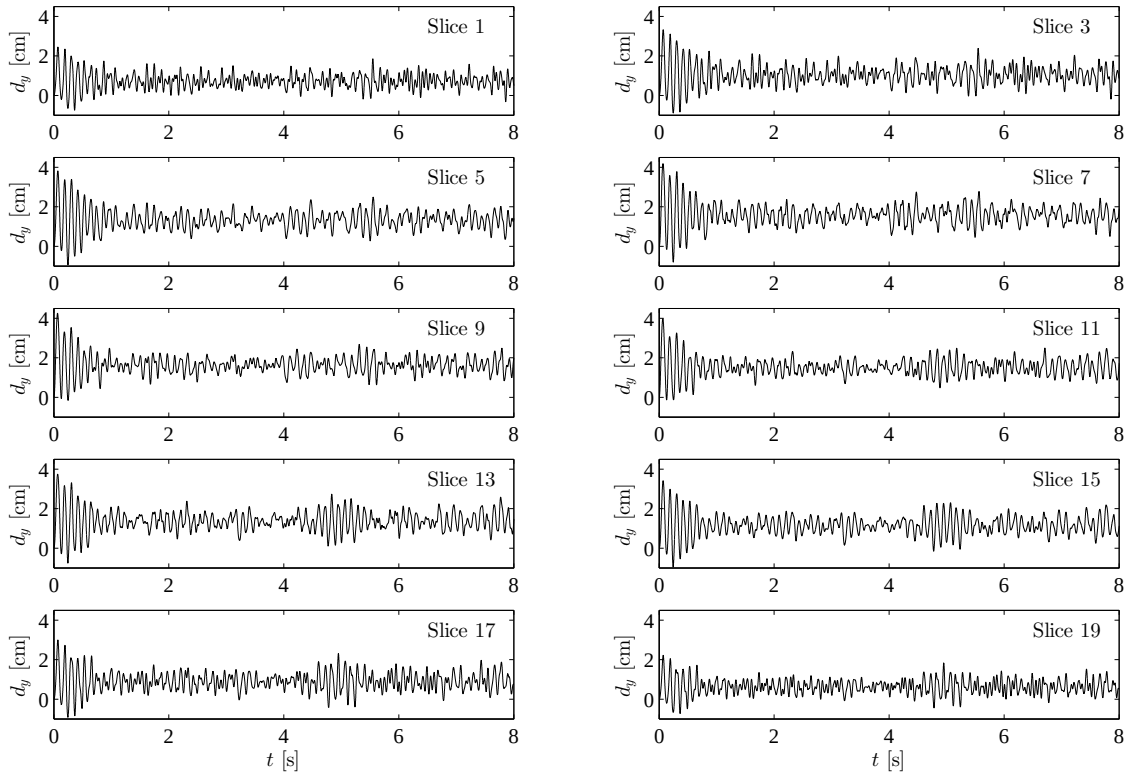

Figure 15: Tip displacement of the roof system at different slices under wind speed of 50 m/s.

influence of incoming turbulence on the dynamics of roof system is of particular study interest for future. The thin-walled circular tower system under vortex-induced vibration can be studied also.

Abstract

The highway bridge design code in most countries does not consider the live load in seismic design of highway bridges. However, traffic jams on urban highway bridges occur with high probability, and the inertial effect of passing vehicles due to earthquakes thus could not be negligible in the context of seismic design of bridges when vehicle's weight is large enough compared with the dead load of bridges. It is therefore of engineers' interest to conduct a seismic analysis of bridges considering the vehicle dynamics effect on the seismic behavior of the bridge. Earthquakes occur unexpectedly and recently more and more strong motions were recorded, which are important for seismic engineering. This paper investigates nonlinear dynamic responses of a highway bridge considering vehicle‑bridge interactions (VBI) subjected to particular large earthquakes: Tohoku earthquake in 2011 and Kumamoto earthquake in 2016. Observations showed that, compared with those of disregarding vehicles, VBI changed the bridge displacement responses, plastic deformations, relative displacements of bearings and acceleration responses of the bridge but to different tendency and degree under different ground motions. The results revealed the importance of vehicle dynamic effect on seismic responses of bridges and view point that the current assumption of ignorance of vehicle effect in seismic design of highway bridges might be non-conservative.

Keywords: Bridge Non-linear Behavior, Moving Vehicle, Particular Earthquakes, Seismic Analysis, Vehicle‑bridge Interaction.

1 INTRODUCTION

Earthquakes occur randomly and such strong motion records are important for seismic design. On March 11, 2011, the 2011 off the Pacific Coast of Tohoku Earthquake (hereafter, the "Tohoku Earthquake") occurred in Japan. The magnitude was reported as being 9.0, the highest magnitude ever recorded in Japan. It was the most powerful earthquake ever recorded to have hit Japan, and the scale of the Tohoku Earthquake stands out in comparison even with some of the most destructive past earthquakes. It caused enormous damage due to the ground motion and the tsunami it triggered. About 200 highway bridges and numerous railway bridges were damaged, e.g., elevated bridges of the Tohoku Shinkansen. The Tohoku Earthquake was an inter-plate earthquake, occurring on the boundary between the Pacific plate and the Continental plate. The observed ground motions had a typical characteristic of a long duration because of the large scale of the fault plane, or the large number of waveforms observed, which was higher than massive earthquakes in the past. This phenomenon caused severe liquefaction effects for the ground in the Tokyo Bay area. Liquefaction resulted in much of the destruction associated with this earthquake, such as sand/mud boiling, ground cracking, depressions of pavement, ground settlement, leaning buildings and the exposure of underground pipes. The Kumamoto earthquake in 2016 consists of two strong ground motions and a series of smaller foreshocks and aftershocks. The first large ground motion hit the area on April 14, 2016, which was categorized into the foreshock before the larger ground motion on April 16, 2016. Such earthquakes caused strong response and significant damage to bridges. It was mentioned that this type of repeated strong motions has not been taken into account in conventional seismic design practices [1]. The repeated strong motions increase damage in all types of structures significantly. Service on the Shinkansen was suspended after a train derailed due to the earthquake. Thus, more research is needed to estimate and prevent the damage caused by such strong earthquakes.

Heavy traffic jams on urban highway bridges occur frequently and encountering an earthquake in urban areas of earthquake prone regions becomes more possible. The dynamic effect of vehicles could not be negligible in the context of seismic design of bridges. It is necessary to review the seismic performance of bridges, considering traffic loading. However, very few studies have specifically examined the vehicle effect on bridge seismic responses.

In seismic design of monorail bridges the effect of the train load is considered as additional mass [2]. He et al. [3] investigated the seismic responses of Shinkansen viaducts for high-speed trains under moderate earthquakes. Their results show that the train can act as a damper for the bridge. A study by Zeng and Dimitrakopoulos [4] studied a horizontally curved railway bridge subjected to train crossings and moderate ground motions of different periods. Results verified the favorable damping effect that the running vehicles have on the deck vibration. The study by Kim et al. [2] showed that consideration of the monorail train as additional mass rather than a dynamic system in numerical modeling overestimated the effect of the train load on seismic performance of monorail bridges. Kim and Kawatani [5] concluded that a train acts as a damper and tends to decrease acceleration response under a particular earthquake compared with the system which consider train as an additional mass.

In contrast to the railway system, the highway bridge design code of Japan Road Association does not consider the live load in seismic design of highway bridges due to the low probability of simultaneously encountering critical vehicle load and earthquake. A study by Sugiyama et al. [6] showed that the dynamic effect of the vehicles was more dominant in the transverse direction and that the vehicle loading tended to reduce the bridge response. A study addressing this matter was done by Kameda et al. [7], which concluded that seismic responses of the bridge increase or decrease depending on the phase difference between the bridge and

the vehicle. Kameda et al. [8] stated that the vehicles tended to amplify the bridge response when the vehicles and bridge were in phase and tended to decrease the response when they were out of phase. Another study by Kim et al. [9] concluded that the seismic response of the highway bridge subject to moderate earthquakes increased when the vehicle was considered as mass; and decreased when the vehicle was simulated as dynamic system. Kawatani et al. [10] demonstrated that heavy vehicles reduced the seismic response of bridges under a moderate ground motion with lower frequency characteristics; but slightly amplified the seismic response of the bridge under higher frequency ground motions. Borjigin et al. [11] proposed a seismic response analysis framework incorporating vehicle–bridge interactions (VBI) with nonlinear dynamic analysis, and the effects of vehicle dynamics on seismic responses of a highway bridge was clarified and the seismic performance of the bridge was checked.

As reviewed above, most studies were related to moderate earthquakes that caused linear behavior of bridges, and some studies discussed the seismic responses of bridges considering effect of vehicle dynamics under limited number of modified ground motions. It is therefore necessary to proceed with a seismic analysis of bridges considering vehicle effect, and describe the non-behavior of bridges for strong ground shakings of different levels. This study was conducted to investigate non-linear dynamic analysis incorporating vehicle–bridge interactions (VBI) subjected to particular earthquakes to clarify the effect of vehicles on the seismic responses of an urban highway viaduct. To investigate the seismic responses of the bridge under particular earthquakes, two strong ground motions recorded on-site with different frequency components are adopted for analysis. A numerical method, Recursive Substructure Method, was utilized, which integrates a commercial FEA package, ABAQUS®, into the authors' in-house VBI-solving programs developed with MATLAB®.

2 ANALYTICAL MODELS

2.1 Vehicle model

The vehicle model of a truck consists of a rigid body with single axle. The mass of the vehicle model is 25.0 ton. The vehicle model has five degree of freedoms (DOFs) considering transversal, longitudinal, vertical, pitching, and rolling motions as shown in Figure 1. The properties are shown in Table 1. The length of truck is 7 m. The natural frequency of longitudinal motion of the vehicle model is about 2.052 Hz. The slip or turning over of vehicles on the bridge during the earthquakes was not considered in this study.

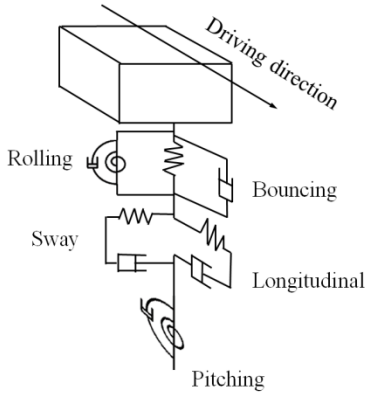

Figure 1: Vehicle model of 5DOF. (reproduced from [11])

	Natural frequency	Spring constant	Damping coefficient
Transversal & longitudinal	2.052 Hz	4.156×10^6 N/m	4.284×10^4 N·s/m
Vertical	3.477 Hz	1.193×10^7 N/m	5.871×10^4 N·s/m
Pitching	2.697 Hz	2.326×10^7 N·m/rad	1.505×10^5 N·m·s/rad
Rolling	1.739 Hz	9.665×10^6 N·m/rad	4.756×10^4 N·m·s/rad

Table 1: Properties of 5DOF vehicle model. (reproduced from [11])

2.2 Bridge model

The target bridge was designed in 2009 according to the design specifications for the Japan highway bridges. The bridge model (Figure 2) used in this study was a 3-span continuous non-composite steel plate girder bridge with two vehicle lanes. The superstructure of the bridge model contains an orthotropic plate supported by five girders. The girders, reinforced concrete (RC) piers and abutments were modelled with beam elements and the plate was modeled with shell elements. The properties of cross section and mechanical properties are given in Table 2 and Table 3. Rayleigh damping was adopted [12].

Strong earthquakes may cause non-linear behaviors of bridges. The failure mode of this bridge was predicted to be in the longitudinal direction. The bridge included isolation bearings of bi-linear force-displacement relationship on each abutment and pier (Table 4) which moved in the longitudinal direction, and plastic hinges of tri-linear moment-rotation relationships on the piers base (Table 5) which rotated along the transversal axis. The abutments were made of concrete and performed linear behavior, while the piers were made of reinforced concrete and performed non-linear behavior.

θ_{pu} (rad)	0.048174	0.047547

Note. Initial cracking moment M_{pc} and its corresponding rotational angle θ_{pc} specifies the initial cracking point and elastic limit, the yielding moment M_{py0} and rotation angle θ_{py0} specifies the yielding point, the ultimate moment M_{pu} and rotation angle θ_{pu} specifies the ultimate point.

Table 5: Properties of plastic hinge. (reproduced from [11])

The road condition was considered to be good in this study. The roadway profile generated based on ISO standard [13] is shown in Figure 3. Usually effects of vehicle vibrations actuated during moving on a bridge by road roughness are relatively small compared with seismic load effects. However, before an earthquake bridge vibration is mainly excited by vehicle vibrations, and the bridge vibration due to moving vehicles can be applied as initial conditions in the dynamic analysis of bridges during earthquakes. Before seismic responses, the responses by vehicles only should be identified. Therefore, this study considers the road roughness in the analysis [9].

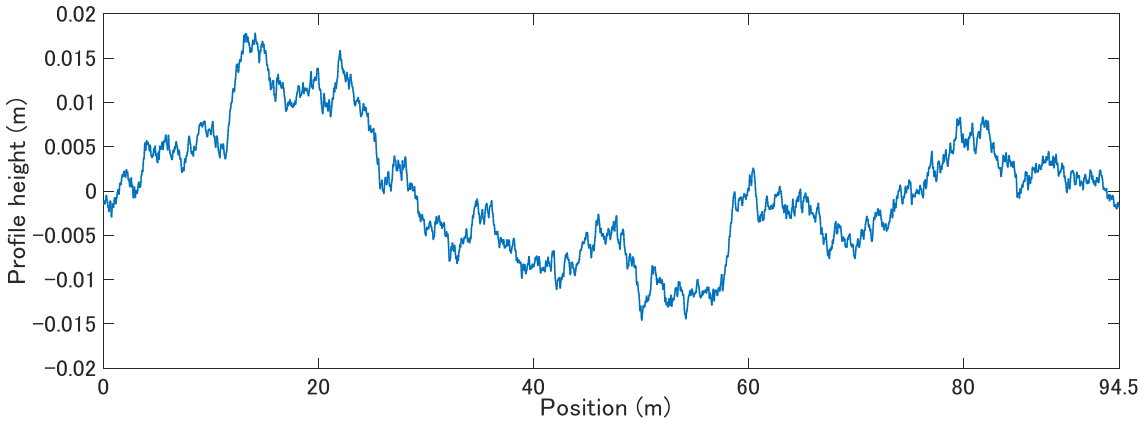

Figure 3: Road roughness profile. (reproduced from [11])

Since the vehicle position on the bridge varies with time, the natural frequency of bridge with vehicles standing at different loading locations were examined through eigenvalue analysis of the vehicle-bridge interactive system. There were five vehicles equally spaced on each lane and totally ten vehicles were considered in the VBI system. The natural frequency of the first longitudinal mode of the bridge without vehicle was 1.82 Hz. Position 1 (see Table 6) is a special condition with 2 vehicles exactly standing on the top of two piers on each lane. As shown in Table 6, the first mode is piers' longitudinal bending and rubber bearings' deformation mode. Two longitudinal modes and frequencies of the vehicle-bridge interactive sys-

tem corresponds to the first longitudinal mode: vehicles in-phase (vehicles move in the same direction as the bridge's movement) and out-of-phase (vehicles move in the opposite direction of the bridge's movement) with the bridge, with the frequency of 1.43 Hz and 2.02 Hz, respectively. Position 2 (Table 6) is one vehicle standing on the top of left abutment on each lane, while Position 3 (Table 6) is one vehicle standing on the top of right abutment on each lane and symmetrical with Position 2. For this reason, the discussion with position 3 scenario is omitted in following sections. With position 2 and 3, frequency of vehicles in-phase mode is 1.17 Hz and that of out-of-phase mode is 1.89 Hz. Position 4 (Table 6) is a random position different from the above 3 ones. Frequency of vehicles in-phase mode is 1.35 Hz and that of out-of-phase mode is 1.97 Hz.

It can be found that the bridge has varied fundamental natural frequencies as the vehicles were moving on the bridge. Due to the presence of vehicles, the frequency of the bridge may be changed to be larger or smaller than that of bridge alone, e.g. at position 1 the frequency of vehicles in-phase mode is 1.43 Hz that is smaller than the natural frequency of the first mode of bridge alone 1.82 Hz, while frequency of out-of-phase mode is 2.02 Hz, which is larger than the natural frequency of the first mode of bridge alone 1.82 Hz. Such frequency variation may significantly cause change in seismic responses of the bridge, as discussed below.

Bridge without vehicle	Bridge with 10 vehicles (position 1)	Bridge with 10 vehicles (position 2,3)	Bridge with 10 vehicles (position 4)
			1.82 Hz 	vehicles in phase with the bridge 1.43 Hz  vehicles out of phase with the bridge 2.02 Hz 	vehicles in phase with the bridge 1.17 Hz  vehicles out of phase with the bridge 1.89 Hz 	vehicles in phase with the bridge 1.35 Hz  vehicles out of phase with the bridge 1.97 Hz 
Table 6: Comparison of natural frequencies and mode shapes of the bridge based on equivalent stiffness without vehicle and with vehicles standing on different positions. (reproduced from [11])

2.3 Moving vehicle configuration

To investigate the effect of moving vehicles on the seismic response of the highway viaduct, the following scenario was considered. Figure 4 shows the moving pattern of heavy vehicles. It was assumed that the earthquake happened when the bridge was fully loaded with

moving vehicles. In other words, only the seismic response of the bridge fully loaded by moving vehicles is discussed in this study. All vehicles are assumed to travel with the constant speed of 2.7 m/s (9.72 km/h). The spacing between adjacent vehicles is 18.9 m. Comparing the responses in this scenario with another scenario, disregarding vehicular loadings, can be useful to elucidate the effects of continuously moving vehicles.

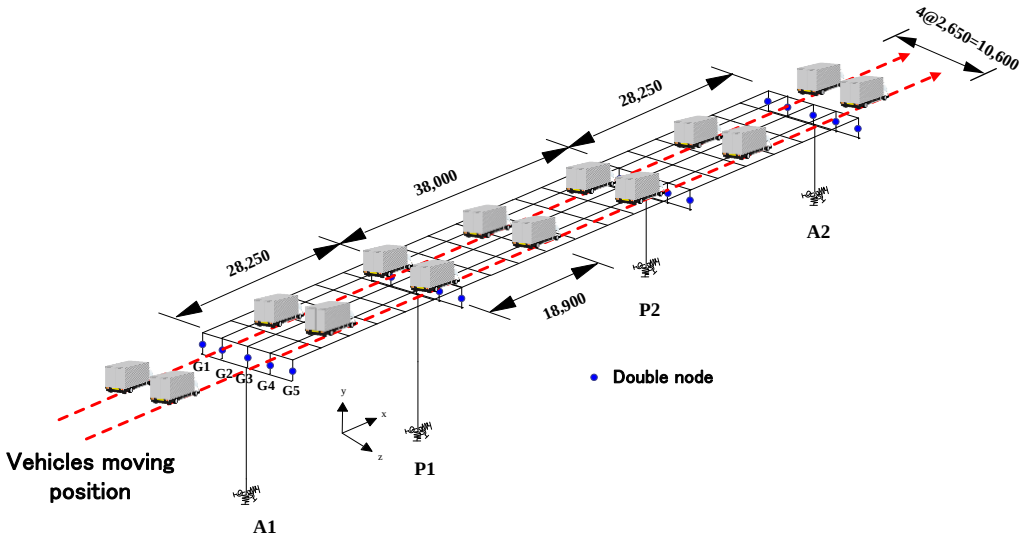

Figure 4: The bridge model with continuously moving vehicles. (reproduced from [11])

3 GROUND MOTIONS

Two particular ground motions were considered herein: 2011 Tohoku earthquake and 2016 Kumamoto earthquake. Their characteristics are given as follows.

3.1 Tohoku earthquake

The strong ground motion records of Tohoku earthquake clearly showed that this earthquake generated ground motions with multiple pulses and longer duration, compared to the 1995 Kobe Earthquake lasting about 20 seconds. Figure 5 shows the time history of Kaihoku Bridge, Ishinomaki EW component, a modified ground motion of Level 2 Type I recommended by JRA [14] used herein, which was obtained from the recorded ground motion in the Tohoku earthquake at the measurement station of Kaihoku Bridge, Ishinomaki. The designation of EW indicates data channels of East-West direction. The Level 2 ground motion indicates the extreme design ground motion with low occurrence probability such as Kobe earthquake in 1995 and Type I indicates inter-plate earthquakes. For the highway bridge adopted in this analysis, the ground condition is classified as Group I soil in the design code, which is defined as dense to stiff soil having a natural period of 0.16 – 0.6 s in the surface ground.

As shown in Figure 5, the ground motion contains two attacks with a spacing of about 50 seconds and lasts for about 240 seconds. The first attack has smaller peak value of acceleration (5.12 m/s^2) than the second attack does (7.95 m/s^2). The figure shows a drastic change in amplitude and spike-like phases, which all corresponds to the characteristics of the records on the liquefied ground. The sampling frequency is 100 Hz.

Figure 6 shows the acceleragram, Fourier amplitude spectrum and pseudo acceleration response spectrum (damping ratio h = 0.05) of the modified ground motion. The modified

ground motion was obtained by fitting its response spectrum to the target response spectrum. Periods (and frequencies) in the legend of response spectrum and Fourier amplitude spectrum are natural periods (frequencies) of vehicle's longitudinal mode, the first natural periods (frequencies) of the bridge's longitudinal modes disregarding vehicles and regarding vehicles as dynamic system (at Position 1, 2 and 4) respectively.

For computation efficiency, a shorter ground motion (referred to as GM1 hereafter) was extracted from the 20th to 140th second of the full record and then applied to the aforementioned VBI model. The ground motion was applied in the longitudinal direction because the piers' bending resistance is weakest in this direction according to the formal design.

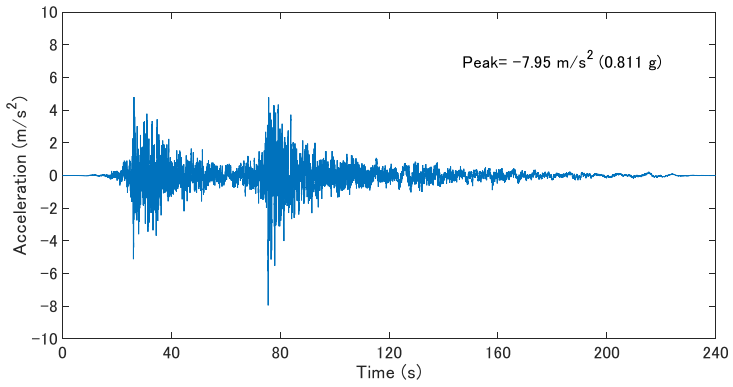

Figure 5: Kaihoku Bridge, Ishinomaki EW component (GM1).

(c)

Figure 6: Accelerogram, response spectrum and Fourier spectrum of strong shaking interval (20 s ~ 140 s) of Kaihoku Bridge EW component (GM1): (a) accelerogram, (b) Fourier amplitude spectrum, (c) pseudo acceleration response spectrum.

3.2 Kumamoto earthquake

Figure 7 shows the acceleration time histories of the NS and EW components of the ground motion recorded at Mashiki town (referred to as GM2 hereafter) [15]. The strong mo-

tion record above the heavily damaged Mashiki residential area recorded over 1.0g in the EW direction. The designations of EW and NS in the figures, respectively, indicate data channels of East-West, North-South directions. The maximum acceleration is 6.53 m/s^2 in the NS component and 11.57 m/s^2 in the EW component. In the seismic analysis, EW component was applied to the longitudinal direction and NS was applied to the transverse direction of the bridge structure.

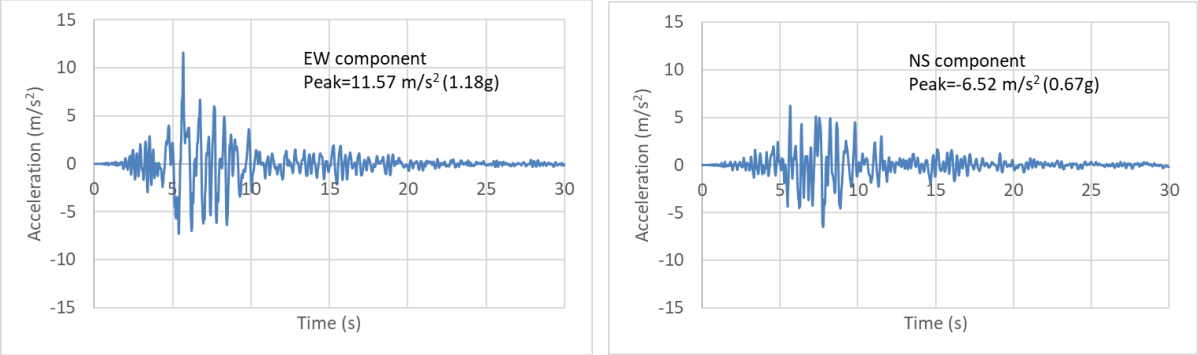

Figure 7: Accelerogram of Mashiki town EW component and NS component (GM2).

4 NUMERICAL METHOD

The equation of motion for a vehicle is written as [16] [17]

$$\boldsymbol{M}_v\ddot{\boldsymbol{u}} + \boldsymbol{C}_v(\dot{\boldsymbol{u}} - \dot{\boldsymbol{y}}_c) + \boldsymbol{K}_v(\boldsymbol{u} - \boldsymbol{y}_c) = \boldsymbol{0} \tag{1}$$

where $\boldsymbol{M}_v$, $\boldsymbol{C}_v$, and $\boldsymbol{K}_v$ respectively denote the mass, damping, and stiffness matrices of the vehicle, and where $\boldsymbol{u}$ represents the vector of vehicle's displacements and rotations at its degrees of freedom. A dot denotes the derivative with respect to time. $\boldsymbol{y}_c$ is the wheel displacement vector at the contact point. It is the summation of bridge displacement $\boldsymbol{w}_c$ and roughness $\boldsymbol{r}_c$ at that point.

The equation of motion for the bridge model is written as

$$\boldsymbol{M}_b\ddot{\boldsymbol{v}} + \boldsymbol{C}_b\dot{\boldsymbol{v}} + \boldsymbol{K}_b\boldsymbol{v} = \boldsymbol{f}_{seis} + \boldsymbol{f}_{vb} \tag{2}$$

where $\boldsymbol{M}_b$, $\boldsymbol{C}_b$ and $\boldsymbol{K}_b$ respectively stand for the mass, damping, and stiffness matrices of the bridge, and where $\boldsymbol{v}$ represents the vector of bridge's displacements and rotations at its degrees of freedom. Also, $\boldsymbol{f}_{seis}$ is the seismic loading. The force exerted by vehicle to bridge $\boldsymbol{f}_{vb}$ is the summation of vehicle weight, spring forces, and damping forces.

The two equations of motion (1) and (2) above are solved in a direct time integration manner to solve them at a certain time step $t+\Delta t$ (Δt is a finite small time increment) using the solution in previous time step t and the approximations for the derivatives. Newmark β-method [26] is adopted to solve equations of the equations of the vehicle and bridge system. The value of 0.25 is adopted for β to obtain stable and accurate solutions.

The Recursive Substructure Method (RSM) [11] was utilized to simulate the dynamic responses of bridges and moving vehicles under particular earthquake [18] [19]. It integrates the conventional nonlinear dynamic analysis in ABAQUS into the authors' in-house VBI-solving programs developed with MATLAB. The bridge Finite Element model is built in ABAQUS, and nonlinear dynamic analysis of bridge is conducted in ABAQUS. The vehicle model is built and the roughness profile is constructed in MATLAB. MATLAB controls the recursive ABAQUS executions and to perform time integrations in VBI problem. The time step of simulations was 0.01 s, being the same as the sampling period of the ground motion record.

5 SEISMIC RESPONSES OF HIGHWAY BRIDGE

5.1 Displacement responses of pier top and relative displacement of bearing

The shear force-displacement hysteresis loops of bearing, the longitudinal displacement responses of pier top and the moment-rotation hysteresis loops at pier base of P1 under GM1 are depicted in Figures 8-10 as typical example, and those of A1, P2 and A2 are omitted here for simplicity. As shown in Figure 9, the maximum displacement of pier top P1 under GM1 is about 0.04 m during first attack, and nonlinear behavior happened that caused a drift in the response of approximately 0.01 m. There is very little difference between the results with and without vehicle during the first attack. However, during the following second attack, which is like a strong aftershock of the first attack, the maximum displacement of the bridge appears and the displacement responses under second attack have larger amplitudes than those during first attack. From this phenomenon the larger residual displacement can be predicted. It is noteworthy that significant difference between two scenarios disregarding and regarding vehicles in the second attack could be found and the moving vehicles tend to reduce the displacement responses of the bridge, which indicates the presence of vehicles mitigates the variation tendency of the displacement response of the bridge while subjected to multi-attacks ground motions.

The relative displacements of bearings considering VBI under GM1 were slightly changed from those disregarding vehicles as indicated in Figure 8 and Table 7. The maximum relative displacements decreased by 0.6% for A1, by 3.8% for P1 and by 0.8% for P2, but increased by 2.4% at A2. The reason may be added damping and mass damper effect due to vehicle on the bridge. Another reason may be that the vehicle-bridge out-of-phase modes were excited by the ground motion and the vehicle's suspension system would suffer a larger deformation and dissipate more energy that was supposed to be dissipated by the rubber bearings. For example, the natural frequency of the vehicle-bridge out-of-phase mode in the Position 4 scenario is 1.971 Hz and it might be excited by the ground motion as indicated in Figure 6(b), and the out-of-phase mode might be excited by the ground motion. It can be said that the current seismic design disregarding vehicle dynamics was conservative if the rubber bearings were of concern.

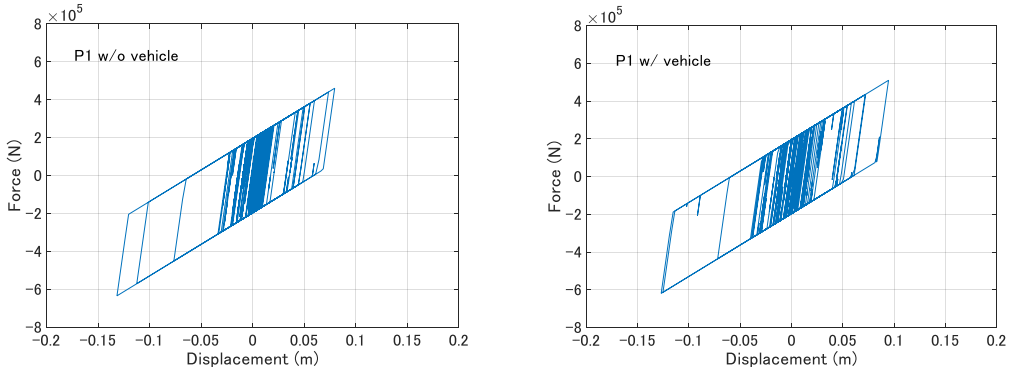

Figure 8: Hysteresis loop of bearing at P1 pier top under GM1, disregarding moving vehicles (left) and considering moving vehicle (right).

		Displacement	Reduction ratio * %
A1	w/o	0.164	0.6
	w/	0.163	
P1	w/o	0.132	3.8
	w/	0.127	
P2	w/o	0.126	0.8
	w/	0.125	
A2	w/o	0.168	-2.4
	w/	0.172	

Note. *reduction ratio is defined as the average displacement reduction from the w/o-vehicles case to the w/-vehicles case divided by the average displacement in the w/o-vehicles case.

Table 7: Maximum relative displacement of bearing under GM1 (unit: m).

The maximum longitudinal displacements of span center under GM1 were reduced when the moving vehicles presented by 1.8% as indicated in Table 8. Span center displacement is the summation of pier top displacement and bearing's relative displacement. Referring to Table 7 and 8, the span center maximum displacements and the bearing's maximum relative displacements are at a similar level (0.12 – 0.17 m), while the span center maximum displacements and the pier top maximum displacements (only about 0.06 m from Figure 9) are not. It indicates that the span center maximum displacements were more dominated by bearings' maximum relative displacements. As mentioned above, when the vehicles were considered on the bridge system, two modes appeared relevant to the first longitudinal mode of the bridge alone: vehicle-bridge in-phase and out-of-phase modes. Although the out-of-phase modes were excited by the ground motions to a similar level with the original bridge-alone mode was (see the pseudo acceleration response spectrum in Figure 6(c)), the phase-difference between vehicles and bridge might help bearings absorb energy and therefore reduce the bearings' relative displacements as well as the span center displacements.

The maximum displacements of pier tops were generally reduced when the moving vehicles presented (see Figure 9), and so were the residual displacements of pier tops as well as span center. Such ground motion caused the maximum displacement up to about 0.066 m and the residual displacement about 0.03 m at pier tops. But if vehicle-bridge interaction was considered, the reduction for maximum displacements was up to 19% and for residual displacement responses was 36%. The maximum displacement decreased by 13.8% at P1 pier top and 19.3% at P2 pier top; the residual displacement decreased by 31.6% at P1 pier top, 35.9% at P2 pier top, and 21.4% at span center, when vehicle–bridge interaction was considered. It could be concluded that the vehicles have a significant positive effect on the bridge's nonlinear displacement responses. When the moving vehicles were considered, the maximum rotation of the plastic hinge at pier base was smaller than those without vehicle under the ground motion (see the moment-rotation hysteresis loops in Figure 10), indicating that the bridge suffered from weaker plastic deformations. Table 9 quantifies the reduction of the maximum rotation: 37.5% at P1 pier base and 39.3% at P2 pier base. This trend is in line with that of the maximum longitudinal displacement of the pier tops, because pier top displacements and pier base rotations are related to each other acknowledging the fact that pier top displacements were majorly caused by pier-base rotations and pier deformations. The reason for the reduction in these responses can be pier base rotation and pier deformation's complex combination with out-of-phase motion of the system.

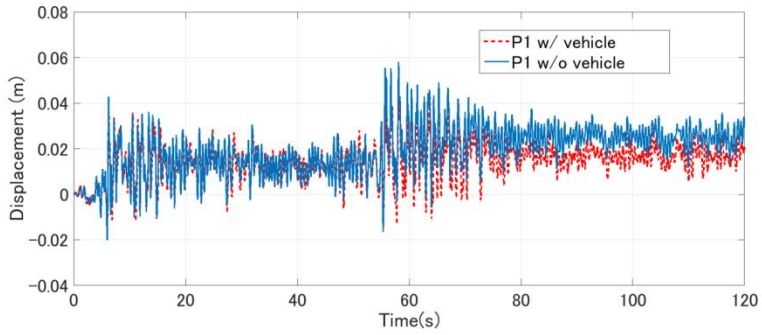

Figure 9: Longitudinal displacement responses of the pier top P1 under GM1.

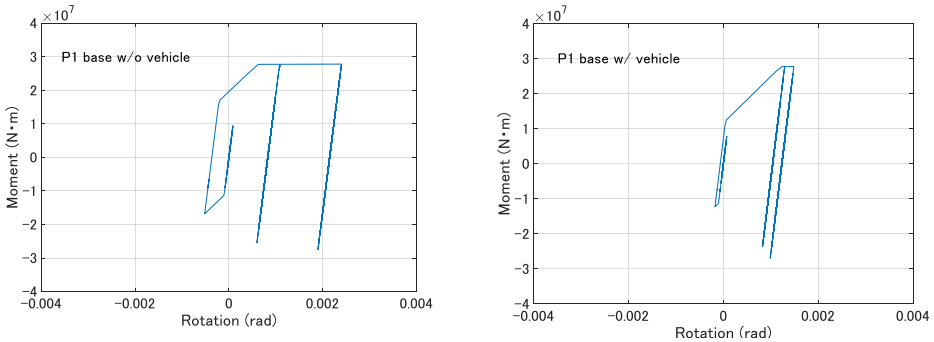

Figure 10: Hysteresis loop of plastic hinge at pier P1 base under GM1, disregarding moving vehicles (left) and considering moving vehicle (right).

Pier		Maximum displacement	Reduction ratio * %	Permanent dis-placement	Reduction ratio * %
Span center	w/o	0.166	1.8	0.014	21.4
	w/	0.163		0.011	
P1	w/o	0.058	13.8	0.025	31.6
	w/	0.050		0.017	
P2	w/o	0.066	19.3	0.031	35.9
	w/	0.053		0.020	

Note. *reduction ratio is defined as the average displacement reduction from the w/o-vehicles case to the w/-vehicles case divided by the average displacement in the w/o-vehicles case.

Pier		Rotation	Reduction ratio* %
P1	w/o	0.0024	37.5
	w/	0.0015	
P2	w/o	0.0028	39.3
	w/	0.0017	

Note. * reduction ratio is defined as the average rotation reduction from the w/o-vehicles case to the w/-vehicles case divided by the average rotation in the w/o-vehicles case.

Table 9: Maximum rotation of plastic hinge at pier base under GM1 (rad).

The hysteresis loop of bearing at P1 pier top and the longitudinal displacement responses of pier top under GM2 are depicted in Figures 11 and 12 as typical example, and those of A1, P2, A2 and the moment-rotation hysteresis loops at pier base are omitted here for simplicity. The maximum relative displacements of bearings considering VBI under GM2 increased up to 10% at A1, P1 and P2, but decreased slightly at A2 as indicated in Table 10. The maximum longitudinal displacements of pier tops were slightly reduced and the maximum displacement of span center was amplified a little, when the moving vehicles presented as shown in Table 11. The residual displacements of observation points were amplified by considering vehicle-bridge interaction up to 17% compared with those without considering vehicle-bridge interaction. Under strong ground motion GM2, the consideration of vehicle dynamics might yield larger longitudinal displacement and maximum relative displacement of bearing than those with bridge alone. The maximum rotation of the plastic hinge at pier base was reduced about 10% under moving vehicles compared with those with bridge alone subjected to GM2.

Pier		Rotation	Reduction ratio*%
P1	w/o	-0.026298	10.1
	w/	-0.023652	
P2	w/o	-0.026038	9.7
	w/	-0.023504	

Note. * reduction ratio is defined as the average rotation reduction from the w/o-vehicles case to the w/-vehicles case divided by the average rotation in the w/o-vehicles case.

Table 12: Maximum rotation of plastic hinge at pier base under GM2 (unit: rad).

In general, in case of fully loaded traffic condition under strong earthquakes, ignoring vehicle effects would be on the non-conservative side. The vehicles had a significant negative effect on the bridge's nonlinear displacement responses.

5.2 Acceleration responses

Figure 13 shows the time history of the longitudinal acceleration observed at P1 pier top for example. The peak and RMS values of longitudinal acceleration responses of observation points are summarized in Figure 14.

From the peak and RMS values of longitudinal acceleration responses at span center and pier tops shown in Fig. 12, it is readily apparent that vehicles reduced the peak at span center and RMS values at span center and pier tops compared with that of disregarding vehicles, even if the peak values of acceleration responses at pier tops were amplified. The reduction in bridge acceleration could be explained by the relationship between the bridge's fundamental frequency and the response spectra of ground motions. The in-phase modes of the system were excited by the ground motions to cause the seismic responses of the bridge to a level lower than the original bridge-alone modes was. For example, in the pseudo acceleration response spectrum of the ground motion (Figure 6(c)), the spectral acceleration corresponding to the natural period (0.742 s, i.e. 1.348 Hz to the natural frequency) of the vehicle-bridge in-phase mode in Position 4 scenario, is smaller than that corresponding to the natural period (0.549 s, i.e. 1.822 Hz) of the bridge alone. The additional vehicle dynamics might move the system's fundamental period to a more favorable part of the spectrum where the spectral accelerations are less than the conventional case disregarding vehicle. Another reason may be the vehicles act as mass-spring-damper systems on the bridge. The natural period (0.549 s, i.e. 1.822 Hz) of the bridge alone and the longitudinal natural period (0.487 s, i.e. 2.052 Hz) of the vehicle are indicated in pseudo acceleration responses spectra of the ground motion in Fig. 6(c) and the vehicle and bridge would be excited by the ground motions. The vehicle resonated out of phase with the bridge motion and caused a phase difference in the bridge structural response, which affects the acceleration responses in way of a damper-like action.

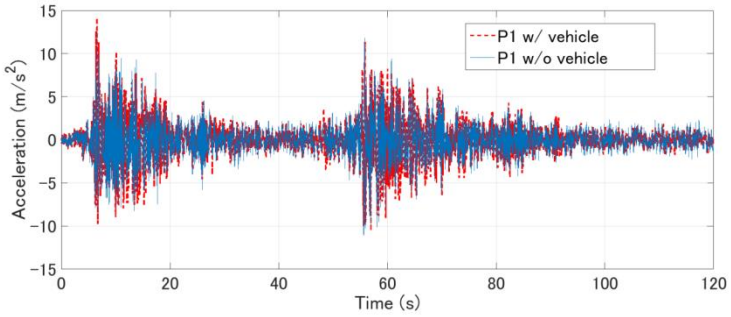

Figure 13: The time history of longitudinal acceleration responses of the bridge at pier top of P1 under GM1.

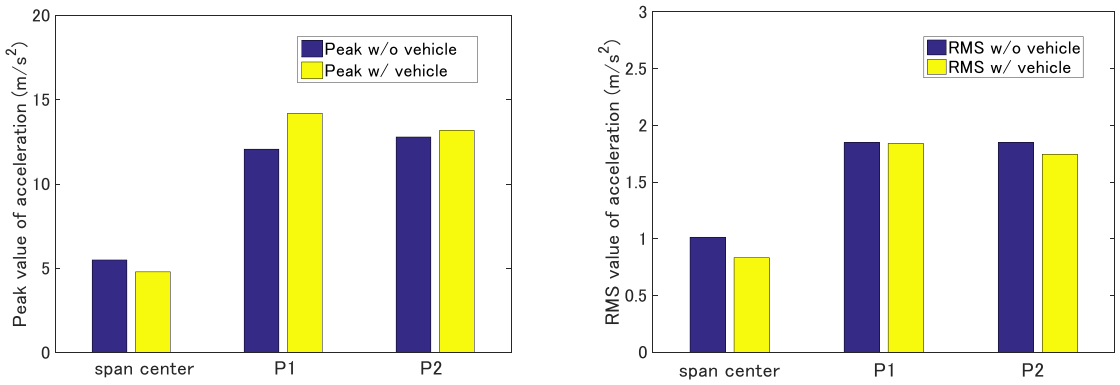

Figure 14: Peak (left) and RMS values (right) of longitudinal acceleration response of the bridge under GM1.

Figure 15 shows the time history of longitudinal acceleration responses of P1 pier top under GM2 as a typical example. Figure 16 shows the peak and RMS values of longitudinal acceleration responses of P1, P2 pier top and span center under GM2. As expected, they presented differently between the cases of regarding and disregarding moving vehicles. From the time histories, peak value and RMS values of longitudinal acceleration responses of observations points, it can be known that the longitudinal acceleration responses of the bridge generally decreased when the vehicles were considered in comparison with those when the vehicles were not considered. The observations presented herein showed that ignoring vehicle effects might be conservative when the acceleration responses were of concern.

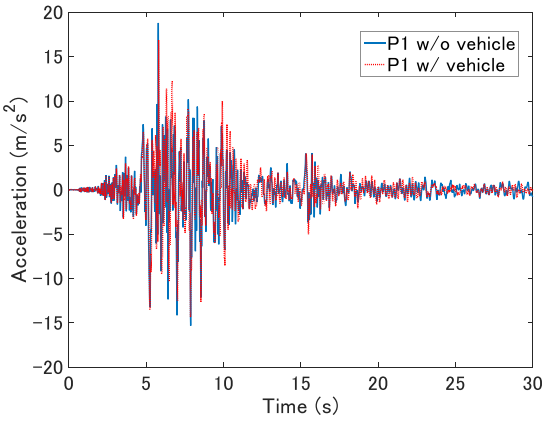

Figure 15: The time history of longitudinal acceleration response of P1 pier top under GM2.

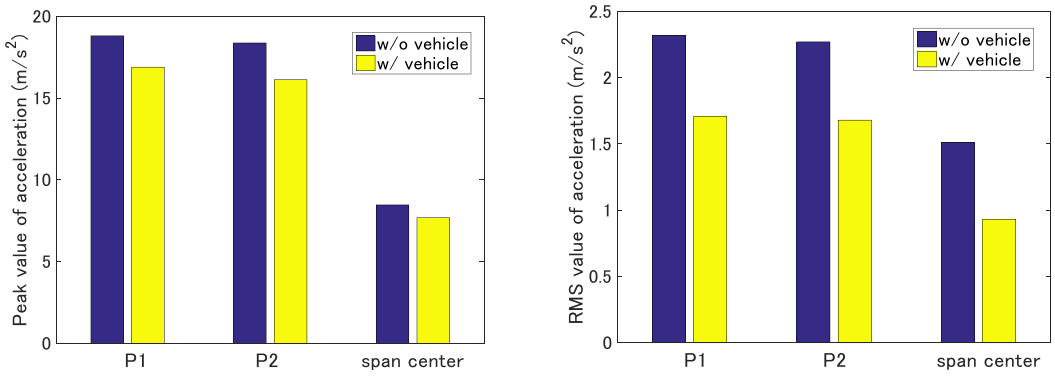

Figure 16: Peak (left) and RMS values (right) of longitudinal acceleration response of the bridge under GM2.

6 CONCLUSIONS

- In the longitudinal displacement, the presence of moving vehicles tends to reduce the maximum displacement and the permanent displacement under ground motion of Tohoku earthquake; reduce the maximum displacement and amplify the permanent displacement under ground motion of Kumamoto earthquake.
- In the bearing's relative displacement, the presence of moving vehicles tends to reduce the maximum displacement under ground motion of Tohoku earthquake, and amplify under ground motion of Kumamoto earthquake.

- The presence of moving vehicles reduced the RMS values of acceleration responses slightly even if increased the peak values of acceleration responses of bridge under ground motion of Tohoku earthquake;
- The results emphasized the need and importance of considering vehicle-bridge interaction as well as different ground motions in seismic design of bridges.
- The current assumption of ignorance of vehicle effect in seismic design of highway bridges might be non-conservative.

Keywords: Tuned liquid dampers, Equivalent mechanical model, Non-linear modeling, Experimental analysis, Earthquake engineering.

Abstract. *The behavior of tuned liquid dampers subjected to random base motion has been investigated extensively. However, their efficiency in reducing the dynamic response of structures under earthquake excitation is still not completely understood. A non-linear modeling strategy based on Yu's model was implemented to perform numerical analyses on a 21-story building subjected to seismic base excitation. Three tank shapes were investigated: a rectangular tank, a vertical cylindrical tank, and a horizontal cylindrical innovative TLD. An experimental campaign has been conducted on a scaled physical model in order to calibrate the numerical model and validate its results. The effects of the dampers were evaluated in terms of structural relative displacements and absolute accelerations. Dampers efficiency in reducing the structural response was evaluated for different mass ratios. The non-linear numerical model showed good capability in reproducing experimental results for the rectangular tank. Some limitation has been evidenced for the other tank shapes, suggesting the use of different numerical techniques or the development of specific non-linear mechanical models. Results obtained from experimental and numerical analyses show that reduction of peak response during earthquake excitation is often limited and dependent on ground motion history. However, TLDs where found to be effective in reducing structural response when the structure experience free vibration motion.*

1 INTRODUCTION

Tall buildings can experience large displacements when excited by wind or earthquakes. Various methods for vibration control of tall buildings have been developed through the years. One of such methods is the use of the tuned mass damper (TMD) which is a mass connected to the main structure. The TMD-structure connection is designed so that the vibration frequency of the TMD is tuned to one of the structural frequencies. The purpose of such device is to diminish the structural response by oscillating out of phase with the structure and to dissipate energy. There have been various applications of TMDs [1] and in many of the cases they occupy a large amount of space in the structure, sometimes even whole floors. One particular variation of the TMD is the tuned liquid damper (TLD) which was first studied by Fujino et Al. [2] and Sun et Al. [3]. A TLD is a container partially filled with a liquid. It is similar to the TMD in the sense that the contained liquid acts as the mass of a TMD. The sloshing of the liquid inside the container can dissipate energy in many different ways compared to a solid mass. It is thus necessary to model the dynamics of the contained fluid in depth, in order to be able to predict the behavior of the TLD. In this context, Sun et Al. [4] proposed a non-linear model based on shallow water wave theory which considered wave breaking. Reed and Al. [5] and Yu et Al. [6] studied the behavior of tuned liquid dampers under large amplitude excitation and developed a non-linear mechanical model with stiffness and damping parameters which are dependent on the TLD base excitation amplitude. Kareem et Al. [7] developed a numerical model which is capable to simulate the slamming phenomenon and can predict the pressure peaks on tank walls due to this effect. Tanks with non-horizontal bottoms, such as conical or spherical, were investigated by Casciati et Al. [8] and Gardarrson et Al. [9]. Particular emphasis in the study of curved bottom TLDs was given by the works of Tait and Deng [10] and Bandyopadhyay et Al. [11]. In particular, Tait and Deng [10] showed that the horizontal cylinder TLD is more robust and offers greater performance in the reduction of structural response due to harmonic load, compared with rectangular and vertical cylinder TLD. Bandyopadhyay et Al. [11] developed a boundary element method (BEM) to estimate the sloshing frequency of parabolic shaped bottom TLDs. The main sloshing frequency of a horizontal cylinder TLD is less dependent on the liquid height with respect to other tank shapes, so it is less sensitive to detuning problems due to variations in the water depth. The capability of tuned liquid dampers in reducing structural response of buildings under earthquake excitation was investigated by Banerji et Al. [12], who used a numerical method based on shallow water wave theory to solve the water motion in the TLD. Further relevant studies include the work of Novo et Al. [13], who investigated the reduction response provided by TLDs installed on a 9-floors concrete building. A new experimental testing technique called Real-Time Hybrid Simulation (RTHS) was successfully employed by Lee et Al. [14] and Wang et Al. [15] to study multi-degree-of-freedom (MDOF) structures with installed TLDs. This approach recalls the hardware-in-the-loop method used by Yalla [16] and allows to perform experimental dynamic shaking table tests on complex MDOF systems by physically representing only a part of them. The other part is represented and solved numerically in real time. This technique allows to avoid building large and heavy structural models and to test tuned liquid dampers at the full scale. In any case, to do this, there is the need for a shaking table which can carry the weight of the full-scale water tank.

In the present work we experimentally investigate the effect of tuned liquid dampers on the response of a 21-floor concrete building. The structure was modeled as a single-degree-of-freedom (SDOF) system and the TLDs were represented with plexiglass and glass containers filled with water. Three tank shapes have been investigated: a rectangular tank, a vertical cylin-

drical tank and a horizontal cylindrical tank. The performance of the TLDs was determined in terms of reduction of peak response for relative displacements and absolute accelerations. Then, a non-linear mechanical model was implemented following the formulation proposed by Yu et Al. [6]. The model was validated on experimental results and tested with a recorded ground motion, for different values of mass ratio.
The paper is organized as follows. The second section presents a description of the case study. In the third section of the paper the experimental setup and results are presented. The fourth section deals with the numerical modeling of the TLD-structure system and the numerical analysis results. In the fifth section main conclusions are summarized and further developments are proposed.

2 CASE STUDY DESCRIPTION

The case study presented in this work is a 21-floor concrete building located in Baku, Azerbaijan. The building is composed by two adjacent blocks, as indicated in figure 1, separated by a $16cm$ wide joint. Resistance for horizontal seismic actions is provided by columns and shear walls. The plan dimensions of the east block are 22x20m while those of the west block are 22x32m. The maximum height of the building is $68m$. In this study we analyzed the ability of a TLD installation to reduce the maximum displacement experienced by the east block during a seismic event. The possibility of limiting the peak displacements of the blocks appears desirable, in order to limit damage due to pounding between the two structures. In the following of the paper we will refer to the east block as "the building" or "the structure", as it was taken as the block where TLD system is to be installed. Modal analysis of the structure provides a first mode which has a period $T_p = 4.06s$, a modal participation factor $\Gamma_p = 50.175\%$ and a participating mass $M_p = 3104t$. The total mass of the structure is $9783.22t$. In this study, we modeled the structure as a single-degree-of-freedom (SDOF) system, with mass, stiffness and damping properties equal to those of the first vibration mode of the real building. Damping ratio was assumed equal to $\xi = 2\%$ and stiffness is equal to $K_p = 7416kN/m$.

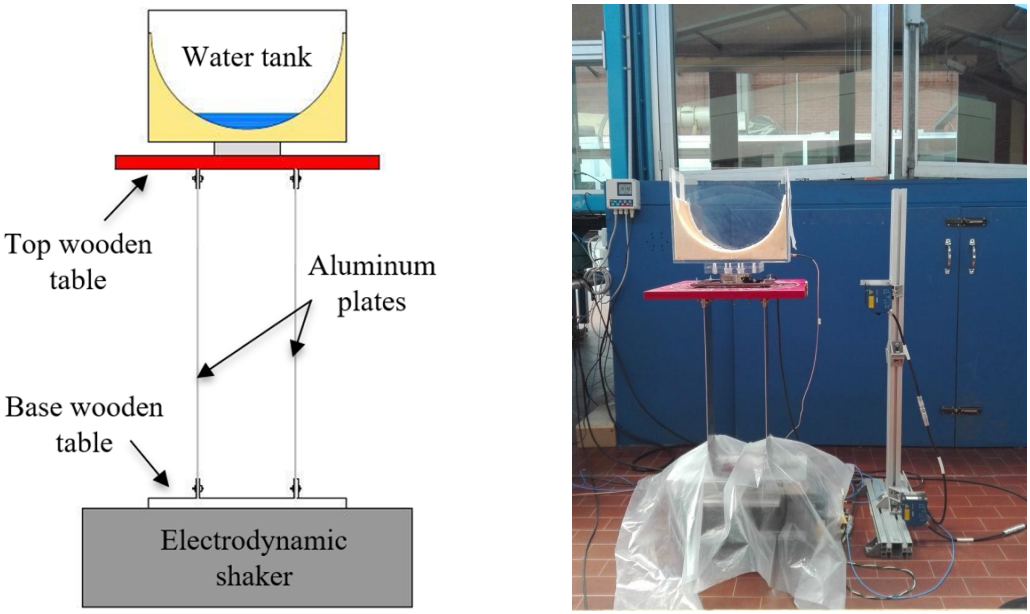
3 EXPERIMENTAL TESTS

3.1 Scale model for TLD-structure interaction

In order to conduct experimental tests, the SDOF structure was represented with a scaled reverse pendulum physical model, composed of a wooden table supported by two rectangular aluminum plates fixed to a wooden base, as shown in figure 2. The mass of the system was represented by the upper wooden table and by the mass of the container, while the stiffness was provided by the flexural stiffness of the two steel plates. The shear-type lateral deformation of the two steel plates presents an equivalent stiffness $k_m = 890N/mm$ and a damping ratio $\xi_m = 0.007$. Since the damping ratio for the experimental model is out of scale, numerical comparisons have been made using the experimental value ξ_m for time history analyses. Three different tank shapes have been investigated, namely rectangular, vertical cylindrical and horizontal cylindrical. Due to the restriction given by the available tank dimensions and load bearing capacity of shaking table, the three physical models which represent the prototype have different scale ratios and the number of the installed TLDs was different for every tank shape. The consequence is that the mass ratio μ, calculated as the ratio between total liquid mass and total mass of the structure, was different for every tank shape.



(a) (b)

Figure 2: a) Sketch of the experimental setup, b) Horizontal TLD-structure system.

Water depths were chosen in order to tune the TLD to the structure. Linear sloshing formulations, as reported by Ibrahim [17], were employed to calculate sloshing frequencies for rectangular and vertical cylindrical tanks. Horizontal cylinder sloshing frequency has been evaluated using the formulation proposed by McIver [18]. The rectangular tank dimensions were 150x$150mm$; the vertical cylinder has a radius of $67mm$ and the horizontal cylinder radius was $145mm$. Since the liquid density and the gravity acceleration were the same for the prototype and the experimental model, the length scale ratio allows to determine scale ratios for all the other variables.

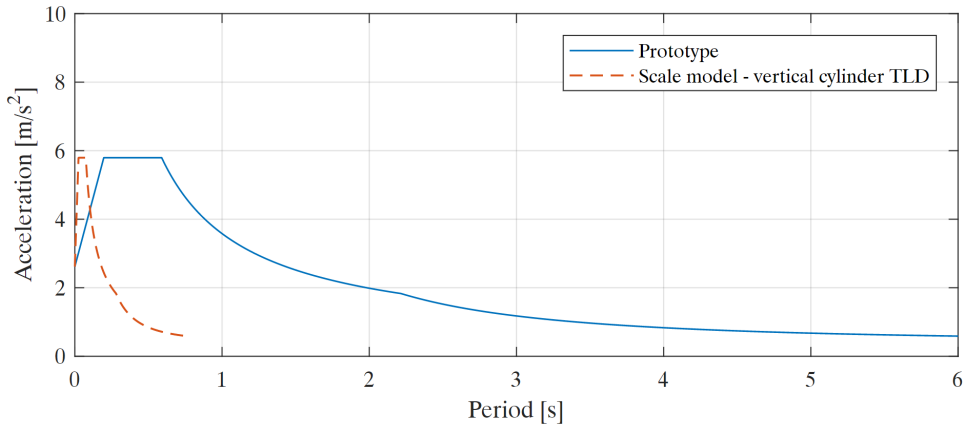
Tank shape	$h[m]$	$m_w[kg]$	$m_s[kg]$	$m_s^{tot}[kg]$	$\mu[\%]$	$f_w[Hz]$	λ	n
Rectagular	0.024	0.540	10.013	31.765	1.7	1.554	39.6	5
Vertical cylinder	0.023	0.324	6.384	20.250	1.6	1.954	62.5	2
Horizontal cylinder	0.032	0.596	7.730	24.833	2.4	1.333	51	3

Table 1: Parameters of the three experimental models.

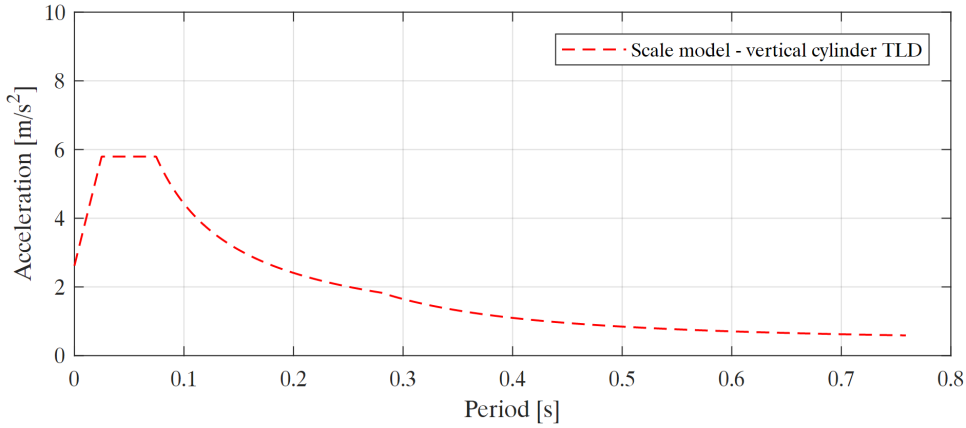
In table 1 the values of liquid height h, total liquid mass m_w (assumed equal to the convective mass), structural mass of the SDOF system m_s, scaled total structural mass m_s^{tot}, mass ratio μ, sloshing frequency f_w, number of required TLDs n and length scale ratio λ are reported.

3.2 Response reduction for artificial ground motion

The three TLD-structure systems were tested with an artificially generated accelerogram. The design acceleration response spectrum was chosen according to Akhundov et Al. [19] and is presented in figure 3. The original design spectrum was scaled along the time axes using the scale ratio for the vertical cylinder model, in order to obtain the scaled response spectrum for the experimental model.



(a)



(b)

Figure 3: a) Original and scaled response spectra, b) Spectrum for vertical cylinder model.

A ground motion compatible with the scaled spectrum was generated using the software SIMQKE-I developed by Gasparini and Vanmarcke [20]. The generated accelerogram was scaled along the time axes in order to obtain ground motions for the rectangular and horizontal cylinder setups. After that, the three ground motions were scaled along the acceleration axes to obtain acceleration time histories with different values of peak ground acceleration (PGA). Three values of PGA were used, namely, $2.5m/s^2$, $3.5m/s^2$, $4.5m/s^2$.

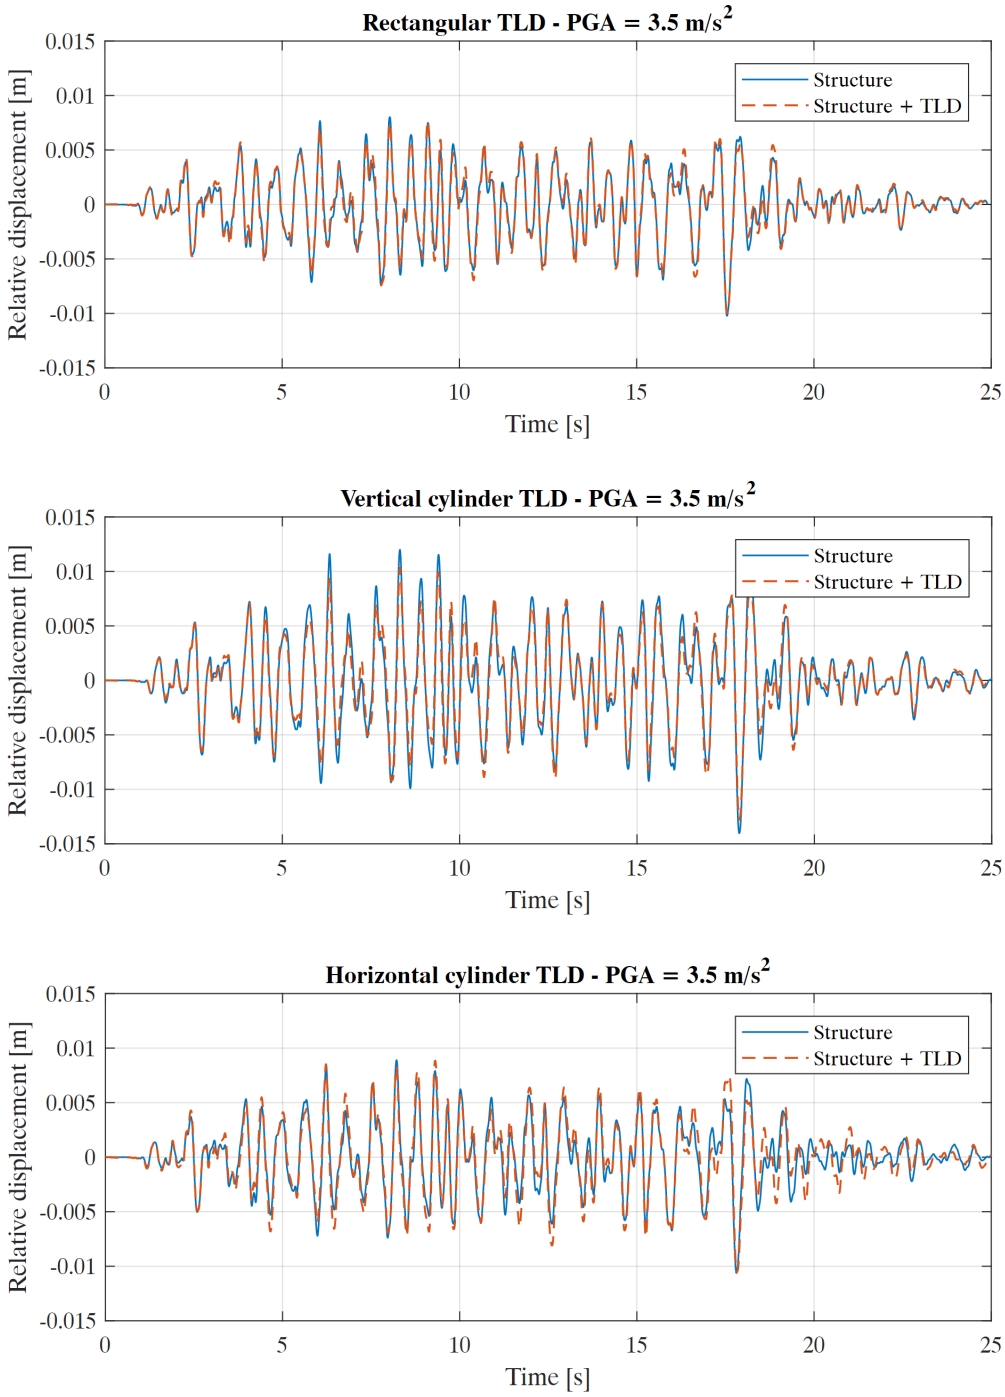


Figure 4: Example of relative displacements time histories for the three experimental models.

The ground motion inputs were applied by a long stroke electrodynamic shaker, controlled by a Labview routine. Acceleration and displacement were measured at the base and at the top of the structure, by means of capacitive accelerometers and laser displacement transducers. Measured data were filtered using a lowpass filter with a cutoff frequency equal to $20Hz$ for displacements and $25Hz$ for accelerations. Relative structural displacements are directly related to the shear force acting on the structural elements, and they also are responsible for pounding between adjacent structures when the buildings experience the same base motion. Moreover, absolute acceleration at the top of the structure generates seismic force on appendages and non-structural elements at the top floor of the building. For the previous reasons, the evaluation of TLD efficiency was measured in terms of reduction of relative displacement and absolute accelerations at the top of the structure. An example of time history comparison of relative displacement response for the three TLD-structure systems are presented in figure 4 for the case of $PGA = 3.5m/s^2$. For this comparison, vertical cylinder and horizontal cylinder response have been scaled at the same scale of the rectangular TLD, in order to have comparable time and displacement measures.

It can be seen that the design procedure adopted for the experimental setups has led to different maximum displacements for the different scale ratio sets. For further studies it will be important to consider the same scale ratio set for every tank shape. In figure 5 experimentally measured reduction of peak response (RPR) are presented for the three tank shapes. The RPRs for relative displacements and absolute accelerations have been defined as:

$$R_d = \frac{\max\{|d_r^{(s)}|\} - \max\{|d_r^{(s+TLD)}|\}}{\max\{|d_r^{(s)}|\}} \qquad R_a = \frac{\max\{|a_r^{(s)}|\} - \max\{|a_r^{(s+TLD)}|\}}{\max\{|a_r^{(s)}|\}}$$

Results evidence that RPR for relative displacement varies in the range of $-2\% \div 13\%$ and RPR for absolute acceleration ranges between 2.5% and 19%.

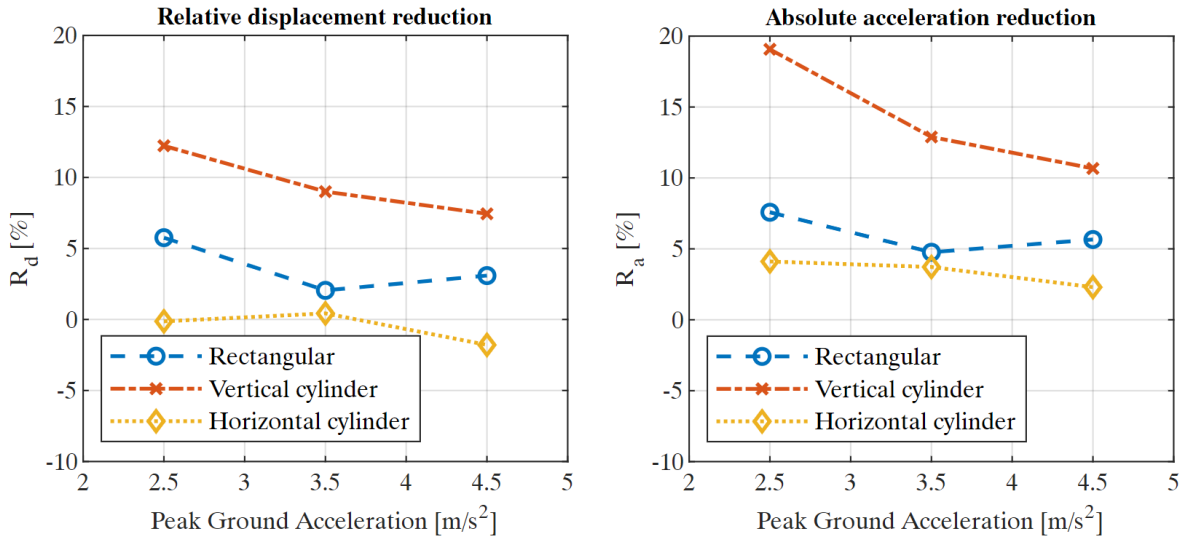

Figure 5: Reduction of peak response in terms of relative displacements and absolute accelerations for the three experimental models.

It is hard to identify a trend which is confirmed for all the tank shapes. In fact, since the ground motions for the different $PGAs$ have the same peaks distribution in time but different acceleration values, the displacement histories experienced by the base of the structure are significantly different. For this reason, the comparison of peak reductions for different $PGAs$ doesn't necessarily provide a trend, as in the case of the rectangular tank.

4 NUMERICAL MODELLING AND RESULTS

4.1 Non-linear mechanical model

In order to perform numerical time history analysis, a non-linear mechanical model was implemented to describe the TLD behavior. The formulation developed by Reed et Al. [5] and Yu et Al. [6] provides an equivalent mechanical model called "Non-linear Stiffness and Damping model" (NSD) in which stiffness and damping parameters of the TLD vary with amplitude excitation at the base of the water tank. The model was originally developed for a rectangular TLD and it was calibrated by matching the numerical energy dissipation curves to their corresponding experimental counterparts which were determined under harmonic base excitation. Say A is the amplitude of the harmonic motion experienced by the tank. The non-dimensional base excitation Λ can be expressed as:

$$\Lambda = \frac{A}{L}$$

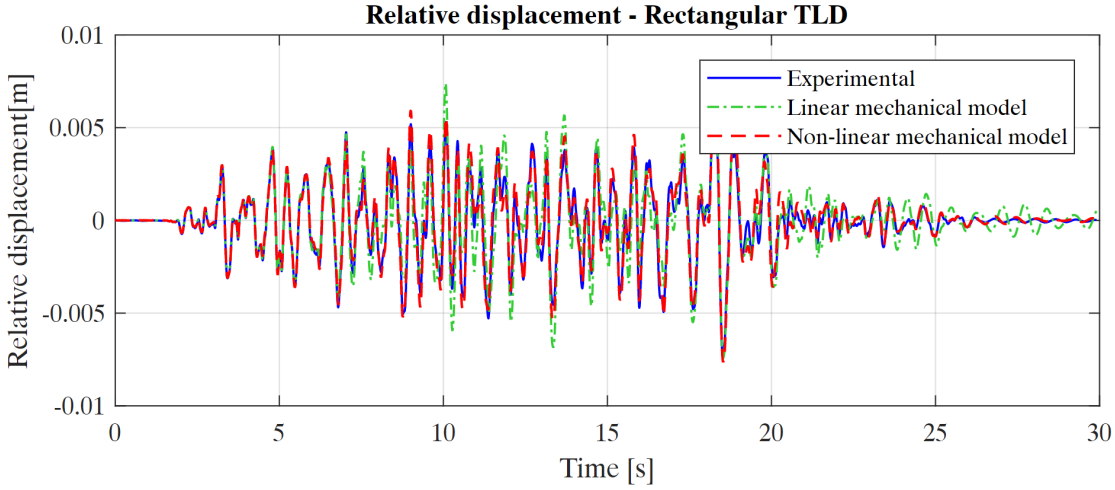
where L is the length of the rectangular tank. The amplitude dependent damping ratio can be expressed as:

$$\xi_{NSD} = 0.52 \cdot \Lambda^{0.35}$$

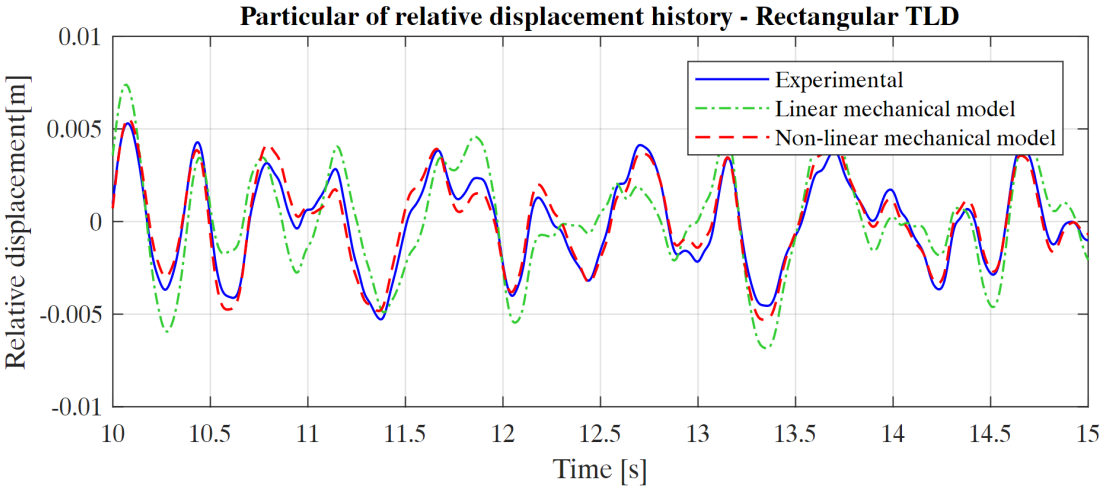
The stiffness of the equivalent system k_{NSD} can be defined as the product of the linear modeling stiffness k_l (obtained from the linear sloshing frequency of the rectangular tank) and an amplitude dependent stiffness coefficient κ, defined as:

$$\begin{aligned} \kappa &= 1.075 \cdot \Lambda^{0.007} \qquad & \Lambda \leq 0.003 \\ \kappa &= 2.52 \cdot \Lambda^{0.25} \qquad & \Lambda > 0.003 \end{aligned}$$

In order to use the NSD model for a tank shape different from the rectangular one, it is necessary to treat the tank as it would be a rectangular tank, by calculating its equivalent length and width such that the water mass, water height and sloshing frequency would be the same as those of the rectangular tank. In figure 6 the time history of relative displacement for the experimental model with the rectangular TLD and $PGA = 2.5m/s^2$ is presented. It can be seen that, while the linear model overestimates the response in several parts, the non-linear mechanical model shows a good capability in reproducing the structural response.



(a)



(b)

Figure 6: Comparison of experimental and numerical relative displacement history for rectangular TLD for the case with $PGA = 2.5m/s^2$ a) Complete time history, b) Range between $10s$ and $15s$.

In order to quantify the accuracy of numerical models, a measure of the error done by the numerical model over the whole response time history was defined as:

$$e = \frac{RMS_{num} - RMS_{exp}}{RMS_{exp}} \cdot 100 \quad [\%]$$

where RMS_{exp} and RMS_{num} are the root mean squares of the experimental and numerical relative displacement time history respectively. In table 2 the values of the error e are showed for every experimental test. It can be seen that the non-linear model performs well for the rectangular tank shape, while larger errors can be found for the vertical cylindrical and horizontal cylindrical tank shapes. For the rectangular and the vertical cylindrical TLD both the linear and the non-linear model overestimate the experimental results. For the horizontal cylindrical TLD the linear model provides displacement values which are greater than those experimentally mea-

sured. On the other side, non-linear model behaves in the opposite manner. These differences in error values can be addressed to the dissipation mechanisms of the water mass that occur in the rectangular tank, compared with those of the other tank shapes. A better accuracy in the modeling of non-rectangular shape TLDs can be achieved by using different approaches such as other numerical methods or ad hoc developed non-linear mechanical models.

Errors [%] for $\mathbf{PGA = 2.5 m/s^2}$

	Rectangular	Vertical cylinder	Horizontal cylinder
Linear model	5.1	10.6	3.9
Non-linear model	4.0	14.1	-6.5

Errors [%] for $\mathbf{PGA = 3.5 m/s^2}$

	Rectangular	Vertical cylinder	Horizontal cylinder
Linear model	7.3	14.8	4.0
Non-linear model	3.6	24.6	-5.7

Errors [%] for $\mathbf{PGA = 4.5 m/s^2}$

	Rectangular	Vertical cylinder	Horizontal cylinder
Linear model	9.5	35.0	4.6
Non-linear model	2.9	21.9	-5.8

Table 2: Numerical models percentage errors for relative displacements time histories.

4.2 Analyses with recorded ground motion

In order to test the numerical model with a recorded accelerogram the Kobe ground motion was selected and scaled in order to have a PGA equal to $0.5g = 4.903 m/s^2$. Only the rectangular TLD was used and the non-linear numerical model was employed. Figure 7 illustrates the applied ground motion.

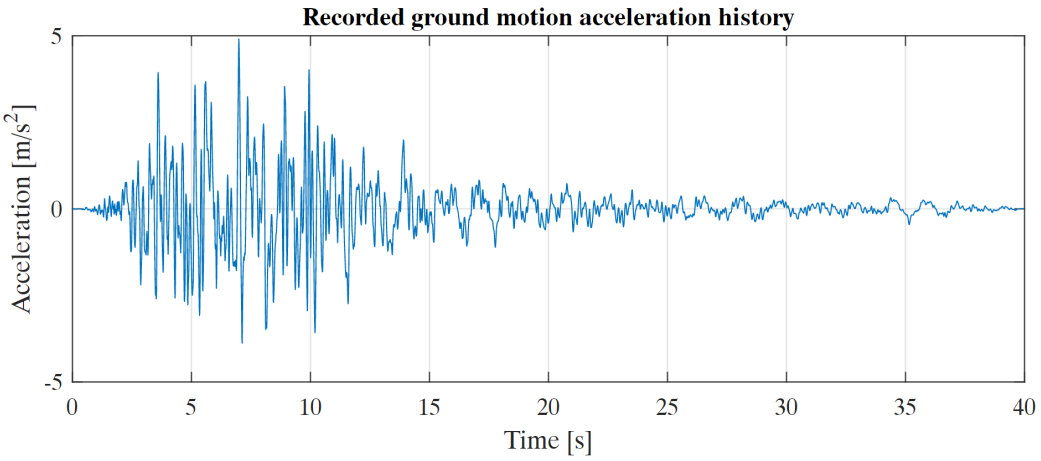


Figure 7: Kobe earthquake ground motion acceleration history used for the numerical analysis.

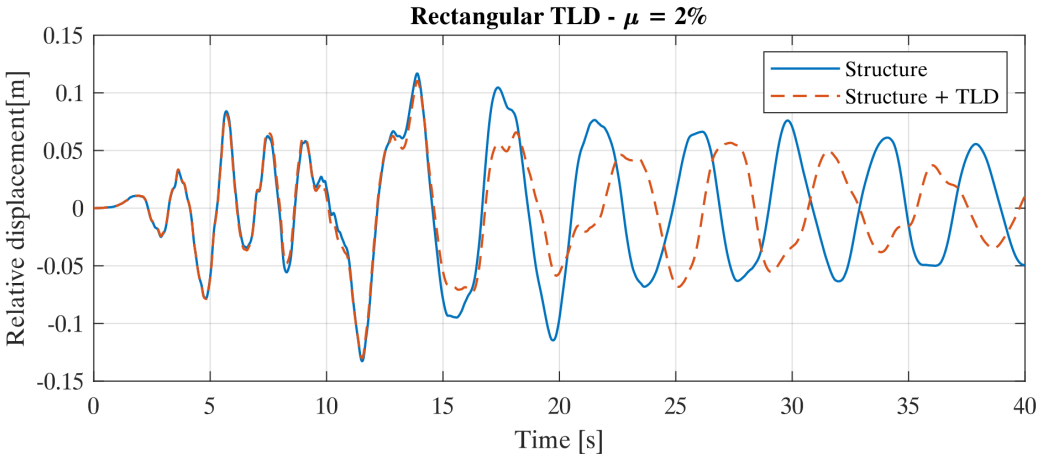

Figure 8: Numerical results for the rectangular TLD-structure system under Kobe earthquake.

The numerical analysis was conducted at the prototype scale and five TLDs were employed, with length $L = 6m$, width $b = 7m$ and water depth $h = 0.95m$. The mass ratio was equal to 2%. The relative displacement response is represented in figure 8. The reduction of the peaks in relative displacement and absolute acceleration responses are $R_d = 1.67\%$ and $R_a = 4.9\%$ respectively. A greater reduction in relative displacements is observed in the part of the response where the structure is in free vibration (i.e. the part of the response history after $15s$) as recognized by Fujino et Al. [2]. Figure 9 depicts the variation of RPR with the mass ratio, for relative displacements and absolute accelerations. It can be seen that, while the absolute acceleration reduction increases with the mass ratio, for the relative displacement there is an optimum value, after which the performance of the TLD decreases. However, it is important to underline that these graphs have been evaluated for the present structure and for the Kobe ground motion. The peak reduction (for response peaks which occur during the forced part of the history, i.e. when the particular part of the solution is prevailing) is strongly dependent on the ground motion and even when it exists, the reduction is often nearly negligible.

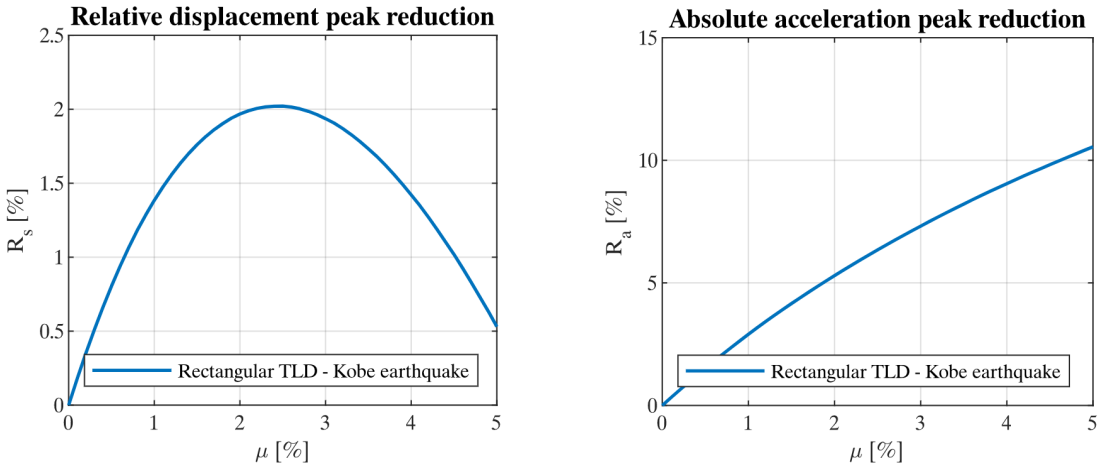

Figure 9: Relative displacement and absolute acceleration peak reduction variation with mass ratio for structure subjected to the Kobe earthquake for rectangular TLD.

5 CONCLUSIONS

This work investigated the seismic response of a tall building with tuned liquid dampers of different shapes installed. Three different scale models of the TLD-structure system were designed, built and tested with an artificially generated accelerogram applied at the base of the model by an electrodynamic shaker. Time histories of relative displacement and absolute acceleration of the structure were compared, for the structure only and for TLD-structure system. Results show that reductions of peak response are in the range of $0 \div 20\%$. However, in some cases, an increase in peak response was found. Numerical analyses showed that the non-linear mechanical model proposed by Yu et Al. [6] is suitable for performing time history analysis with seismic base excitation. The model can be employed for every tank geometry, by converting it into an equivalent rectangular tank, with the same liquid height, liquid mass and sloshing frequency. This approach yields good results when the sloshing motion and the energy dissipation curves for the tank are similar to those of a rectangular tank. For the horizontal cylindrical TLD a better modeling strategy could be obtained by using, for instance, a pendulum mechanical model, a specifically developed non-linear mechanical model, or a different numerical technique. Numerical analyses with a recorded ground motion showed that a TLD installation can effectively reduce the structural motion only when the structure experience a free vibration motion. TLDs are consequently not the best choice as a retrofit, in case the seismic response mitigation is necessary for a tall building. However, the capability of limiting the structural response during harmonic motions can be particularly useful for reducing the response of non-structural elements in resonance conditions. In fact, when the building vibrates with its own period, a secondary element can experience resonant conditions if both the secondary element and the building have similar vibration frequencies. In this case, a TLD installation above the secondary element can be very effective in reducing its peak response.

ACKNOWLEDGEMENTS

Part of the experimental campaign was conducted using the facilities of the CRIACIV boundary layer wind tunnel laboratory. The authors would thank Prof. Gianni Bartoli and Dr. Tommaso Massai from University of Florence for their very useful ideas and suggestions.

Abstract

Passive vibration absorbers are widely used in structural control. They usually consist in a single-degree-of-freedom appendage of the main structure, tuned to a selected structural target mode by means of frequency and damping optimization. A classical configuration is the pendulum type, whose mass is bilaterally constrained along a curved trajectory and is typically connected to the structure through viscous dashpots. Although the principle is well known, the search for improved arrangements is still under way. In recent years this investigation has inspired a new type of bidirectional pendulum absorber (BPA), consisting of a mass moving along an optimal three-dimensional (3D) concave-up surface. For the BPA, the surface principal curvatures are conceived to ensure a bidirectional tuning to both principal modes of the structure, while damping is provided either by horizontal viscous dashpots or by vertical friction dampers between the BPA and the structure. In this paper, a BPA variant is proposed, in which damping is produced by the variable tangential friction force developing between the pendulum mass and the 3D surface, because of a spatially-varying friction coefficient. In fact, a friction coefficient pattern is proposed that varies along the pendulum surface proportionally to the modulus of the surface gradient. With this assumption, the absorber dissipative model proves nonlinear homogeneous at low response amplitudes. The resulting homogeneous BPA (HBPA) has a fundamental advantage over conventional friction-type absorbers, in that its equivalent damping ratio is independent of the amplitude of oscillations, i.e. its optimal performance is independent of the excitation level. At the same time, the HBPA is more compact and simpler than viscously damped BPAs, not requiring the installation of dampers. This paper presents the analytical modelling framework of the HBPA and a method for its optimal design. Numerical simulations under wind and earthquake loads are reported to compare the HBPA with classical viscously damped BPAs. Finally, the HBPA proves a promising alternative to existing pendulum absorbers, and the homogeneous tangential friction proves an effective way to realize amplitude-independent damping in structural systems.

Keywords: Amplitude-independent Damping, Homogeneous Friction, Pendulum Nonlinear Dynamics, Structural Control, Vibration Resonant Absorbers.

1 INTRODUCTION

Passive vibration absorbers are widely used in controlling civil engineering structures. Currently, they consist of single-degree-of-freedom (SDOF) appendages, tuned to the target structural mode through frequency and damping optimization [1-5]. One classical scheme is the pendulum absorber (PA), that exploits gravity to produce the restoring force, and consists of a damped mass moving along an arched trajectory. A PA can be conceived either as a hanging pendulum, suspended through cables or bars, or a supported pendulum, rolling or sliding on a physical track. In recent years, supported PAs have found several applications, because of their compactness, durability and versatility. Classical examples are the ball pendulum [6], the rolling and sliding pendulums [7], and the rocking pendulum.

Despite the numerous implementations reported in the literature and realized in practice, the research for novel arrangements is still ongoing, resulting in several new configurations, including the unbalanced rolling PA [8], the multiple-ball PA [9], and several types of track nonlinear energy sinks [10]. Among the others, this research has recently inspired the proposal of the so-called bidirectional pendulum absorber (BPA), made of a mass moving along an optimal three-dimensional (3D) concave surface, whose principal curvatures are chosen to ensure a bidirectional tuning to both principal modes of the main structure. The BPA has been proposed in two variants, respectively belonging to the supported pendulum and to the hanging pendulum types. The first variant is represented by the rolling-pendulum absorber proposed in [11]. Its 3D surface is manufactured as a double 3D rolling-pendulum bearing, comprising two equal concavities between which a rolling ball is interposed. Modifying the shape of the two concavities and the ball radius generates any possible 3D surface. The second variant is represented by the hanging-pendulum absorber proposed in [12]. Its 3D surface is realized through a Y-shaped configuration of the suspending cables. Modifying the length of the cables realizes any possible toroidal surface. In the first variant, energy dissipation is provided by horizontal viscous dampers, in the second variant it is provided by a vertical friction damper. In this latter case, the orthogonality between the damper and the 3D surface ensures an amplitude-independent equivalent damping, which should make the two variants approximately equivalent in terms of vibration suppression capability.

In this work, a further alternative of BPA is presented, in which damping is produced by the variable tangential friction developing between the pendulum mass and the 3D surface, as a result of a spatially-varying friction coefficient law [13, 14]. Namely, the friction coefficient is assumed to vary along the surface in proportion to the modulus of the surface gradient. This ensures a dissipative model which is nonlinear homogeneous at low response amplitudes [15]. Such a homogeneous BPA (HBPA) demonstrates superior to conventional friction ball absorbers (characterized by a constant friction coefficient), since its equivalent damping ratio proves amplitude independent, so that its performance does not vary with the excitation level. On the other hand, compared with the said existing BPAs ([11] and [12]), the HBPA is more compact, because it does not require the installation of additional dashpots. In the HBPA, friction is generated either by rolling [16] or by sliding, depending on the chosen type of pendulum. Friction can be spatially varied by changing the surface roughness or the material or the thickness of the surface coating, either continuously or discretely.

This paper describes the analytical model of the HBPA and presents an optimal methodology for its design. Simulations of single- and multi-story buildings under wind and seismic loads are reported, showing the pros and cons of the HBPA with respect to conventional viscously damped BPAs (VBPA) [17]. The results reveal that the HBPA is a promising alternative to conventional VBPAs, and that the homogeneous tangential friction is an effective solution to design mechanical systems having amplitude-independent damping.

2 GENERAL DESCRIPTION AND MODELING OF THE HBPA

2.1 Problem description

A BPA incorporating both viscous damping and tangential friction is shown in Fig. 1.

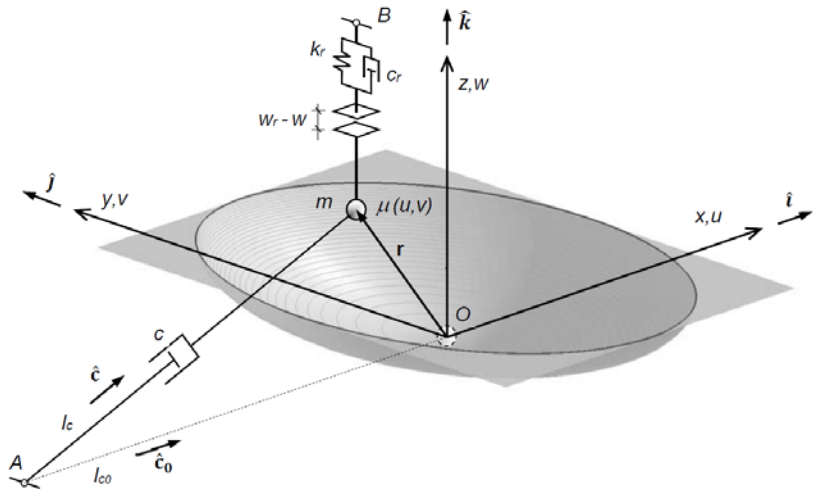

Figure 1: Schematic drawing of the BPA model.

Its model comprises a point mass m subject to gravity g and constrained to move along a 3D surface, connected to the structure at its minimum in O. The motion of m along the surface is opposed by: (i) the viscous damper linking m to the structure in A; (ii) the friction force acting on the surface; and (iii) the restrainer linking m to the structure in B. If structural rotations are negligible, the surface and the structural supports in A and B merely translate as the support in O. Denoting with u, v and w the coordinates of m w.r.t. the local reference system xyz fixed in O, and with $w = w(u,v) = w(\mathbf{q})$ the pendulum surface equation, the relative displacement of the HBPA w.r.t. the structure is $\mathbf{r} = [u,v,w]^T = [\mathbf{q}^T, w(\mathbf{q})]^T$, where u and v are the two independent coordinates, w is the dependent coordinate, and $\mathbf{q} = [u,v]^T$ is the HBPA degree-of-freedom vector. The structural support acceleration vector is $\mathbf{a} = [a_x, a_y, a_z]^T = [\mathbf{a}_h^T, a_z]^T$, and the BPA relative velocity vector is derived as $\dot{\mathbf{r}} = (\partial \mathbf{r}/\partial \mathbf{q})\dot{\mathbf{q}} = \mathbf{J}\dot{\mathbf{q}}$, where $\mathbf{J} = \partial \mathbf{r}/\partial \mathbf{q} = [\mathbf{I}, \nabla w]^T$ is the Jacobian matrix of the kinematic transformation and $\nabla w = \partial w/\partial \mathbf{q}$ is the surface gradient.

2.2 The dissipative model

The model in Fig. 1 accounts for three different dissipative mechanisms: (i) one or more viscous dashpot; (ii) the tangential friction; and (iii) the fail-safe restrainer.

Assuming for brevity a single viscous dashpot with damping coefficient c, undeformed length l_{c0}, deformed length l_c, and undeformed and deformed coaxial versors $\hat{\mathbf{c}}_0$ and $\hat{\mathbf{c}}$, and denoting by $s_c = l_c - l_{c0}$ its axial elongation, the corresponding viscous force vector acting on m is $\mathbf{f}_c = -f_c \hat{\mathbf{c}}$, where $f_c = c\dot{s}_c$ and $\dot{s}_c = \hat{\mathbf{c}}^T \dot{\mathbf{r}} = \hat{\mathbf{c}}^T \mathbf{J}\dot{\mathbf{q}}$.

Assuming a dry friction coefficient varying along the pendulum surface according to an assigned law $\mu = \mu(u,v) = \mu(\mathbf{q})$, and denoting by N the modulus of the normal contact reaction force $\mathbf{N}$, the friction force can be expressed as $\mathbf{f}_\mu = -f_\mu \hat{\mathbf{t}}$, where $\hat{\mathbf{t}} = \dot{\mathbf{r}}/\|\dot{\mathbf{r}}\| = \mathbf{J}\dot{\mathbf{q}}/\sqrt{\dot{\mathbf{q}}^T \mathbf{J}^T \mathbf{J}\dot{\mathbf{q}}}$ is the tangent versor, and

$$f_\mu = \mu(\mathbf{q}) N \tag{1}$$

In particular, the focus is here on a special friction pattern, where the friction coefficient varies along the pendulum surface proportionally to the surface gradient vector, according to:

$$\mu(\mathbf{q}) = \mu_0 \left\| \nabla w \right\| \tag{2}$$

where μ_0 is a proportionality factor, called the friction ratio. As shown later, Eq. (2) ensures a homogeneous first-order model.

Assuming a restrainer with stiffness k_r, damping coefficient c_r and initial clearance w_r, the restrainer force vector is $\mathbf{f}_r = -f_r \hat{\mathbf{k}}$, where $f_r = 0$ if $w \le w_r$ and $f_r = k_r(w - w_r) + c_r \dot{w}$ if $w > w_r$, with $\dot{w} = \nabla w^T \dot{\mathbf{q}}$.

The total dissipative force applied to m by the three mechanisms is therefore $\mathbf{f}_d = \mathbf{f}_c + \mathbf{f}_\mu + \mathbf{f}_r$. Denoting by $\mathbf{w} = -mg\hat{\mathbf{k}}$ the weight of m, and by $\boldsymbol{\lambda}_d = m(\mathbf{a} + \ddot{\mathbf{r}})$ the dynamic interaction force between the BPA and its support, the dynamic equilibrium of m reads $\mathbf{w} + \mathbf{N} + \mathbf{f}_d = \boldsymbol{\lambda}_d$, which finally provides N in Eq. (1) as the modulus of the vector $\mathbf{N} = \boldsymbol{\lambda}_d - \mathbf{w} - \mathbf{f}_d$.

2.3 The nonlinear three-dimensional model of the BPA

The BPA dynamic equation can be obtained by applying the Euler-Lagrange equation to the mass m:

$$\frac{d}{dt}\left(\frac{\partial T}{\partial \dot{\mathbf{q}}}\right) - \frac{\partial T}{\partial \mathbf{q}} + \frac{\partial V_g}{\partial \mathbf{q}} + \mathbf{Q}_i + \mathbf{Q}_e = \mathbf{0} \tag{3}$$

where $T = m\dot{\mathbf{r}}^T\dot{\mathbf{r}}/2$ is the kinetic energy of m; V_g=mgw is its gravitational potential energy; $\mathbf{Q}_i$ = $-\mathbf{J}^T\mathbf{f}_d$ is the generalized internal force due to the total dissipative force $\mathbf{f}_d$; and $\mathbf{Q}_e = m\mathbf{J}^T\mathbf{a}$ is the generalized external force due to the support acceleration. Deriving the first three terms of Eq. (3), and denoting by $\mathbf{M}^q = m\mathbf{J}^T\mathbf{J}$ the BPA generalized mass matrix, the BPA fully nonlinear 3D model is finally obtained as

$$\mathbf{M}^q\ddot{\mathbf{q}} + \mathbf{Q}_i + mg\nabla w = -m\mathbf{J}^T\mathbf{a} - \left(\dot{\mathbf{M}}^q\dot{\mathbf{q}} - \frac{\partial T}{\partial \mathbf{q}}\right) \tag{4}$$

In Eq. (4), the dissipative term on the left-hand side can be expressed as

$$\mathbf{Q}_i = -\mathbf{J}^T\mathbf{f}_d = f_c\mathbf{J}^T\hat{\mathbf{c}} + f_\mu\mathbf{J}^T\hat{\mathbf{t}} + f_r\mathbf{J}^T\hat{\mathbf{k}} \tag{5}$$

where

$$f_c\mathbf{J}^T\hat{\mathbf{c}} = c\left(\mathbf{J}^T\hat{\mathbf{c}}\hat{\mathbf{c}}^T\mathbf{J}\right)\dot{\mathbf{q}} \tag{6}$$

$$f_\mu\mathbf{J}^T\hat{\mathbf{t}} = \mu(\mathbf{q})N\mathbf{J}^T\mathbf{J}\dot{\mathbf{q}} / \sqrt{\dot{\mathbf{q}}^T\mathbf{J}^T\mathbf{J}\dot{\mathbf{q}}} \tag{7}$$

$$f_r\mathbf{J}^T\hat{\mathbf{k}} = f_r\nabla w \tag{8}$$

are the generalized viscous, friction and restrainer force vectors, respectively.

2.4 The nonlinear three-dimensional model of the BPA-MDOF system

The dynamic equation of a linear multi-degree-of-freedom (MDOF) structure coupled with the BPA and subjected to external forces and ground accelerations is

$$\mathbf{M}_s\ddot{\mathbf{q}}_s + \mathbf{C}_s\dot{\mathbf{q}}_s + \mathbf{K}_s\mathbf{q}_s + \mathbf{L}^T\boldsymbol{\lambda}_d = \mathbf{f}_s - \mathbf{M}_s\mathbf{R}_s\ddot{\mathbf{r}}_g \tag{9}$$

where $\mathbf{q}_s$ is the vector of structural DOFs; $\mathbf{M}_s$, $\mathbf{C}_s$ and $\mathbf{K}_s$ are the structural matrices of mass, damping and stiffness; $\mathbf{f}_s$ is the vector of external forces; $\ddot{\mathbf{r}}_g$ is the vector of ground accelerations; $\mathbf{L}$ and $\mathbf{R}_s$ are kinematic and topological matrices. Combining Eqs. (4) and (9), the fully nonlinear coupled dynamic equation can be finally expressed as

$$\begin{aligned}&\begin{bmatrix}\mathbf{M}_s+m\mathbf{L}^T\mathbf{L} & m\mathbf{L}^T\mathbf{J}\\ m\mathbf{J}^T\mathbf{L} & \mathbf{M}^q\end{bmatrix}\begin{bmatrix}\ddot{\mathbf{q}}_s\\ \ddot{\mathbf{q}}\end{bmatrix}+\begin{bmatrix}\mathbf{C}_s & \mathbf{0}\\ \mathbf{0} & \mathbf{0}\end{bmatrix}\begin{bmatrix}\dot{\mathbf{q}}_s\\ \dot{\mathbf{q}}\end{bmatrix}+\begin{bmatrix}\mathbf{K}_s & \mathbf{0}\\ \mathbf{0} & \mathbf{0}\end{bmatrix}\begin{bmatrix}\mathbf{q}_s\\ \mathbf{q}\end{bmatrix}+\\ &+\begin{bmatrix}\mathbf{0}\\ \mathbf{Q}_i\end{bmatrix}=\begin{bmatrix}\mathbf{f}_s\\ \mathbf{0}\end{bmatrix}-\begin{bmatrix}\mathbf{M}_s+m\mathbf{L}^T\mathbf{L}\\ m\mathbf{J}^T\mathbf{L}\end{bmatrix}\mathbf{R}_s\ddot{\mathbf{r}}_g-\begin{bmatrix}m\mathbf{L}^T\mathbf{J}\dot{\mathbf{q}}\\ \dot{\mathbf{M}}^q\dot{\mathbf{q}}-\dfrac{\partial T}{\partial\mathbf{q}}\end{bmatrix}.\end{aligned} \tag{10}$$

2.5 The first-order approximated model

Some fundamental properties of the BPA can be demonstrated by considering its response at low amplitudes. By developing in Taylor series Eqs. (4) to (8), and by truncating higher-order terms, the first-order 3D model of the BPA is obtained as

$$m\ddot{\mathbf{q}}+\mathbf{C}\dot{\mathbf{q}}+N_0\mathbf{K}_w\mathbf{q}+\mu_0N_0\|\mathbf{K}_w\mathbf{q}\|\dot{\mathbf{q}}/\|\dot{\mathbf{q}}\|=-m\mathbf{a}_h \tag{11}$$

where: $\mathbf{C}$ is the BPA viscous damping matrix, given by

$$\mathbf{C}=c\begin{bmatrix}\hat{c}_{0x}^2 & \hat{c}_{0x}\hat{c}_{0y}\\ \hat{c}_{0x}\hat{c}_{0y} & \hat{c}_{0y}^2\end{bmatrix} \tag{12}$$

if the viscous damper is set parallel to the xy plane; $N_0 = N/(mg) = 1+a_z/g$ is the normalized normal component of the reaction force; $\mathbf{a}_h = [a_x, a_y]^T$ is the vector of horizontal accelerations at the support; and $\mathbf{K}_w$ is the equivalent pendular stiffness matrix, given by:

$$\mathbf{K}_w=\begin{bmatrix}k_{wx} & 0\\ 0 & k_{wy}\end{bmatrix}=mg\begin{bmatrix}1/L_x & 0\\ 0 & 1/L_y\end{bmatrix}=mg\mathbf{H}_w \tag{13}$$

where $\mathbf{H}_w$ is the Hessian matrix of $w(\mathbf{q})$ in $\mathbf{0}$, and L_x and L_y are the pendulum lengths along x and y.

Accordingly, the first-order 3D model of the BPA-structure coupled system is

$$\begin{aligned}&\begin{bmatrix}\mathbf{M}_s+m\mathbf{L}_h^T\mathbf{L}_h & m\mathbf{L}_h^T\\ m\mathbf{L}_h & m\mathbf{I}\end{bmatrix}\begin{bmatrix}\ddot{\mathbf{q}}_s\\ \ddot{\mathbf{q}}\end{bmatrix}+\begin{bmatrix}\mathbf{C}_s & \mathbf{0}\\ \mathbf{0} & \mathbf{C}+\mu_0N_0\|\mathbf{K}_w\mathbf{q}\|/\|\dot{\mathbf{q}}\|\end{bmatrix}\begin{bmatrix}\dot{\mathbf{q}}_s\\ \dot{\mathbf{q}}\end{bmatrix}+\\ &+\begin{bmatrix}\mathbf{K}_s & \mathbf{0}\\ \mathbf{0} & N_0\mathbf{K}_w\end{bmatrix}\begin{bmatrix}\mathbf{q}_s\\ \mathbf{q}\end{bmatrix}=\begin{bmatrix}\mathbf{f}_s\\ \mathbf{0}\end{bmatrix}-\begin{bmatrix}\mathbf{M}_s+m\mathbf{L}_h^T\mathbf{L}_h\\ m\mathbf{L}_h\end{bmatrix}\mathbf{R}_s\ddot{\mathbf{r}}_g,\end{aligned} \tag{14}$$

where $\mathbf{L}_h$ is the vector containing the first two columns of $\mathbf{L}$.

Based on Eq. (11), the following observations can be formulated:

1) the inertia force $m\ddot{\mathbf{q}}$ and the restoring force $N_0\mathbf{K}_w\mathbf{q}$ are linear and uncoupled along x and y; this holds for the viscous force $\mathbf{C}\dot{\mathbf{q}}$, provided that all viscous dampers are aligned with the coordinate axes;
2) the friction force has modulus $\mu_0N_0\|\mathbf{K}_w\mathbf{q}\|$ and has direction and sign of the tangent versor $\dot{\mathbf{q}}/\|\dot{\mathbf{q}}\|$; because its modulus, direction and sign are nonlinear and coupled, the friction force is a nonlinear coupled function of $\mathbf{q}$ and $\dot{\mathbf{q}}$;
3) because its modulus increases proportionally with $\mathbf{q}$ and does not depend on $\dot{\mathbf{q}}$, the friction force is a homogeneous function of $\mathbf{q}$ and $\dot{\mathbf{q}}$; Eq. (11) is therefore homogeneous and

its solution is proportional to $\mathbf{a}_h$, which definitely makes the HBPA a first-order nonlinear but homogeneous system.

2.6 The simplified two-dimensional model

The 3D first-order models in Eqs. (11) and (14) can be further simplified for design purposes, assuming that: (i) the motion occurs in a vertical coordinate plane, e.g. the *xz* plane, so the model becomes two-dimensional (2D); (ii) in the *xz* plane the structural target frequency is far from the other ones, so the MDOF structure can be reduced to a 1DOF mode-generalized system; (iii) the vertical acceleration input a_z is negligible, so $N_0 = 1$. Under these conditions, Eqs. (11) and (14) become respectively

$$m\ddot{u} + c_x\dot{u} + k_{wx}[1 + \mu_0 \text{sign}(u\dot{u})]u = -ma_x \tag{15}$$

$$\begin{bmatrix} m_{sx}+m & m \\ m & m \end{bmatrix}\begin{bmatrix} \ddot{u}_s \\ \ddot{u} \end{bmatrix} + \begin{bmatrix} c_{sx} & 0 \\ 0 & c_x \end{bmatrix}\begin{bmatrix} \dot{u}_s \\ \dot{u} \end{bmatrix} + \\ + \begin{bmatrix} k_{sx} & 0 \\ 0 & k_{wx}[1+\mu_0 \text{sign}(u\dot{u})] \end{bmatrix}\begin{bmatrix} u_s \\ u \end{bmatrix} = \begin{bmatrix} f_{sx} \\ 0 \end{bmatrix} - \begin{bmatrix} m_{sx}+m \\ m \end{bmatrix}\ddot{u}_g, \tag{16}$$

where u_s is the horizontal displacement of the structure w.r.t. the ground; m_{sx}, c_{sx} and k_{sx} are the generalized mass, damping and stiffness of the structure along *x*; and c_x is the BPA viscous damping coefficient along *x*.

Eqs. (15) and (16) can be finally recast in modal form as

$$\ddot{u} + 2\varsigma_x\omega_x\dot{u} + \omega_x^2[1 + \mu_0 \text{sign}(u\dot{u})]u = -a_x \tag{17}$$

$$\begin{bmatrix} 1+m_{Rx} & m_{Rx} \\ 1 & 1 \end{bmatrix}\begin{bmatrix} \ddot{u}_s \\ \ddot{u} \end{bmatrix} + 2\omega_{sx}\begin{bmatrix} \varsigma_{sx} & 0 \\ 0 & \varsigma_x\omega_{Rx} \end{bmatrix}\begin{bmatrix} \dot{u}_s \\ \dot{u} \end{bmatrix} + \\ + \omega_{sx}^2\begin{bmatrix} 1 & 0 \\ 0 & \omega_{Rx}^2[1+\mu_0 \text{sign}(u\dot{u})] \end{bmatrix}\begin{bmatrix} u_s \\ u \end{bmatrix} = \begin{bmatrix} \bar{f}_{sx} \\ 0 \end{bmatrix} - \begin{bmatrix} 1+m_{Rx} \\ 1 \end{bmatrix}\ddot{u}_g, \tag{18}$$

where $m_{Rx} = m/m_{sx}$ is the BPA mass ratio along *x*; $\omega_{sx} = \sqrt{k_{sx}/m_s}$ and $\omega_x = \sqrt{g/L_x}$ are the structure and BPA circular frequencies along *x*; $\omega_{Rx} = \omega_x/\omega_{sx}$ is the BPA frequency ratio along *x*; and $\varsigma_{sx} = c_{sx}/(2\omega_{sx}m_{sx})$ and $\varsigma_x = c_x/(2\omega_x m)$ are the structure and BPA viscous damping ratios along *x*.

3 THE DESIGN PROCEDURE

A design methodology is here presented for a BPA of either viscous type (VBPA) or homogeneous friction type (HBPA). Their models can be obtained from those derived in Section II, by respectively annulling the friction or the viscous terms. The methodology comprises two steps: (1) a 2D first-order optimization; and (2) a 3D second-order completion.

3.1 The two-dimensional first-order optimization

According to the simplified 2D model in Eq. (18), which admits an uncoupled motion along *x* and *y*, and assuming the structure known, both the VBPA and the HBPA are completely determined, in each direction, by three dimensionless design parameters: m_{Rx}, ω_{Rx} and ς_x for the VBPA, and m_{Rx}, ω_{Rx} and μ_0 for the HBPA. If the mass ratio m_{Rx} is fixed based on cost-benefit expectations, the two remaining free parameters can be obtained by solving an H_∞ design problem [18], i.e. by minimizing the H_∞ norm of a significant input-output transfer function (TF) of the structure-BPA system. Denoting by ω the circular frequency of the excitation in-

put, two possible TFs are here considered for each BPA type: the force-to-displacement transfer function $T_f(\omega)$ (significant for wind load applications), and the ground acceleration-to-displacement transfer function $T_g(\omega)$ (significant for seismic load applications). Denoting as the response ratio R_x the ratio between the controlled and the uncontrolled H_∞ norm of those TFs, optimization can be formalized as follows, respectively for a wind-oriented VBPA:

$$R_{xopt} = \min_{\omega_{Rx},\varsigma_x} R_x = \min_{\omega_{Rx},\varsigma_x} \max_{\omega} \left(\left| T_f(\omega) \right|^{con} \Big/ \left\| T_f \right\|_\infty^{unc} \right) \tag{19}$$

for a seismic-oriented VBPA:

$$R_{xopt} = \min_{\omega_{Rx},\varsigma_x} R_x = \min_{\omega_{Rx},\varsigma_x} \max_{\omega} \left(\left| T_g(\omega) \right|^{con} \Big/ \left\| T_g \right\|_\infty^{unc} \right) \tag{20}$$

for a wind-oriented HBPA:

$$R_{xopt} = \min_{\omega_{Rx},\mu_0} R_x = \min_{\omega_{Rx},\mu_0} \max_{\omega} \left(\left| T_f(\omega) \right|^{con} \Big/ \left\| T_f \right\|_\infty^{unc} \right) \tag{21}$$

and for a seismic-oriented HBPA:

$$R_{xopt} = \min_{\omega_{Rx},\mu_0} R_x = \min_{\omega_{Rx},\mu_0} \max_{\omega} \left(\left| T_g(\omega) \right|^{con} \Big/ \left\| T_g \right\|_\infty^{unc} \right) \tag{22}$$

Eqs. (19) and (20) give the optimal VBPA parameters ω_{Rxopt} and ς_{xopt}, respectively for wind and seismic control. Eqs. (21) and (22) give the optimal HBPA parameters ω_{Rxopt} and μ_{0opt}, respectively for wind and seismic control.

The min.max. problems in Eqs. (19) to (22) are here numerically solved using a branch & bound search algorithm analogue to the one used in [5], followed by a nonlinear least-square solver for improved local convergence. The computation of the VBPA TF in Eqs. (19) and (20) is straightforward, based on classical closed-form expressions available for linear mechanical models, whereas the computation of the HBPA TF in Eqs. (21) and (22) needs simulating the system response time-history at each input frequency until stabilization of the response amplitude.

Assuming a structural damping ratio $\zeta_{sx} = 2\%$, the optimization results are reported in Fig. 2 for the VBPA (dashed lines) and the HBPA (continuous lines), as a function of the mass ratio m_{Rx}. The wind-oriented optimization is reported on the left (subfigures a, c and e), while the seismic-oriented optimization is reported on the right (subfigures b, d and f). Subfigures a and b show the optimal frequency ratio; subfigures c and d show the optimal damping ratio (for the VBPA) and the optimal friction ratio (for the HBPA), this latter normalized to π; and subfigures e and f show the optimal response ratios. Whereas the results obtained for the VBPA are well known (see for instance [19]) and do not deserve specific comments, the results obtained for the HBPA reveal that the optimal HBPA slightly improves the VBPA performance, especially for large values of m_{Rx}. To achieve this, ω_{Rxopt} is always larger for the HBPA than for the VBPA, except for very small mass ratios, when the optimal frequency ratio converges to unity for both types. On the other hand, μ_{0opt} converges to $\pi \cdot \varsigma_{xopt}$ for small mass ratios, but tends to be increasingly smaller than $\pi \cdot \varsigma_{xopt}$ as the mass ratio increases. The same trends are appreciated for the wind-oriented and the seismic-oriented design types.

Assuming that the structural target modes have the same damping ratio and the same generalized mass in the two horizontal directions, the results obtained above hold along x and y, and the x subscript can be dropped for brevity. Together with the mass ratio m_R and with the structural parameters, the resulting optimal dimensionless parameters ω_{Ropt}, ς_{opt} and μ_{0opt} allow the computation of all BPA dimensional parameters involved in the low amplitude domain, i.e. the BPA mass m, the BPA circular frequencies ω_x and ω_y, the BPA pendulum

lengths L_x and L_y, the VBPA damping coefficients c_x and c_y, and the HBPA friction pattern around the origin, this latter given around by

$$\mu(\mathbf{q}) = \mu_{0opt}\|\nabla w\| \approx \mu_{0opt}\sqrt{u^2/L_x^2 + v^2/L_y^2} \tag{23}$$

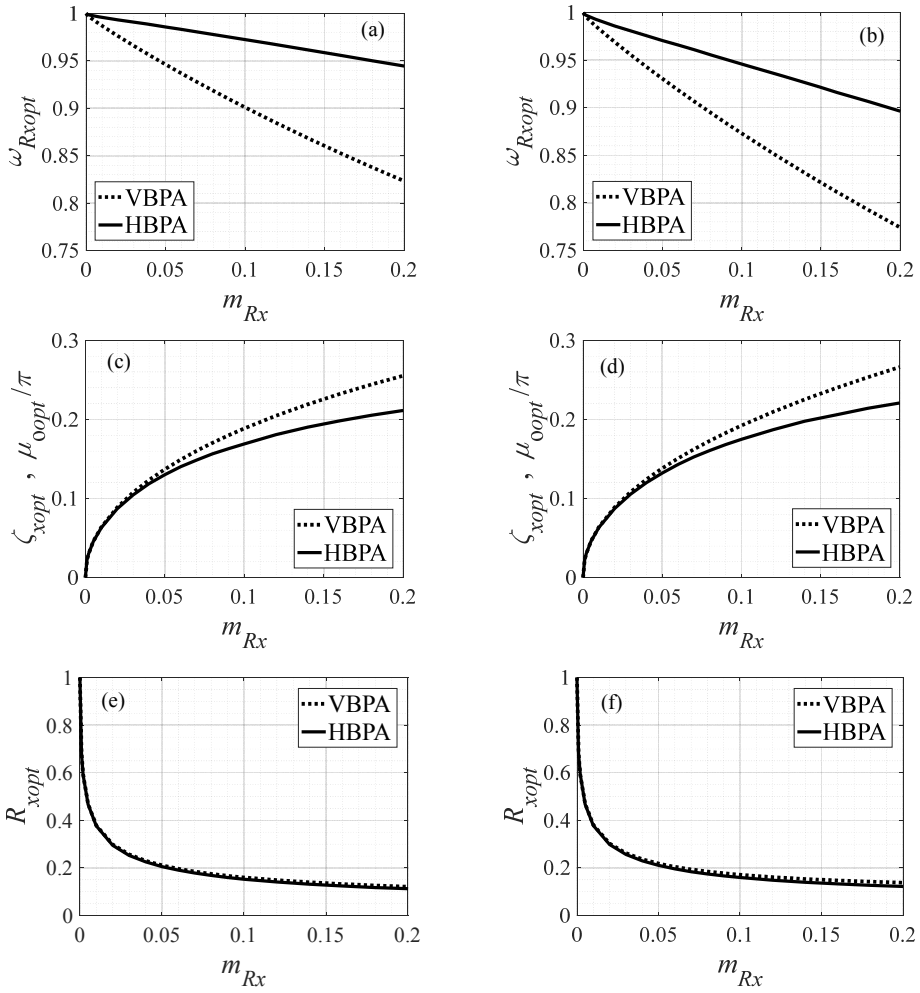

Figure 2: H_∞ optimal design of a VBPA (dotted lines) and a HBPA (continuous lines), as a function of m_{Rx}, for ζ_{sx} = 2%. Left: wind-oriented design. Right: seismic-oriented design. First row: optimal frequency ratios. Second row: optimal viscous/friction damping ratios. Third row: optimal response ratios.

3.2 The three-dimensional second-order completion

The subsequent completion step provides the BPA parameters which, involved only in the large-displacement domain, are excluded from the previous optimization step. These parameters include the pendulum shape (and consequently the friction pattern) far from the origin, the length and number of viscous dashpots, and the restrainer properties.

By providing L_x and L_y, the optimization step determines the pendulum shape around the origin. Far from it, however, different shapes correspond to the same pair of L_x and L_y. Among the possible choices are, for example, the ellipsoid, the torus or the elliptic paraboloid. If the ellipsoid is chosen, infinite ways of assigning its semi-axes b_x, b_y and b_z exist, all providing the desired L_x and L_y pair. Then, by imposing that $b_z = \sqrt{b_x b_y}$, only one admissible

ellipsoid exists, of semi-axes $b_x = \sqrt[4]{L_x^3 L_y}$, $b_y = \sqrt[4]{L_x L_y^3}$ and $b_z = \sqrt{L_x L_y}$. This choice is systematically assumed in the sequel.

With this assumption, the friction pattern defined by Eq. (2) becomes:

$$\mu(\mathbf{q}) = \mu_{0opt} \sqrt{\left(\frac{u^2}{L_x^2} + \frac{v^2}{L_y^2} \right) \Big/ \left(1 - \frac{u^2}{b_x^2} - \frac{v^2}{b_y^2} \right)} \tag{24}$$

where $\mu(\mathbf{q})$ tends to zero around the origin, tends to infinite at the ellipsoid equator, and describes iso-friction curves intersecting the level curves, as shown in Fig. 3 for an ellipsoid having $L_y/L_x = 2$, truncated at $w_r = b_z/2$. Both Figs. 3 (a) and (b) represent nine level curves, uniformly spaced between 0 and w_r, and nine iso-friction curves, uniformly spaced between 0 and 2 μ_{0opt}.

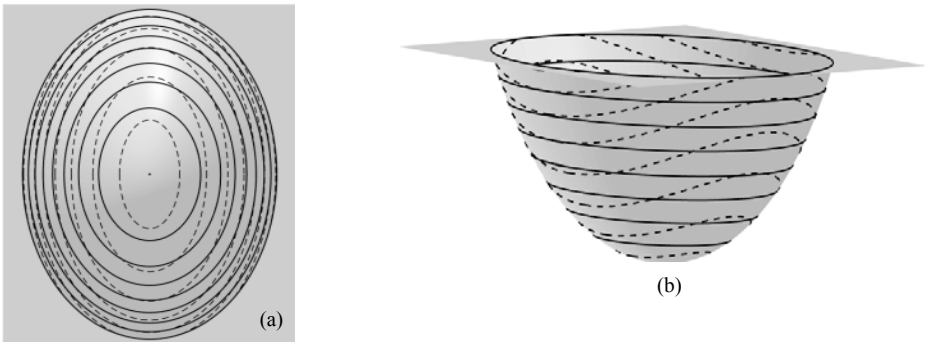

Figure 3: Level curves (continuous) and iso-friction curves (dashed) if $L_y/L_x = 2$: (a) planar view; (b) axonometric view (with the z dimension doubled for clarity).

Regarding the design of the viscous dampers, the optimization step provides the optimal values of c_x and c_y, in the assumption of a single damper for every direction. If more dampers are used in the same direction, the optimal damping coefficient must be subdivided among them. The length of the viscous dampers does not enter the optimization step. In the sequel, two dampers will be systematically assumed in each direction, each having length $l_{c0} = b_z = \sqrt{L_x L_y}$.

Finally, the restrainer too does not enter the optimization step. Its mechanical properties can be assigned to simulate a dissipative impact. In the remaining of this paper, its stiffness is systematically chosen as $k_r = m\omega_r^2$, where $\omega_r = 20\sqrt{\omega_x \omega_y}$; its damping is assigned as $c_r = 2\varsigma_r \omega_r m$, where $\varsigma_r = -\ln e_r \Big/ \sqrt{\pi^2 + \ln^2 e_r}$ and $e_r = 0.5$ (elastic restitution coefficient); its clearance is assigned as $w_r = b_z/2$.

4 TWO-DIMENSIONAL SIMULATIONS OF THE FIRST-ORDER MODEL

The optimal VBPA and the optimal HBPA are here compared at low amplitudes, by assuming the first-order 2D models expressed by Eqs. (16) or (18). The structure is a 2% damped SDOF system.

4.1 White noise force excitation

Optimized according to the wind-oriented design procedure described in Section 3, the VBPA and the HBPA are compared by subjecting the SDOF structure to a stationary Gaussi-

an zero-mean white-noise force $\bar{f}_{sx}$. For the uncontrolled and for the VBPA-controlled structure (linear cases), the system stationary root-mean-square (rms) response is computed solving the Lyapunov equation [18]. For the HBPA-controlled structure, the rms response is computed through Monte Carlo simulations, using 100 realizations of the input process. Each realization has lasts $3600T_{sx}$, with a sampling time of $0.01T_{sx}$, T_{sx} being the structural period.

The BPA performance is evaluated in terms of the rms structural displacement, rms(u_s), and the rms BPA relative displacement (stroke), rms(u). Two performance indices are considered, computed dividing the controlled value of the rms responses by the uncontrolled value of the rms structural displacement: the displacement response ratios R_{dx} = rms(u_s)$_{con}$/ rms(u_s)$_{unc}$, and the stroke response ratio R_{sx} = rms(u)$_{con}$/ rms(u_s)$_{unc}$.

The two response ratios are shown in Fig. 4, where they appear nearly identical for the two BPA types. The substantial equivalence already observed under a harmonic force input in Fig. 2 (e) is therefore confirmed under a white-noise force input. Expectedly, the absorber results more effective in H_∞ terms than against a white-noise input (i.e. in H_2 terms).

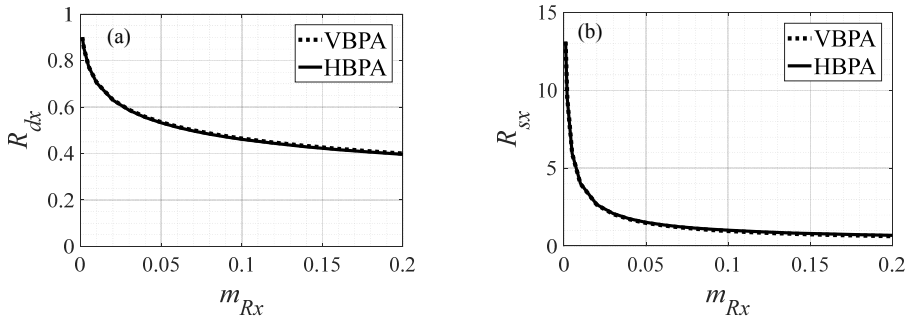

Figure 4: 2D first-order model. VBPA and HBPA response ratios under a unidirectional white-noise force input.

4.2 Natural seismic records

Optimized according to the seismic-oriented design procedure, the evaluation of the VBPA and the HBPA under a white-noise ground acceleration $\ddot{u}_g$ leads to very similar results to those presented in Fig. 4, which are therefore neglected here for brevity.

More interestingly, the structure (with or without BPA) is here subjected to an ensemble of 338 near-field real seismic records, and its period T_{sx} is varied from 0.1 s to 6.0 s, to obtain uncontrolled and controlled spectra. For each interesting response quantity, i.e. the maximum structural displacement $u_{s,max}$ and the maximum BPA stroke u_{max}, the 338 spectra are condensed into their rms spectrum. Dividing, at each period, the controlled rms response spectra by the uncontrolled structural displacement response spectrum, two rms response ratio spectra are obtained, respectively expressed in terms of structural displacement (R_{dx} = rms($u_{s,max}$)$_{con}$/ rms($u_{s,max}$)$_{unc}$), and of BPA stroke (R_{sx} = rms(u_{max})$_{con}$/ rms($u_{s,max}$)$_{unc}$). Results are presented in Fig. 5 for three mass ratios (m_{Rx} = 1%, 3% and 10%). Again, the VBPA and the HBPA exhibit very similar performances, both in terms of structural displacement and absorber strokes.

5 THREE-DIMENSIONAL SIMULATIONS OF THE FIRST-ORDER MODEL

This section broadens the analysis to 3D models, still operating at low amplitudes, according to (14). The equations of motion are still linear and uncoupled for the VBPA but nonlinear and coupled for the HBPA. The structure is a 2%-damped system having 1 DOF in each direction.

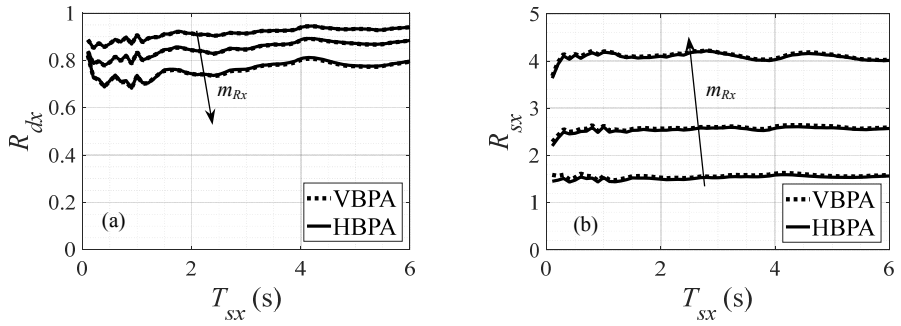

Figure 5: 2D first-order model. VBPA and HBPA response ratio spectra under a unidirectional seismic input, for m_{Rx} = 1%, 3%, 10%.

5.1 White noise force excitation

The structure, with T_{sx} = 1 s and T_{sy}/T_{sx} varying from 1 (axial-symmetry) to 2, is excited by two independent white-noise force input components f_{sx} and f_{sy}, having the same rms value $f_{sx0} = f_{sy0}$. The mass ratio $m_R = m_{Rx} = m_{Ry}$ is alternatively 1%, 3%, or 10%. The BPA performance is evaluated by considering the average response to 100 realizations of the input process, each one lasting 600 s with a sampling time of 0.01 s. The performance is expressed by the following two bidirectional response ratios: $R_d = \sqrt{R_{dx}R_{dy}}$ and $R_s = \sqrt{R_{sx}R_{sy}}$, which extend to 3D the 2D response ratios introduced in Section 4.1.

Results are shown in Fig. 6, where R_d and R_s are plotted as a function of T_{sy}/T_{sx}. The VBPA performance appears constant with T_{sy}/T_{sx}. The HBPA performance appears approximately constant with T_{sy}/T_{sx}, and quite similar to the VBPA performance, with only slightly larger structural displacements and moderately smaller BPA strokes.

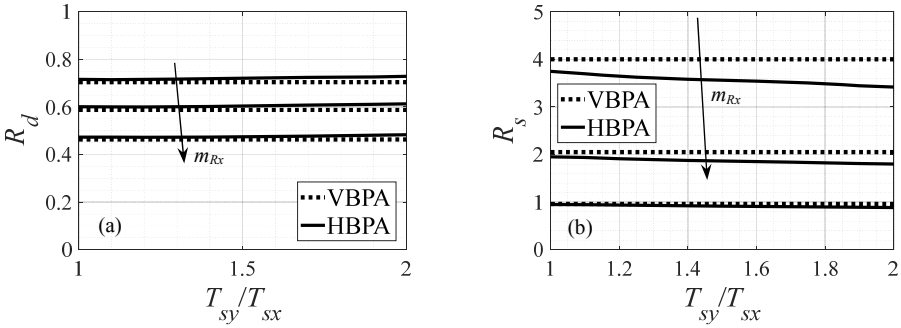

Figure 6: 3D first-order model under a bidirectional white-noise force input. VBPA and HBPA response ratios as a function of T_{sy}/T_{sx}, for m_{Rx} = 1%, 3%, 10%.

5.2 Natural seismic records

The bidirectional performance of the VBPA and of the HBPA is here assessed adopting the same ensemble of seismic records used in Section 4.2. Spectra are computed in terms of 3D rms response ratios, obtained by averaging the corresponding 2D rms response ratios along x and y, according to: $R_d = \sqrt{R_{dx}R_{dy}}$ and $R_s = \sqrt{R_{sx}R_{sy}}$. Fig. 7 shows R_d and R_s evaluated under the assumption that T_{sy}/T_{sx} = 1, for $T_{sx} = T_{sy}$ ranging from 0.5 to 4.0 s, and for m_R alternatively 1%, 3%, or 10%. As in Fig. 6, it appears that under bidirectional excitation, because of friction coupling, the nearly perfect coincidence between the VBPA and the HBPA response is lost. Friction damping implies a slightly larger structural response, and a slightly smaller stroke. The extent of this reduction is however quite limited.

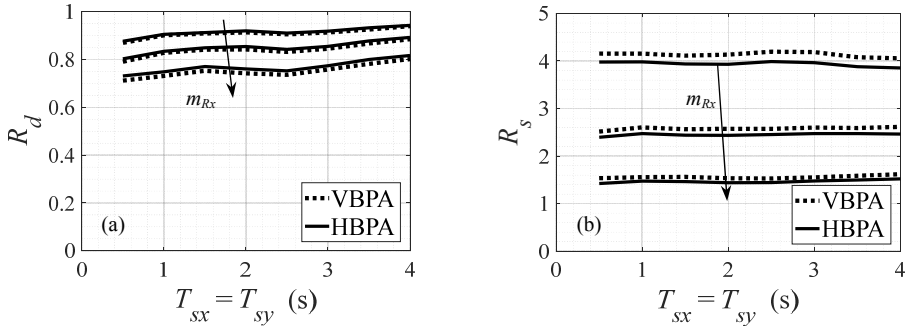

Figure 7: 3D first-order model. VBPA and HBPA response ratio spectra under a bidirectional seismic input, for $T_{sy}/T_{sx} = 1$ and $m_{Rx} = 1\%, 3\%, 10\%$.

6 TWO-DIMENSIONAL SIMULATIONS OF THE FULLY NONLINEAR MODEL

To show the influence of the excitation intensity on the BPA performance, the optimal VBPA and the optimal HBPA are here compared in the large-displacement domain, by assuming fully nonlinear 2D models. The structure is once again a 2% damped SDOF system.

6.1 White noise force excitation

A structure controlled through a wind-optimal BPA having $m_{Rx} = 3\%$ is simulated under a unidirectional white-noise force input of rms amplitude $\bar{f}_{sx0}$, duration 600 s and sampling time 0.01 s. The response ratios R_{dx} and R_{sx} are shown in Fig. 8 for the two types of BPA as a function of $\bar{f}_{sx0}$ ranging from 0 to 5 N/kg.

For $\bar{f}_{sx0} = 0$, the results are those already obtained in Fig. 4 for first-order models. As $\bar{f}_{sx0}$ increases, the effectiveness in mitigating the structural displacement diminishes, as typical of pendulum devices, and the absorber stroke decreases, as a result of bumping and loss of tuning. The effectiveness reduction appears delayed for the HBPA with respect to the VBPA, because of its amplitude-increasing dissipation capabilities.

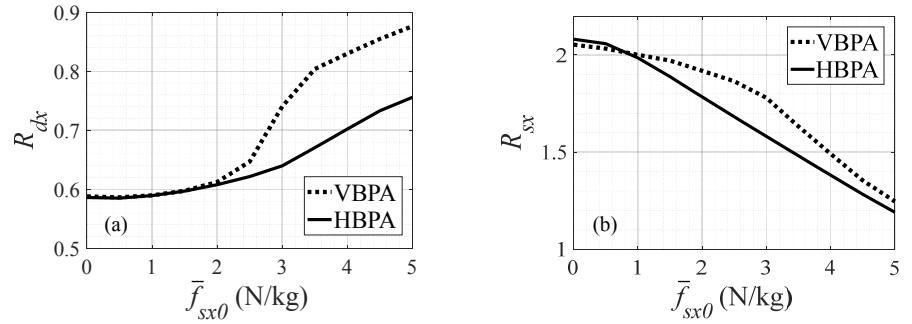

Figure 8: 2D fully nonlinear model. VBPA and HBPA response ratios under a unidirectional white-noise force input, as a function of the input level and for $m_{Rx} = 3\%$.

6.2 Natural seismic records

A structure controlled through a seismic-optimal BPA having $m_{Rx} = 3\%$ is simulated under the ensemble of real records already used in previous sections, for increasing seismic intensities. Denoting by I the intensity ratio, i.e. the dimensionless factor adopted to scale the entire ensemble of records, Fig. 9 reports R_{dx} and R_{sx} as a function of I, for the two BPA types and

for two possible periods of the structure, namely T_{sx} = 0.5 s (top subfigures) and T_{sx} = 4.0 s (bottom subfigures).

For I = 0, the results are those already obtained in Fig. 5 for first-order models. As I increases, both R_{dx} and R_{sx} decrease, as already observed in Section 6.1 under force excitation. However, significant variations are solely observed for T_{sx} = 0.5 s, because of the limited stroke capacity of small-period pendulums. In this case, the HBPA appears again superior to the VBPA, because of the increasing damping provided by the proposed friction pattern.

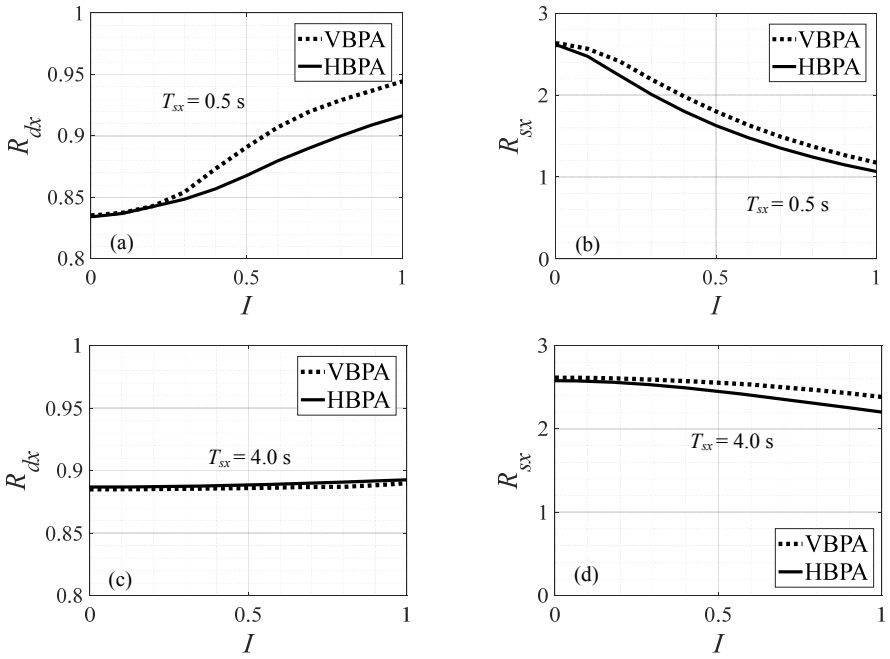

Figure 9: 2D fully nonlinear model. VBPA and HBPA response ratio spectra under a unidirectional seismic input, as a function of I and for m_{Rx} = 3%. Top figures: T_{sx} = 0.5 s; bottom figures: T_{sx} = 4.0 s.

7 THREE-DIMENSIONAL SIMULATIONS OF THE FULLY NONLINEAR MODEL

7.1 White noise force excitation

The optimal BPAs are mounted on a 2%-damped structure having 1 DOF in each direction, with $T_{sx} = T_{sy}$ = 1 s. The structure is excited by a bidirectional white-noise force input, having identical rms amplitude in the two directions, $\bar{f}_{sx0} = \bar{f}_{sy0}$, duration of 600 s, and sampling time of 0.01 s. Simulations are conducted for $\bar{f}_{sx0} = \bar{f}_{sy0}$ ranging from 0 to 5 N/kg, and results are shown in Fig. 10. The performance loss trends already observed for a unidirectional input in Fig. 8 are confirmed. Again, the HBPA performance is similar to the VBPA performance at low intensities, and better for large ones.

7.2 Natural seismic records

Table 1 reports the response ratios obtained by subjecting the controlled structure to the bidirectional seismic records included in the selected ensemble, for m_R = 3% and for the intensity ratio increasing from 0 to 0.5 to 1.0. Two cases are considered, with the first structural period T_{sx} being fixed at 1.0 s and the second structural period T_{sy} equaling either 1.0 s or 1.5 s. Table 1 confirms that under a bidirectional shaking the VBPA is preferable if second-order effects are negligible (I = 0), and the HBPA is preferable if they are not.

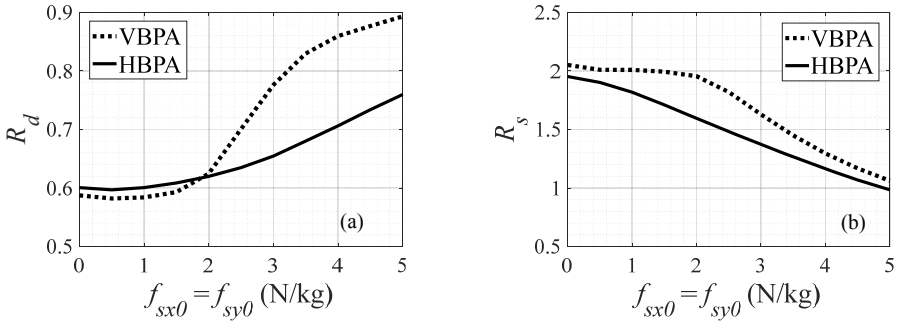

Figure 10: 3D fully nonlinear model. VBPA and HBPA response ratios under a bidirectional white-noise force input, as a function of the input level and for m_{Rx} = 3%. T_{sx} = T_{sy} = 1.0 s.

		R_d		R_s	
	I	VBPA	HBPA	VBPA	HBPA
T_{sx} = 1.0 s T_{sy} = 1.0 s	0.0	0.83	0.84	2.60	2.47
	0.5	0.90	0.88	1.81	1.52
	1.0	0.95	0.92	1.16	1.00
T_{sx} = 1.0 s T_{sy} = 1.5 s	0.0	0.84	0.85	2.58	2.35
	0.5	0.88	0.87	2.00	1.64
	1.0	0.94	0.91	1.38	1.15

8 CASE STUDY: MDOF BUILDING UNDER WIND LOAD

An MDOF high-rise building structure subjected to wind loads is here simulated with or without a BPA atop, using the fully nonlinear model expressed by Eq. (10). The BPA is either of the VBPA or of the HBPA type, in both cases optimized according to the wind-oriented design procedure exposed in Section 3.

The structure is 168 m tall, with a 25 m x 25 m square section. Its shape, mass and stiffness are drawn from [20], but scaled to augment the building sensitivity to the across-wind component. Modelled as a 10-elements cantilever beam, the structure has a flexural stiffness which in the *y* direction is 1.21 times smaller than in the *x* direction. The natural periods along *y* are thus 1.10 times larger than along *x*. Along *x*, the first three periods are 4.00 s, 1.23 s, and 0.52 s, with participating modal masses of 45.3%, 21.8%, and 11.1%. Damping is 2% in every mode.

The BPA mass is 1% the total building mass, corresponding to an effective mass ratio of 6.45% according to Warburton [1]. By applying the design procedure presented in Section 3, the VBPA and the HBPA parameters are exposed in Table 2.

	ω_R	ς	μ_0	L_x	L_y	b_x	b_y	b_z	l_{c0}	w_r
	(-)	(-)	(-)	(m)	(m)	(m)	(m)	(m)	(m)	(m)
VBPA	0.93	0.15	-	4.57	5.53	4.79	5.27	5.03	5.03	2.51
HBPA	0.98	-	0.45	4.12	4.99	4.32	4.76	4.53	-	2.27

Table 2: BPA design parameters on the tall building.

Simulations are conducted under a moderate-to-high wind flow, blowing for 1 hour either along x or along y. Deterministic wind load time-histories are determined as the realization of a stationary, spatially nonhomogeneous, stochastic process, comprising both along-wind and across-wind components, acting simultaneously on the structure. Along- and across-wind components are derived according to classical wind load spectra ([21], [22]).

Results are presented in Table 3 only for the wind blowing in the x direction. Four cases are compared, corresponding to: (1) the uncontrolled structure; (2) the linear VBPA; (3) the (geometrically nonlinear) VBPA; and (4) the HBPA. For each case, several response quantities are investigated, including: (i) the maximum modulus of the top story displacement, $r_{N,max}$; (ii) the maximum modulus of the BPA stroke, r_{max}; (iii) the maximum friction damping ratio activated by the HBPA, μ_{max}; (iv) the rms of the modulus of the top story displacement, $r_{N,rms}$; (v) the rms of the modulus of the BPA stroke, r_{rms}; and the mean value of the instantaneous power dissipated by the structure, $W_{s,mean}$.

Case	$r_{N,max}$ (cm)	r_{max} (cm)	μ_{max} (-)	$r_{N,rms}$ (cm)	r_{rms} (cm)	$W_{s,mean}$ (kW)
Uncontrolled	79.4	0.0	-	27.3	0.0	31.1
Linear VBPA	39.6	110	-	13.7	37.5	8.12
VBPA	39.7	109	-	13.8	37.4	8.17
HBPA	38.4	107	0.10	13.7	37.8	8.63

Table 3: Building responses for wind blowing along x.

Table 3 reveals that:

1) With respect to the uncontrolled structure, the linear VBPA achieves a significant response reduction: 50% in $r_{N,max}$ and in $r_{N,rms}$, and 74% in $W_{s,mean}$.
2) The VBPA, accounting for geometrical nonlinearities, gives nearly identical results. The absorber strokes are relatively small and the restrainer is far from being activated, which makes the first-order model accurate enough.
3) The HBPA performance is also very similar to the VBPA performance. The greatest differences are in $W_{s,mean}$, which is 6% larger for the HBPA, and in $r_{N,max}$, which is 3% larger for the VBPA. The maximum friction coefficient met by the HBPA during motion is 0.10.

It can be concluded that the three controlled cases are substantially equivalent.

9 CONCLUSION

Main conclusions of this study can be formulated as follows:

1) The HBPA is shown to be roughly equivalent to the VBPA, especially when responding to a unidirectional excitation at low response amplitudes.
2) Both BPA types undergo a performance loss if the stroke demand exceeds their stroke capacity, as it often occurs in rigid structures under large input intensities. This drawback is partially compensated for the HBPA by its larger dissipation capacity at large displacements. Despite such loss, in all examined simulations both types still ensure a significant vibration mitigation effect.

Abstract

In many applications of structural dynamics, it is desirable to transfer energy from a primary system using a dynamic absorber to protect the structure from destructive vibration amplitudes. Nonlinear Energy Sinks (NESs) are local attachments used to rapidly and passively dissipate energy from a primary structure in a phenomenon known as Targeted Energy Transfer (TET). Consequently, many types of NESs, which incorporate an essential nonlinear property, have been proposed, designed and tested in the literature. Based on numerical and experimental investigations of these types, Single-Sided Vibro-Impact (SSVI) NESs, where impacts, usually between the top floor of the primary structure and the NES, are utilized to further dissipate energy, proved to be the most efficient for TET in small- and large-scale structures. In literature, researchers have mostly considered steel-to-steel impacts which correspond to a coefficient of restitution of approximately 0.7. In this work, the effect of changing this coefficient of restitution is analyzed and investigated in a two-story physical primary structure. The coupled systems are optimized to achieve the maximum energy transfer and dissipation by measuring the normalized weighted-averaged effective modal damping criteria. It is found that lowering the coefficient of restitution increases the capability of the SSVI NES to transfer and dissipate initial energy induced into a primary structure for a wide range of impulsive excitations.

Keywords: Nonlinear Energy Sink, Targeted Energy Transfer, Vibration Mitigation, Shock Mitigation.

1 INTRODUCTION

Structures are subject to destructive vibration amplitudes from impacts, collisions, earthquakes or wind. Hence, it is desirable to protect the structure by transferring energy to a dynamic absorber in a process known as passive targeted energy transfer (TET). It has recently gained increasing interest in many applications of structural dynamics where a small essentially nonlinear lightweight attachment called nonlinear energy sink (NES) is usually added to the primary structure to enable passive energy transfer for wide range of frequencies through single or cascades of resonance captures. Recently, various NES designs have been numerically, analytically and experimentally investigated to achieve high percentages of energy transfer and dissipation. Depending on the way the nonlinearity is added, these NESs can be categorized into several types such as stiffness-based NESs, impact-based NESs, rotary NESs, and magnet-based NESs. The translational stiffness-based NESs employ an essentially nonlinear (usually cubic) stiffness coupling element to attach the NES mass to a floor in the primary structure [1]. Several enhancements have been proposed to this type where the addition of a linear or nonlinear damping elements [2], additional nonlinearly coupled mass [2-3], additional lateral stiffness elements [4] and negative, unsymmetrical or variable nonlinear stiffness components [5-10] are analyzed for increasing the efficiency of the energy transfer and dissipation. Impact-based NESs employ a linearly coupled NES mass in addition to rigid barriers in the motion domain of the NES to engage in non-smooth impacts that integrate the essential nonlinear property required for cascades of resonance captures. There are two main types of impact-based NESs: (i) double-sided vibro-impact (DSVI) NESs in which two rigid barriers are placed symmetrically from the initial position of the NES mass [11-14] and (ii) single-sided vibro-impact (SSVI) NESs, which are the topic of this paper, realized by removing one of the rigid barriers to allow the NES mass gain considerable momentum during the non-impact phase [15-19]. Rotary-based NESs incorporate an inertially coupled NES mass through a rigid arm rotating about a vertical axis perpendicular to the direction of motion of the primary structure [20-21]. Similarly, this type of NES has been further enhanced by employing an elastic arm instead of the rigid arm [22] or by adding a rigid barrier to incorporate non-smooth impacts with the associated floor of the primary structure [23]. Finally, the magnet-based NES mass is coupled to the associated floor of the primary structure through a nonlinear symmetric or asymmetric coupling magnetic force [24-25]. Out of all the NES types, the SSVI NESs have been proven numerically and experimentally to be the most efficient for energy dissipation and shock mitigation. Hence, the focus of this paper is to investigate further enhancements to the SSVI NESs to improve its capability of engaging in rapid passive and nearly irreversible TET.

During an impact in the SSVI NESs, the coefficient of restitution, a material property depending solely on the materials which get in contact, is defined as the ratio of the magnitude of restitutive impulse to deformative impulse. Most current works related to impact-based NESs consider steel-to-steel impacts which correspond to a coefficient of restitution of 0.7. The aim of this article is to investigate the effect of changing the coefficient of restitution on the performance of SSVI NES when attached to the top floor of a physical two-story linear primary structure excited by an impulsive loading. The paper presents the system description and governing equations, a discussion of the numerical optimization process followed by results and concluded remarks.

2 SYSTEM DESCRIPTION AND NUMERICAL OPTIMIZATION

The physical small-scale two-story structure analyzed in [15,22-23] is considered here where a SSVI NES is attached to the top floor as shown in Fig. 1. The mass, damping and

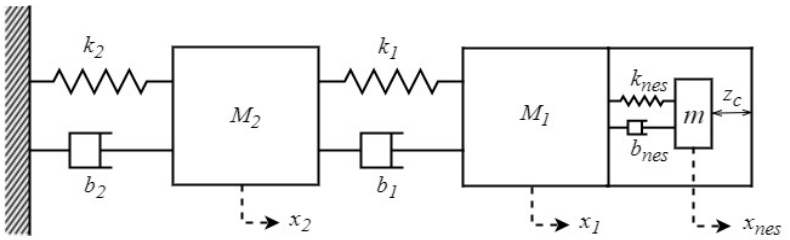

Figure 1: Illustration of 2 DOF primary system with SSVI NES on top floor.

stiffness matrices of the primary structure represented by $\mathbf{M}$, $\mathbf{C}$ and $\mathbf{K}$ identified by the modal analysis of the physical fixture for the system are given as

$$\mathbf{M} = \begin{bmatrix} 24.3 & 0 \\ 0 & 24.2 \end{bmatrix} \text{kg},$$
$$\mathbf{C} = \begin{bmatrix} 1.216 & -0.295 \\ -0.295 & 0.968 \end{bmatrix} \text{N}\cdot\text{s/m}, \tag{1}$$
$$\mathbf{K} = \begin{bmatrix} 15040 & -8220 \\ -8220 & 8220 \end{bmatrix} \text{N/m}$$

Upon updating the mass, damping and stiffness matrices of the whole structure due to the addition of the NES, the governing equations of motion are derived using Newtonian dynamics and numerically integrated using Runge-Kutta formulations. However, the numerical integration is continued until the impact condition for the SSVI NES given by $x_{nes} - x_1 > z_c$ is satisfied where x_{nes} and x_1 are the displacement of the NES mass and the top floor respectively and z_c is the clearance as shown in Fig. 1. After calculating the precise time of the impact, the velocities of the top floor and the SSVI NES after the impact are calculated based on the conservation of momentum and the coefficient of restitution r_c principles as

$$\dot{x}_1^+ = \frac{m\dot{x}_{nes}^- + M_1\dot{x}_1^- - mr_c(\dot{x}_1^- - \dot{x}_{nes}^-)}{m + M_1}$$
$$\dot{x}_{nes}^+ = \dot{x}_1^+ + r_c(\dot{x}_1^- - \dot{x}_{nes}^-) \tag{2}$$

where M_1 and m are the masses of the top floor and NES respectively and the superscripts $+$ and $-$ indicate the velocities after and before the impacts respectively. Accordingly, there are three sources of energy transfer and dissipation in the coupled system. The first is due to the linear damping element, represented by b_{nes} in Fig. 1, coupling the NES mass to the top floor of the structure. The second element is the kinetic energy lost during the inelastic impacts that occur when the NES collides with the rigid barrier attached to the top floor. The third is due to the non-smooth interference from the vibro-impacts which alters the global dynamic response of the structure causing energy to be transferred within its structural modes. Transferring energy from low-frequency high-energy destructive fundamental mode to high-frequency low-energy mode is another element of TET.

One way to quantify the performance of the coupled system for achieving efficient TET is by measuring the enhancement in the damping of the respective effective modal oscillators. This is quantified by the time-independent averaged effective modal damping measures $\lambda_{eff,i}$ expressed as

$$\lambda_{eff,i} = \frac{\dot{q}_i(T_0)^2 - \dot{q}_i(T_f)^2 + \omega_i^2\left(q_i(T_0)^2 - q_i(T_f)^2\right)}{2\int_{T_0}^{T_f} \dot{q}_i^2 dt} = \frac{E_i(T_0) - E_i(T_f)}{\int_{T_0}^{T_f} \dot{q}_i^2 dt} \quad (3)$$

where $\dot{q}_i$ is the modal velocity of the i-th mode, T_0 and T_f are the initial and final simulation times, E_i is the instantaneous energy and ω_i^2 is the effective modal stiffness. Because the modal response of a linear primary structure without the NES leads to no energy transfer within its modes, the nominal modal damping λ_i of the i-th structural mode are obtained from Eq. (3). The nonlinear interaction of the NES causes the energy dissipated by any mode plus its instantaneous energy to not sum up to its initial induced energy due to energy exchange between the structural modes and therefore the energy in each mode is not reserved. The ratio of the time-independent average effective damping measures $\lambda_{eff,i}$ to the nominal modal damping λ_i of the NES-free system is defined as the normalized weighted-averaged effective damping measures $\hat{\lambda}_{eff,i} = \lambda_{eff,i} \big/ \lambda_i$. If $\hat{\lambda}_{eff,i} < 1$, then energy is transferred into the i-th mode and it eventually dissipates more energy than its initial energy and vice versa.

The SSVI NES parameters: r_c, k_{nes} and b_{nes} are tuned in order to investigate the effect of changing the coefficient of restitution on achieving efficient and rapid transfer and dissipation of energy. The simulation time is set to 5 seconds to ensure efficient and rapid TET, the clearance z_c is fixed to $0.02m$ to ensure non-smooth vibro-impacts will occur and the NES mass ($m = 2.5kg \approx 0.05(M_1 + M_2)$) is assumed to be nonparasitic (i.e. do not add mass to the primary structure). Figure 2 shows the normalized weighted-averaged effective damping measures of mode 1 for varying NES parameters for an impulsive excitation induced by identical initial velocity of $0.25m/s$ equally to both floors of the primary structure. Generally, it is noticed that a relatively weak stiffness coupling and strong damping coupling elements are required for the SSVI NES to transfer significant amount of energy from the first fundamental mode to be dissipated the NES damping, inelastic impacts or higher structural modes for all values of the coefficient of restitution. Further, it is observed that the shape of the contour plots is reserved for varying coefficient of restitution values, however, the maximum achievable effective damping measure $\hat{\lambda}_{eff,1}$, indicated by the black crosses, occurs at higher damping values for higher coefficients of restitution values. This outcome can be understood from the fact that at high value of r_c, the energy dissipated by the inelastic collisions is decreased and therefore higher damping values are required to maximize the effective damping measure $\hat{\lambda}_{eff,1}$. Moreover, it is also concluded that low values of the coefficient of restitution enable wider range of stiffness and damping values to transfer and dissipate energy from the fundamental mode of the primary structure as observed from the size of high values of $\hat{\lambda}_{eff,1}$ (red color) in Fig. 2.

3 RESULTS AND DISCUSSION

The results of the numerical optimization are summarized in Fig. 3(a) which shows the maximum achievable normalized weighted-averaged effective mode 1 damping measures $\hat{\lambda}_{eff,1}$ by an optimized system at each specific value of the coefficient of restitution r_c for a clearance of $z_c = 0.02m$ and an impulsive loading through an identical initial velocity of $0.25m/s$ in

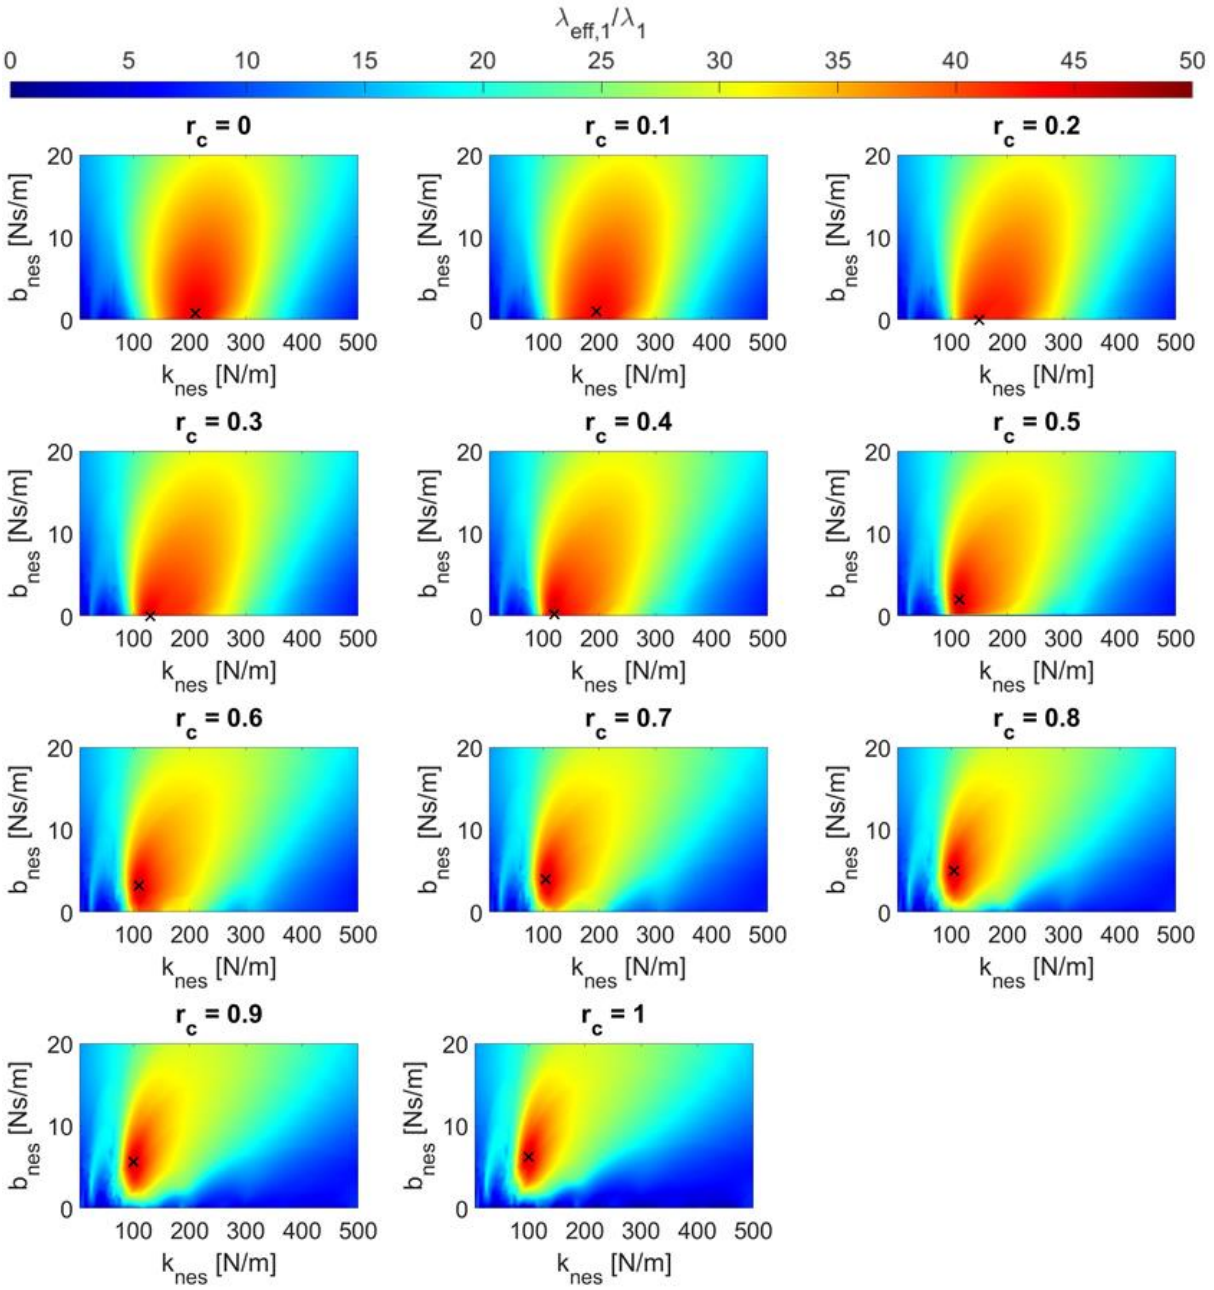

Figure 2: Contour plots of the normalized weighted-averaged effective damping measures for varying stiffness k_{nes}, damping b_{nes} and coefficient of restitution r_c for the two-story primary structure; identical initial velocity 0.25 m/s is considered for each floor, and black crosses indicate optimal system parameters.

duced equally to all floors of the primary structure. First, it is noticed that the optimized coupled systems for all values of r_c result in normalized weighted-averaged effective mode 1 damping measures $\hat{\lambda}_{eff,1}$ that are greater than unity. This indicates that in all cases, energy is being transferred from the high energy low frequency mode 1 to the NES itself or the second structural mode having lower energy and higher frequency. Consequently, this indicates that highly efficient TET has occurred by forcing energy to be transferred through single or cascades of resonance captures in a rapid and nearly irreversible way. In addition, the goal of this paper is to investigate if changing the coefficient of restitution from its typical value of 0.7 which corresponds to steel-to-steel impacts will enhance the energy transfer and dissipation

by resulting in higher values of $\hat{\lambda}_{eff,1}$. Fig. 3(a) shows that the maximum normalized weighted-averaged effective mode 1 damping measure is 46.2 achievable with a coefficient of restitution of 0.4 where the optimized SSVI NES parameters are $k_{nes} = 120N/m$ and $b_{nes} = 0.1078Ns/m$ compared to $\hat{\lambda}_{eff,1} = 45.7$ achievable with a coefficient of restitution of 0.7 where the optimized SSVI NES parameters are $k_{nes} = 106N/m$ and $b_{nes} = 4.0723Ns/m$. Additionally, the performance of the optimized NESs at $r_c = 0.4$ and $r_c = 0.7$ are compared in Fig. 3(b) for varying initial impulsive energies induced equally to all floors. Both system reach their optimum at around $1.4Nm$ which corresponds to the optimization initial energy. However, the new system with coefficient of restitution of 0.4 shows higher normalized weighted-averaged effective mode 1 damping measures $\hat{\lambda}_{eff,1}$ for a wide range of initial impulsive energies indicating that better energy transfer and dissipation is achievable at lower values of the coefficient of restitution.

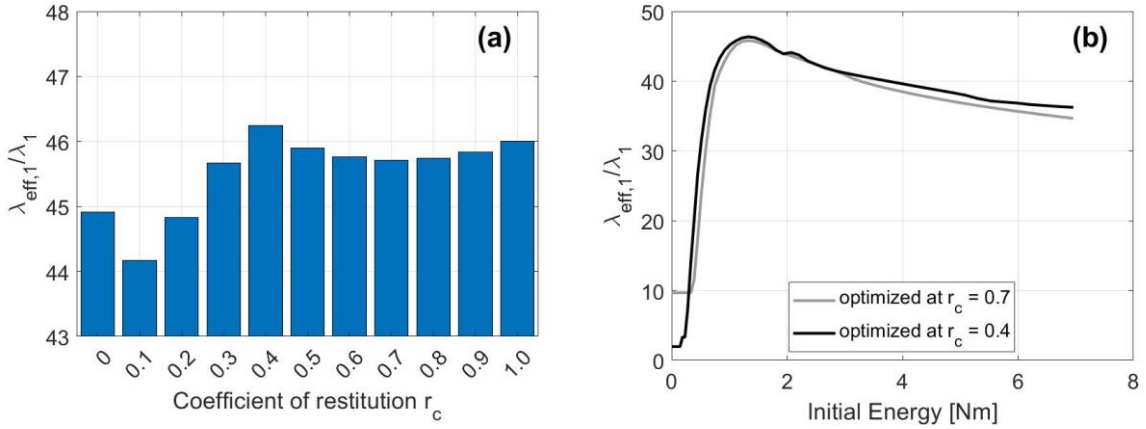

Figure 3: (a) bar chart showing the maximum achievable $\hat{\lambda}_{eff,1}$ at varying values of the coefficient of restitution r_c for the two-story primary structure with identical initial velocity $0.25m/s$ is considered for each floor and a fixed clearance of $0.02m$ (b) normalized weighted-averaged effective damping of the fundamental mode $\hat{\lambda}_{eff,1}$ of the two-story primary structure as function of the applied impulsive energy

4 CONCLUDED REMARKS

Many dynamical structures undergo continuous vibrations induced by shock or seismic excitations resulting from impacts, collisions, wind, earthquake, or fluid-structure interaction. Consequently, integrating dynamic vibration absorbers is becoming a high priority and essential requirement in many engineering applications. Nonlinear energy sinks (NESs) are the most efficient and robust attachments to act as rapid and passive device to transfer and dissipate energy from primary structure. Hence, this paper investigated further improvements to the currently most efficient nonlinear energy sink (NES), the single-sided vibro-impact (SSVI) NES by studying the effect of the coefficient of restitution, which is a ratio of restitutive to deformative impulses during impact, on its capability to irreversibly transfer induced impulsive energy out of the fundamental highly energetic mode. Currently, the coefficient of restitution used in most analytical, numerical and experimental analysis of impact-based NESs is 0.7 which corresponds to the typical steel-to-steel impacts. However, it is found in this paper that reducing the coefficient of restitution to 0.4 enhances the normalized weighted-averaged

effective damping measure of the fundamental mode of a two-story linear physical primary structure. The results are obtained for a simulation time of 5 seconds and using an NES mass of 5% of the whole structure indicating that rapid targeted energy transfer (TET) can occur with using a small mass of NES. The enhanced performance is obtained for a wide range of initial impulsive energies indicating the robustness of the proposed modification. Although the overall enhancement is not highly significant, this paper proves that lowering the coefficient of restitution leads to better shock and vibration mitigation and it is expected that using a large-scale structure will result in highly significant enhancement in the performance of SSVI NES by lowering the coefficient of restitution.

Abstract

The proposed work is based on an experimental activity aimed at comparing the long-term behavior of control devices based on the use of magneterheological (MR) fluids for seismic protection of framed structures. They have been tested three times in ten years: first in 2008, then in 2013 after five years of inactivity, and finally in 2017 after further four years of quiescence. The results of the three campaigns of passive and promptness experimental tests, in terms of force-displacement loops, electrical delay of the electromagnetic circuit, dissipated energy and maximum reacting force. The evolution of the response of such dampers due to inactivity over the time is assessed and discussed, aiming at recognize those phenomena are most probably responsible of a MR fluid deterioration (namely oxidation of iron particles, their sedimentation, fluid thickening, seal wearing), finally trying to give practical suggestions to the designers of smart control systems who should take this issues into account when dealing with the above kind of devices.

Keywords: magnetorheological damper, MR fluid, ageing effects.

1 INTRODUCTION

Magnetorheological (MR) fluids are suspensions of ferromagnetic particles in a carrier oil fluid, with several types of additives; their rheological properties change rapidly, stably, and repeatedly when a magnetic field is applied. The particles, whose diameters range from 1 to 10 μm, align themselves along magnetic fluxes with the external magnetic field, and these clusters generate resistances against the orthogonal flow. The change in the yield stresses that occur due to the intensity of the external magnetic field, is much larger than the effect of the Newtonian viscosity of the base oil.

Actually, this possibility of modulating in real time the damping properties of devices based on MR fluids, represents one of the most promising way to manufacture a semi-active control system for civil structures. Aiming at avoiding structural resonance and maximize energy dissipation, the stiffness and/or damping of MR fluid devices can be varied in real time according to proper control algorithms which require real time acquisition of the external excitation and/or the structural response.

The most commonly applied model of a MR fluid is the simple and effective Bingham model [1]: it is characterized by a variable rigid-plastic component connected in parallel to a Newtonian viscosity element.

The rheological properties of the controllable MR fluids are influenced by the density and concentration of particles, size of particle, carrier fluid's features, type of additives, applied magnetic field, temperature, etc. Recent studies were addressed to the calibration of the above factors in order to improve the mechanical behavior and durability of the MR fluid [2].

In some real situations, MR devices work frequently: this is the case when they are applied for suspensions on vehicles and trains, for brakes, for vibration control of cable-stayed bridges subjected to wind, etc. On the contrary, in earthquake engineering applications, MR devices might be called to give a few seconds long effective response after years of quiescence. The authors [3], after a ten years long campaign, present and discuss the most important experimental results aimed to show the evolution over time of response promptness, dissipating capability, and force reaction of MR dampers.

In the following, a literature review is reported of the scientific research on the "ageing effects" of MR fluids due to long inactivity (i.e. those commonly occurring in case of seismic applications), rather than to fatigue or long-term use.

Two large scale prototype MR dampers, produced by the German firm Maurer Söhne for seismic applications, have been experimentally investigated during the above mentioned ten years long observation time period. The proposed paper tries to draw some conclusions on the possible causes of the small observed changes in the mechanical response over time.

It is worth to point out that the authors' research is addressed only to understand if and how the overall mechanical response of a MR fluid-based seismic dissipative device, at its macro scale, may change in time.

2 AGEING ISSUES OF MR DAMPERS

An MR fluid is a suspension of carbonyl magnetizable particles in a carrier liquid fluid. Various additives are present in the composition to improve the settling rate, reduce oxidation, etc. A literature review of the last twenty years of research on MR fluid are summarized here, by focusing on the main durability issues of MR dampers: many researchers have addressed their efforts to make up a mixture able to represent a satisfactory compromise among different and sometimes conflicting objectives: temperature stability, lower viscosity, lower settling, higher force, prevention of particle oxidation, etc.

A critical issue is represented by the low viscosity of the fluid, being the ratio of maximum (on-state) yield stress to minimum (off-state) viscous stress the responsible of the MR fluid ability to be controllable [1, 4].

Another important choice in the design of a MR fluid is the ratio of particles' weight to carrier fluid's weight (generally 0.1 – 0.5): it is chosen by trading-off its influence on the viscosity (off-state) and its effect on the maximum yield stress of the MR fluid (on-state).

A further issue is the influence of temperature [5], that doesn't affect the magnetically-induced (on-state) force but only the off-state force. If the temperature is in the range 0~100°C, the viscosity is relatively stable and would slightly decline as temperature rises: it is due to the fact that the thermal motion of molecules of carrier fluid is a little higher with temperature, and both attraction and internal friction decline; consequently, the shear stress produced by shear deformation slightly decreases, and as a result, the viscosity declines. In the range −40~0°C, the carrier fluid of MR fluid is solidified and settled, and as a result, large viscosity appears. Once the temperature is higher than 100°C, the carrier fluid would be volatilized and the additives would be decomposed, which make the viscosity gradually increase: some additives may cause irreversible thickening of MR fluid, which influences the chaining of the material in the applied magnetic field, resulting in the reduction of the shear stress and uncontrollability of the variation of the shear stress, the reduction of the transmission stability, and even the failure of transmission.

Long-term modifications of their behavior are a fundamental issue in Earthquake Engineering, because seismic dampers are generally dormant for most of their life, up to the occurring of an earthquake.

According to the literature, durability issues of MR dampers [6, 7, 8] are mainly associated to a) particle sedimentation, b) fluid thickening, c) particle oxidation and d) seal wearing:

a) Particle sedimentation

Magnetic particles are denser than the carrier fluid, so that long-term storage generates particle sedimentation and as such mixing processes might be required [9, 10]. This corresponds to an unexpected response of the fluid to the applied magnetic field.

b) Fluid thickening

Due to the fragmentation of the brittle oxide layer on the surface of the magnetic particles, the fluid can become thicker in time. This phenomenon causes an increase of the off-state viscosity and of the reacting force of the device. The coating of magnetic particles with a protective surface layer can be a solution to enhance the durability of MR fluids from this point of view [11, 12].

c) Particle oxidation

The MR fluid is characterized by a modification of its compositional properties, due to the absorption of carbon dioxide and the corresponding corrosion. This effect gets worse in case of higher shear rate and increasing temperature, that produce stronger collision of iron particles [13, 14]. The oxidation of particles determines a lower magnetization of iron oxides with respect to elemental iron and, consequently, to reduced mechanical performances of MR fluids. Surface protection agents and anti-oxidants can be added to the formulation in order to reduce or eliminate the process.

d) Seal wearing

Seal design and selection of proper seal material are a critical issue for MR devices. Iyengar and Alexandris [15] tested the wear resistance of five polyurethanes–based seal materials, in combination with four types of fluid lubricant, and investigated different abilities to resist wear. Then, Wiehe and Maas [16] made durability tests and showed the suitability of two seal types in terms of wear resistance for long-term usage.

According to previous studies, particle sedimentation in the absence of magnetic field represents the most severe problem for MR fluids, due to large difference of the densities between magnetic particles and carrier fluid. The non-uniform distribution of micro-particles can interfere with MR effect when the magnetic field is applied and hence MR fluid performance may be degraded. This is mainly the case of seismic MR devices where particles are subjected to only gravitational force for long time while not being functional.

Two strategies to reduce sedimentation are the adoption of fluid stabilizers additives or particle coating [17, 18], but high care should be taken in choosing fluid stabilizing additives so that they do not adversely affect the off-state viscosity [19]. The coating process is complicated and involves surface treatment and addition of monomer or stabilizer. Rahim et al. [17] studied the use of nano-particles additives of Al and Cu, simultaneously, to enhance the thermal conductivity and reduce the sedimentation rate of MR fluids. They proposed a procedure to find optimal components of the additives to achieve both the enhancement of the thermal conductivity and the reduction of the sedimentation rate, simultaneously.

The experimental tests showed in the following were conducted under virtually identical environmental conditions, so that a study about temperature effect on the mechanical response of the MR dampers is out of the scope of the work [20]. On the other hand, the authors have demonstrated the short-term readiness and efficacy of the investigated MR dampers through experimental dynamic characterization tests and also shaking table seismic tests on a scaled frame structure [21].

3 TEN YEARS AGEING EXPERIMENTAL CAMPAIGN ON PROTOTYPE MR DAMPERS

Dynamic characterization experimental tests of two prototype MR dampers were done in July 2017 and their results have been compared with those obtained for the same devices when they were tested in February 2008 and March 2013. The same experimental set-up were assumed, in similar environmental conditions. During both time periods, i.e. from 2008 to 2013 and from 2013 to 2017, the devices have been stored in a horizontal position. Then, they have been much slowly displayed to the testing machine for the 2013 and 2017 tests, in order to avoid the shaking of the MR fluid inside. This kind of storage just corresponds to the real inactivity condition of the dampers when they are installed horizontally inside a building at a certain floor level (i.e., under indoor environmental conditions), to seismically protect the structure. The comparison between the results processed from the three experimental testing periods, gave important information on how the devices' mechanical behavior changed after two long periods of rest. The authors tried to associate the variations of the mechanical behavior to the most probable physical modifications in MR fluids.

Figure 1 shows one of the prototypes full-scale MR dampers which were studied during a wide experimental campaign performed in 2008 and in 2013 [3], and were finally experimentally tested in July 2017. The intensity of the feeding current is in the range 0÷3 A and the maximum force, that can be developed at the maximum current intensity, is of about 30 kN. In order to assess the variations in their mechanical behavior due to the time elapsed with non-operating devices, harmonic and constant velocity displacements time-histories have been imposed between the ends of the devices.

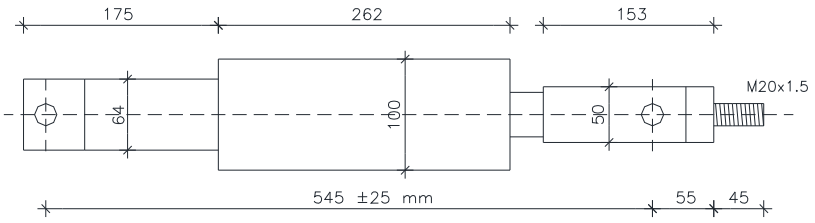

Figure 1: Photo and dimensions (in mm) of the prototype MR damper.

In order to be able to compare the results obtained by the tests performed during three different time periods, in July 2017, the same previous experimental setup has been used and some tests carried out in 2008 and 2013 have been performed again. Table 1 shows the list of tests: for each of them, made of 10 cycles, the type of test and the assumed parameters are reported. The promptness of each MR damper has been evaluated by performing the following tests: at first a harmonic displacement test at 1.5 Hz frequency and 20 mm amplitude; then, four constant velocity tests at 0.1 m/s velocity, 10 mm amplitude and 2 seconds pauses before inverting the sign of the velocity. These constant velocity tests were performed at different current values i=1.0; 2.0; 2.5; 3.0 A. Besides, for MR device 1, seven further passive tests were carried out by applying a harmonic displacement time-history at 1.5 Hz, 20 mm amplitude and different current intensities.

MR #	Type of test	Test No.	i [A]	f / v [Hz / ms^{-1}]	d [mm]
2	promptness	1	2.0	1.5 Hz	20
2	promptness	2	1.0	0.1 m/s	10
2	promptness	3	2.0	0.1 m/s	10
2	promptness	4	2.5	0.1 m/s	10
2	promptness	5	3.0	0.1 m/s	10
1	passive	1	2.7	1.5 Hz	20
1	passive	2	1.8	1.5 Hz	20
1	passive	3	0.9	1.5 Hz	20
1	passive	4	0.0	1.5 Hz	20
1	passive	5	2.7	1.5 Hz	20
1	passive	6	2.7	1.5 Hz	20
1	passive	7	2.7	1.5 Hz	20
1	promptness	8	2.0	1.5 Hz	20
1	promptness	9	1.0	0.1 m/s	10
1	promptness	10	2.0	0.1 m/s	10
1	promptness	11	2.5	0.1 m/s	10
1	promptness	12	3.0	0.1 m/s	10

Table 1: List of tests performed on MR dampers in 2017.

As shown in Table 1, both the MR dampers were subjected to five promptness tests. Their aim was to measure the time delays previously defined within the SA control chain. The change of dampers' behavior were commanded for each zero crossing of the displacement laws (i.e. in the instants in which x=0 occurred during constant velocity tests No. 2 to 5 on MR #2 and No. 9 to 12 on MR #1) or of the velocity curves (i.e. in the instants in which $\dot{x}$=0 occurred during harmonic displacement test No. 1 on MR #2 and No. 8 on MR #1). The electrical delay τ_e of the electromagnetic circuit, which spans from the instant when the current inside the coils starts to rise or to fall, to the stabilization of the current into the damper at its nominal value with a tolerance of 5%, has been measured at a certain number of on→off and off→on switches for each performed test. The minimum and maximum values of the electri-

cal delays τ_e measured in 2017 at on→off and off→on switches, are represented by the black filled circles in Figures 2(a) and 2(b), respectively. For each current intensity, they are compared to the minimum and maximum values measured in 2008, represented by the blank circles in the same Figures. The 2017 response delays fall within the 2008 relating ranges, in almost all the cases: they are within 2-6 ms for the on→off phases, 2-9 ms for the off→on phases.

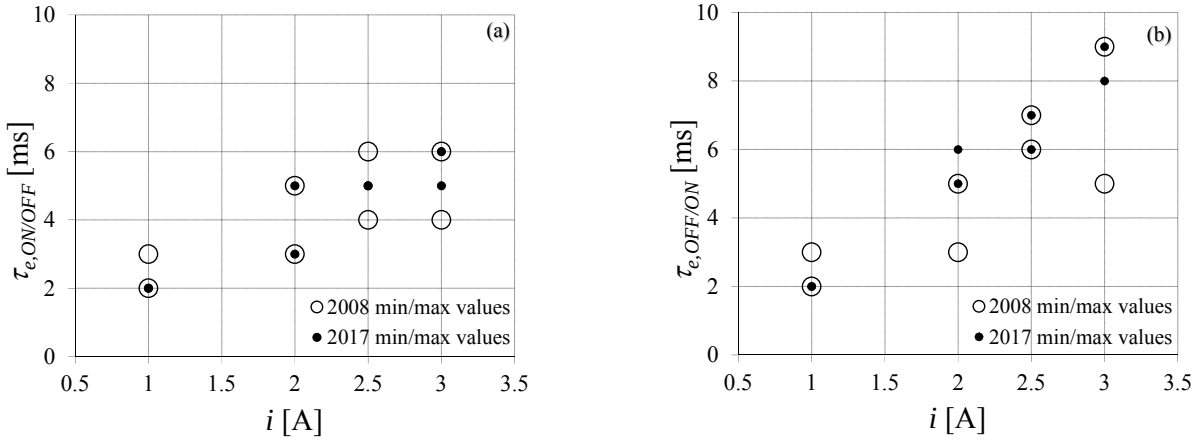

Figure 2: Minimum and maximum values of τ_e measured in 2008 and in 2017 for different levels of current.

Figures 3 and 4 show the most relevant results, in terms of force-displacement loops, of passive tests 1, 2, 4, 5 made on MR damper #1. An elongation of the damper is assumed as positive value of displacement, while a positive value of force indicates the device is in tension. Passive tests 3, 6, 7 are not discussed for the sake of brevity, because the results agree with those described in the following.

Figure 3(a) shows the first force-displacement cycle imposed in 2017 to MR damper #1 at a 2.7 A feeding current (test No. 1), after 4 years of rest. It is compared with the first cycle of the first test performed in 2013 after 5 years of inactivity, and with the first cycle of the same test done in 2008 after a certain number of tests. In the test of 2008 the device almost immediately reached the 27 kN yielding force, while an irregular trend is recognized in the reacting force measured in both 2017 and 2013, but that one recorded in 2017 is more irregular than the one of 2013. For some instant of the 2017 first loop, the maximum damper force is larger than four and nine years before. As already observed after the 2013 experimental tests, the mechanical behavior observed during the 2017 first cycle, performed after 4 years from the last activity, is most probably due to some phenomena occurring in MR fluid: sedimentation of the particles, presence of air bubbles and an increase of the fluid viscosity.

When the motion of the device piston operates a re-mixing of the fluid in its cylinder, the probable air is eliminated, the probable increase of fluid viscosity is recovered, and the recorded irregularities disappear from the following cycles. Figure 3(b) reports the second cycles of the same tests considered in Figure 3(a). It clearly shows that the 2017 second loop globally has a shape very similar to those recorded in 2008 and 2013, but the forces measured in 2017 are slightly lower than the forces of 2008 and 2013. The last part of the considered tests (10^{th} cycle) is in Figure 3(c) and makes in evidence that the 2017 forces become more and more less than those recorded in the 2017 first cycle. It is quite evident the typical Bingham behavior (i.e., friction and viscous components connected in parallel), but the decrease of the 2017 damping forces is probably due to the phenomenon of particle oxidation responsible of a decreasing of fluid's yielding stress, instead of a loss of MR fluid's viscosity.

Therefore, the experimental data explain that particle sedimentation have determined the most significant modifications during the first cycle, but the damper is able to recover after about one cycle through the mixing activity made by the piston within the fluid. Then, the mechanical response of the MR dampers exhibited after the 1st test is similar to that observed during the 10th cycle of the latter.

Figure 4 shows the first cycle of tests No. 4, 2 and 5 on MR #1 performed at 0.0, 1.8 and 2.7 A, respectively: they demonstrate that the viscous behavior in 2017 is quite equal to that in 2008 and 2013 (Figure 4(a)), so that the decay in 2017 damper force, with respect to 2008 and 2013, is depending on the current level. The amount of maximum force reduction is higher with increasing currents and it can be attributed to oxidation of particles which produces a not reversible decline of the MR fluids' mechanical performance, due to the lower magnetization of iron oxides.

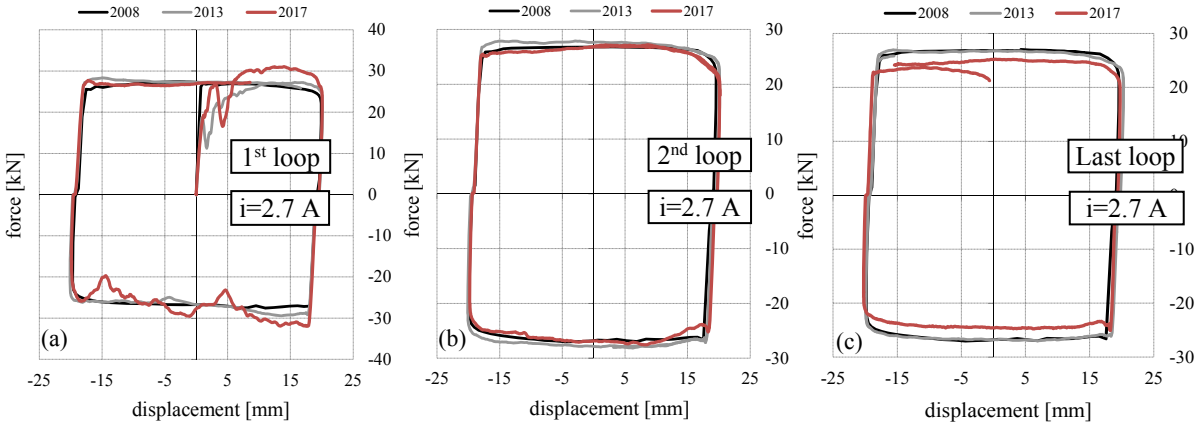

Figure 3: Comparison of force-displacement cycles (1.5 Hz, 20 mm) recorded in 2008, 2013 and 2017 at 2.7 A. Plots (a), (b) and (c) refer to the first, second and 10th loop, respectively.

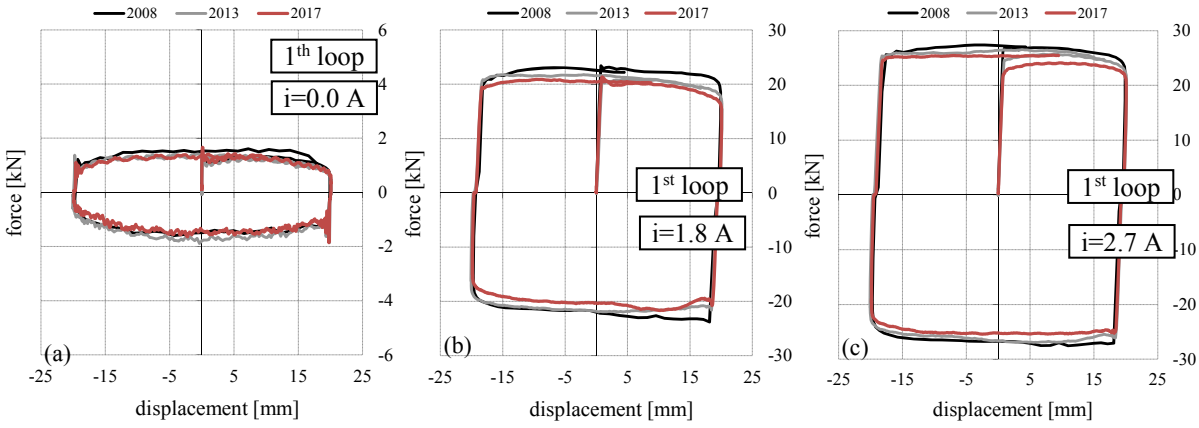

Figure 4: Comparison of force-displacement cycles (1.5 Hz, 20 mm) obtained in 2008, 2013 and 2017 for different levels of current (0.0, 1.8, 2.7 A).

The behavior of MR dampers, in terms of control forces and dissipated energy, is further analysed in the harmonic displacement tests of 2008, 2013, 2017 at 1.5 Hz frequency and 20 mm amplitude. Clearly, the first cycle performed in 2013 and 2017 after long time of device's inactivity were not considered due to the temporary irregularities described above. Figure 5(a) reports the value of maximum damper force at four levels of current intensity: from 2008 to 2013, a percentage reduction of approximately 2% has been found at i = 2.7 A, while an increment of about 4% has been computed at i = 0.0 A; from 2013 to 2017, a reduction of about

5% and 8% has been determined at the two above extreme currents. For the same harmonic tests, Figure 5(b) shows the energy dissipated in one displacement cycle, computed as mean of the of about 1% energy values related to three consecutive loops: from 2008 to 2013, a percentage increment has been calculated at i = 2.7, while a reduction of about 5% has been found at i = 0.0 A; from 2013 to 2017, a reduction of about 4% and 10% has been evaluated at the two extreme current levels.

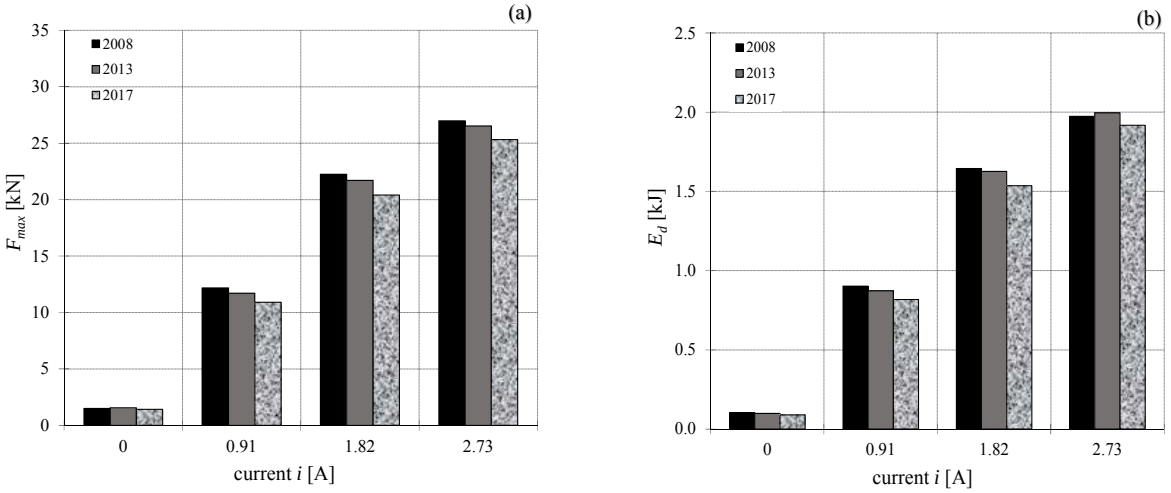

Figure 5: Maximum device force (a) and energy dissipated in one loop (b), for the tests at 1.5 Hz and 20 mm performed in 2008, 2013 and 2017 at currents 0.0, 0.9, 1.8, 2.7 A.

Table 2 reports the percentage of performance decay from 2008 to 2013, from 2013 to 2017, and finally from 2008 to 2013. In case of no current (0 A), the maximum reacting force is reduced by about 5%, while for current intensities 0.9 and 1.8 A the effect due to probable particle oxidation leads to less reacting forces of about 8-10% with respect to 10 years before. However, at current 2.7 A, the performance decay is less (6%) because the higher intensity of the magnetic field makes the device less sensitive to the oxidation of ferro-based particles. The average decay, over the four current levels, is 7%.

On the other hand, on the right side of Table 2 are summarized the results in terms dissipated energy: its decay in 10 years, is almost inversely proportional to current, i.e. from -14% at 0.0 A to -3% at 2.7 A.

	Response time	Maximum reacting force					Dissipated energy				
		0.0 A	0.9 A	1.8 A	2.7 A	*mean*	0.0 A	0.9 A	1.8 A	2.7 A	*mean*
2008 → 2013	Practically unchanged	4%	-4%	-2%	-2%	*-1%*	-5%	-3%	-1%	1%	*-2%*
2013 → 2017		-8%	-7%	-6 %	-5%	*-6%*	-10%	-6%	-6%	-4%	*-6%*
2008 → 2017		**-5%**	**-10%**	**-8%**	**-6%**	***-7%***	**-14%**	**-9%**	**-7%**	**-3%**	***-8%***

Table 1: Ageing effects due to inactivity (minus sign means a decrement).

4 CONCLUSIONS

The authors describe the results of an experimental activity designed to assess the long-term behavior of two prototype MR dampers after many years of rest. Four different phenomena have been found in literature as responsible of deterioration of MR fluids: sedimentation of particles within the fluid, their oxidation, thickening of the fluid and seal wearing. The oxidation phenomenon seems to be the most significant in compromising the effectiveness of a MR device over time. It is worth to point out that the seal wearing was never an issue for the

authors because no fluid leakage has been ever observed in the studied prototype MR devices. The first force-displacement cycle performed after the quiescence was quite irregular due to particles sedimentation and possible air bubble inside the fluid. This issue quickly reversed, both in the 2013 and 2017 years, after the first half of the first cycle. The effects of fluid's thickening on the mechanical response were not detected, as this typically becomes more evident when MR fluids are subjected to long-term high shear stress, rather than inactivity.

As conclusive consideration, it is possible to draw that in the worst case the performance decay caused by 10-years ageing effects is about 10%. It is acceptable, because it's within the limits of the uncertainties generally involved in structural analysis. It is worth to point out that the above conclusions are referred to a type of MR damper and fluid and can't be considered surely valid for all other cases.

Abstract

The Iberian Peninsula is close to the Eurasia-Africa plate boundary resulting in a considerable seismic hazard. In fact, the southwestern Iberian Peninsula is affected by far away earthquakes of long-return period with large-very large magnitude. A project named PERSISTAH (Projetos de Escolas Resilientes aos SISmos no Território do Algarve e de Huelva, in Portuguese) aims to cooperatively assess the seismic vulnerability of primary schools located in the Algarve (Portugal) and Huelva (Spain). Primary schools have been selected due to the considerable amount of similar buildings and their seismic vulnerability. In Portugal, the Decreto Lei 235/83 (RSAEEP) is mandatory while in Spain, the mandatory code is the Seismic Building Code (NCSE-02). In both countries, the Eurocode-8 (EC-8) is recommended. Despite the fact that both regions would be equally affected by an earthquake, both seismic codes are significantly different. This research compares the seismic action of Ayamonte (Huelva) and Vila Real de Santo António (Portugal). Both towns are very close and located at both sides of the border. Moreover, they share the same geology. This analysis has been applied considering a RC primary school building located in Huelva. To do so, the performance-based method has been used. The seismic action and the damage levels are compared and analysed. The results have shown considerable differences in the seismic actions designation, in the performance point values and in the damage levels. The values considered in the Portuguese code are significantly more unfavourable. An agreement between codes should be made for border regions.

Keywords: Performance-based method, seismic code, seismic behaviour, nonlinear analysis, Iberian Peninsula, reinforced concrete building.

1 INTRODUCTION

The Iberian Peninsula (IP) is close to the Eurasia-Africa plate boundary. This results in a considerable seismic hazard for the southern IP. In fact, the southwestern IP is affected by far away earthquakes of long-return period and large-very large magnitude [1]. Buildings in this area have been severely damaged in the past by relevant events such as the 1344, 1531, 1722, 1755, 1859 and 1909 earthquakes [2].

A project named PERSISTAH (*Projetos de Escolas Resilientes aos SISmos no Território do Algarve e de Huelva*, in Portuguese) aims to cooperatively assess the seismic vulnerability of primary schools located in the Algarve (Portugal) and Huelva (Spain) [3]. Primary schools have been selected due to their vulnerability [4], to the amount of buildings sharing a similar configuration and to the seismic hazard of the region. Moreover, a major part of them was constructed in the 1970s. That is, no seismic considerations were taken into account in their design or, if considered, the requirements were not very restrictive.

Despite the fact that both regions would be equally affected by an earthquake, the seismic codes of Portugal and Spain are significantly different [5]. In Portugal, the *Decreto Lei 235/83* (RSAEEP) [6] is mandatory. Whereas in Spain, the Seismic Building Code (NCSE02) [7] must be fulfilled. In both countries, the Eurocode-8 (EC8) [8] is recommended. The most outstanding difference between codes is the seismic action level. Some other specifications such as the ductility requirements and the limit states are very similar.

The European Union promoted a homogenization of the design rules for earthquake resistant structures through the EC8 [9]. However, the determination of the basic parameters such as the seismic action must be provided by the National Annexes. Moreover, the seismic hazard analyses implemented in these seismic codes are outdated. In fact, as pointed out in [10], further research must be performed on the definition of the ground motions including attenuation laws and scenario features.

A few studies are focused on the seismic codes provisions analysis. In [9], the authors performed a comparative study of the seismic hazard assessments in European national seismic codes. They obtained considerable differences in each seismic code. Hence, they concluded that inter-country cooperation would improve the earthquake catalogue and the criteria defining the seismogenic zones. In [11], the seismic design criteria and ground motion selection methods from five different world regions were compared. They demonstrated that despite the incentive for harmonization, obvious differences could be mainly found on the response spectra definitions.

In this context, this research compares the seismic action of Ayamonte (Huelva) and Vila Real de Santo António (Portugal). Both towns are very close and located at both sides of the border. Moreover, they share the same geology. This analysis has been applied considering a reinforced concrete (RC) primary school building located in Huelva. *To* do so, a comprehensive analysis of the seismic action level provisions of each code has been performed. The performance-based method has been used and nonlinear static analyses have been carried out. The seismic action and the damage levels are compared and analysed.

2 METHOD

2.1 Seismic action specific provisions.

In this section, a comprehensive analysis of the seismic action level provisions of each code has been performed. As in [9], Table 1 summarizes the principal parameters analysed and their correspondent values.

Parameter	Decreto Lei RSAEEP	ECEC-88	NCSE-02	Spanish update	EC8 Spanish annex	EC8 Portuguese annex
Date	1983	1998	2002	2012	2010	2010
Earthquake scale	Magnitude	-	Intensity	Magnitude	-	-
Earthquake estimation	Historical Attenuation laws Gumbel III	-	Historical	Historical Attenuation laws	-	-
Attenuation function	Acceleration	-	Macroseismic	Acceleration	-	-
Hazard assessment	Poissonian Gumbel I	-	Poissonian	Poissonian	-	-
Hazard descriptor	PGA	$a_g=a_{gR}\cdot\gamma_I$	$a_c=S\cdot\rho\cdot a_b$	PGA	$a_{gR}=0.8\cdot a_b$	a_{gR}
Importance factor	-	$\gamma_I=1$	$\rho=1$	$\rho=1$	$\gamma_I=1.3$	$\gamma_{I\text{-}T1}=1.45$ $\gamma_{I\text{-}T2}=1.25$
Type of spectrum	Type 1 and 2	Type 1 and 2	Type 1	Type 1	Type 1 and 2	Type 1 and 2
Non-collapse	T_{NCR}=1000yrs	T_{NCR}=475 yrs P_{NCR}=10%	T_{NCR}=500 yrs P_{NCR}=2 ‰	T_{NCR}=475 yrs P_{NCR}=10%	T_{NCR}=475 yrs P_{NCR}=10%	T_{NCR}=475 yrs P_{NCR}=10%
Damage level	-	T_{DLR}=95 yrs P_{DLR}=10%	T_{DLR}=95 yrs P_{DLR}=10%	T_{DLR}=95 yrs P_{DLR}=10%	T_{DLR}=95 yrs P_{DLR}=10%	T_{DLR}=95 yrs P_{DLR}=10%
Hazard value	-	-	Ayamonte a_c=1.597 m/s^2 a_g=1.428 m/s^2	Ayamonte a_c=1.763 m/s^2 a_g=1.5 m/s^2	-	Vila Real $a_{g\text{-}T1}$=2.2 m/s^2 $a_{g\text{-}T2}$=2.1 m/s^2

Table 1: summary of the basic seismic action designation parameters of each code.

In the case of Spain, the imperative seismic code is the NCSE-02 while the EC-8 is recommended. This code provides only requirements to prevent buildings collapse. Therefore, only static analyses are allowed and no damage thresholds are considered. The seismic hazard map followed a similar approach to the 1994 version of the code. The calculation was performed in terms of the European Macroseismic Scale (EMS-98) intensity scale based on a poissonian approach. The data came from the Spanish Geographic Institute, "*Instituto Geográfico Nacional*, National Geographical Institute of Spain (NGIS)". A logarithmical correlation was implemented to determine the horizontal acceleration using the EMS scale. The spectrum is defined according to the *C* and *K* coefficients. The *K* coefficient takes into account the different contribution of the Gibraltar-Azores zone to the seismic hazard. The *C* coefficient considers the influence of the soil. The return period (*T*) and the exceedance probability (*P*) differ from the rest of the codes. The hazard is described by the seismic acceleration (a_c), which is calculated as the product of the soil amplification coefficient (*S*), the importance factor (ρ) and the basic acceleration value (a_b). The coefficient *S* is used to calibrate the value of a_b since it is expressed for soil-type II.

In 2012, an update of the Spanish seismic hazard maps was performed [12]. Its use is recommended but it is not mandatory. This catalogue carried out a revision of earthquakes of other catalogues and specific studies. In addition, a homogenization process to convert all the events into moment magnitude (M_w) by applying different relations was performed. A total amount of 6999 events were implemented, ranging from M_w 3.5-8.5 and depth 0-65 km. A Probabilistic Seismic Hazard Analysis (PSHA) was implemented following a Poisson distribution to determine the probability of exceedance. *T* and *P* were considered similar to the EC8 values. The hazard was expressed as PGA on soil-type I.

In the Portuguese code RSAEEP (1983), the earthquake estimation implemented historical events, attenuation laws and the Gumbel III extreme distribution. The hazard assessment took into account a Poissonian approach as well as a Gumbel I distribution. As established by [10], the process of seismic occurrence was based on the Seismic Catalogue of the Iberian Peninsu-

la taking into account a 2000 years-period of observation. The return period was considerably superior to the other codes. The response spectra were tabulated for each of the four seismic zones and the influence of the soil was taken into account by means of the α-coefficient.

Regarding the EC-8 provisions, a different approach is used to determine the response spectrum. Depending on the soil type, different values of fundamental periods are designated. The hazard is described as the design ground acceleration on Type A-ground (a_g). This is equal to the reference peak ground acceleration (a_{gR}) multiplied by the importance factor (γ_I). The values to be ascribed to a_{gR} can be found in the National annexes. In the Spanish annex, the a_b must be reduced a 80% to obtain the a_{gR} since the a_b is expressed for the soil type II. Regarding the Portuguese annex, no reduction must be performed. Moreover, different values of the γ_I-factor are established in each Annex for the schools' buildings (i.e. 1.3 in the Spanish Annex and 1.45 and 1.25 in the Portuguese Annex, when considering the response spectrum Type 1 and 2, respectively).

The EC-8 and the Portuguese code establish different response spectra types. According to the EC-8 designation, Type 1 (T1) is used if the earthquakes that contribute most to the seismic hazard are far-earthquakes of moderate-high magnitude (M_w>5.5). Type 2 (T2) spectrum is implemented if the earthquakes are near-earthquakes of magnitude not larger than M_w<5.5. Nevertheless, the NCSE-02 considers only the far-earthquake scenario.

Concerning the return periods and the probability of exceedance, they remained the same in the case of the EC-8 and the National Annexes for the non-collapse (NCR) and the damage level cases (DLR). However, in the case of the NCSE-02, the *T* and the *P* for the non-collapse case are different as well as the return period of the Portuguese code.

The response spectra determined according to each seismic code provisions for the border region of Vila Real de Santo António - Ayamonte are shown in Figure 1. The following codes have been considered: the Portuguese *Decreto Lei*; the NCSE-02 response spectrum considering Ayamonte and the values obtained by the 2012 update; and the EC-8 response spectrum considering these former values and the Portuguese seismic action provisions for Vila Real established in the National Annex and in [13].

The soil type selected has been type III or C in the case of the National codes and European provisions, respectively. It should be noted that considerable differences could be found on the hazard value comparing the seismic codes. These values differ up to a 60%.

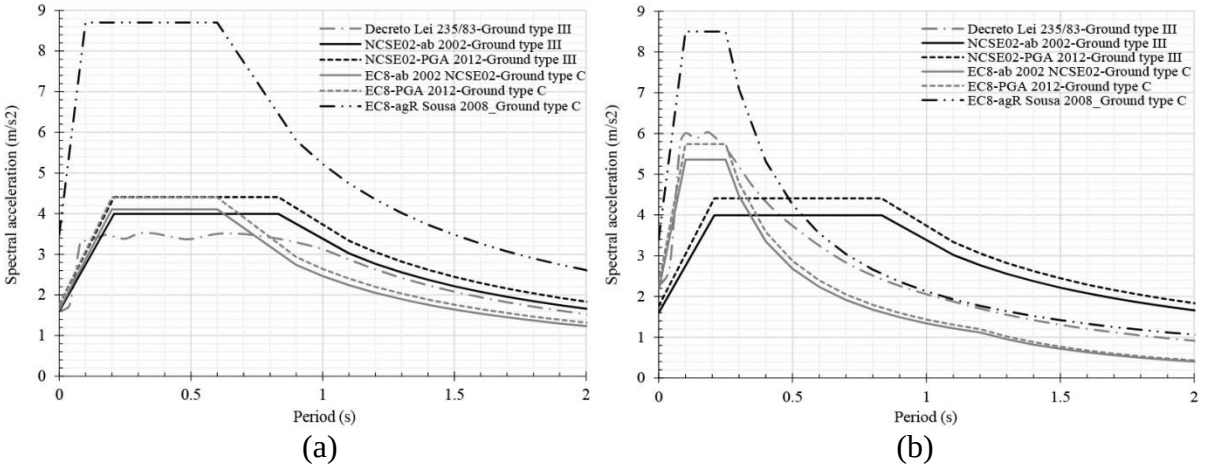

Figure 1: comparison of response spectra of each seismic code considered for a far-earthquake scenario (Type 1) (a) and a near-earthquake scenario (Type 2) (b).

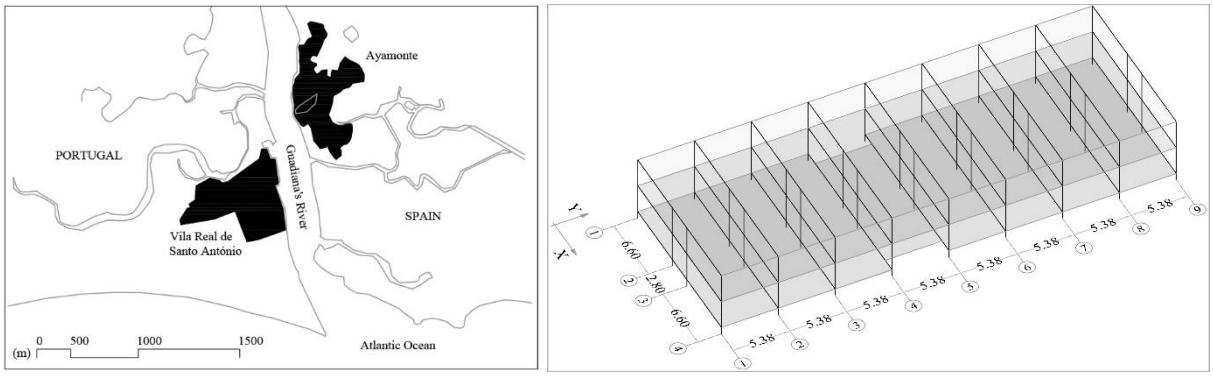
2.2 Building's configurations.

A typical RC primary school has been selected. This is located in Ayamonte (Spain). However, this has been analysed as if it was located in Vila Real de Santo António (Portugal) and in Ayamonte (Spain). These two towns are placed at each side of the border between both countries (Figure 2a). Hence, buildings in this area share the same geology and the seismic hazard should be similar. The building is composed of two storeys and it was constructed during the 1970s. Therefore, basic seismic requirements were considered during its design. The plan and the elevation of the building have been depicted in (Figure 2b).



(a) (b)

Figure 2: towns location (a) and building's configuration (b).

The building is composed of RC wide-beams, columns and ribbed slabs. The frames in the X direction are the load bearing frames. Load beams are designed as 60x30 cm, they have 5Ø16 mm of longitudinal rebar and Ø6 mm each 20 cm of transversal rebar. Tie beams are of 30x30 cm, they have 4Ø12 mm of longitudinal rebar and Ø6 mm each 20 cm of transversal rebar. Columns are of 30x30 cm, they have 4Ø12 mm of longitudinal rebar and Ø6 mm each 15 cm of transversal rebar. The RC compressive strength (f_{ck}) is 17.5 MPa while the steel yield stress (F_y) is 420 MPa. The modulus of elasticity (E_c) are 25,000 MPa and 200,000 MPa, for the RC and the steel, respectively.

The gravitational loads considered in the analysis have been the self-weight of the elements and the permanent and variables loads. The first is automatically considered by the computer software used in the analysis. The dead loads are the sum of the weight of the ribbed slabs, the internal partitions, the ceiling and the ceramic flooring, which is in total 5.5 kPa. The variable load designated, corresponding to classrooms, is 3 kPa. This value is the same in both the Spanish and the Portuguese codes.

2.3 Performance-based method.

The building's performance analysis depends on the capacity and the demand [14]. According to these parameters, it can be obtained the so-called performance point of a building (displacement vs. basal shear force). The performance point is determined by the intersection of the capacity curve of the building and the inelastic response spectrum. This intersection can be performed by two methods: the capacity-demand spectrum method from the ACT-40 [15] and the N2-method [16].

In this work, the N2-method has been taken into account, which is the procedure implemented in the EC-8 to determine the target displacement. The construction of the theoretical bilinear curve has been carried out according to [17]. Different performance points have been obtained for each response spectrum defined in the previous section. These have expressed for

a multi-degree-of-freedom (MDOF) system. Also, the non-collapse safety condition required $d_u^*/d_t^*>1$ according to the EC-8 has been analysed and obtained for a single-degree-of-freedom (SDOF) system.

2.4 Nonlinear static analyses.

Although more accurate results can be obtained by means of dynamic analyses, they require high computational efforts and time to model the structures [18]. Since this study aims to compare the general seismic performance of a building according to different seismic actions, nonlinear static analyses have been carried out (pushover analyses). They have been performed to determine the capacity curves in the two orthogonal directions of the building (X and Y) by means of the SAP2000 v.19 software [19].

Two loads pattern have been considered as indicated in the EC-8. First, a triangular pattern based on lateral forces proportional to the height and the mass of each storey has been applied (mass). Then, a load patter proportional to the displacement produced by the first mode of vibration has been considered (mode). Numerous works can be found on the simulation of the nonlinear behaviour of RC [20]. In the SAP2000 software, RC frames nonlinear behaviour is simulated by means of the plastic hinges. Plastic hinges are added to all the RC frames. Two types of plastic hinges can be determined: default and manual. Manual plastic hinges determination takes considerable amount of time and the results do not differ from those obtained by the default designation [20]. Therefore, in this work, default plastic hinges have been defined according to the ASCE-41-13 [21] as implemented in [20]. PM2M3 plastic hinges have been added to columns whereas M3 hinges have been included in the beams. They have been included at both ends of the frames as established in the EC-8.

2.5 Damage level provisions.

The fragility curves define the probability of reaching a damage state. In this work, these curves have been determined according to the RISK-UE lognormal distribution [22]. The damage probability for each state (no-damage, slight, moderate, severe and collapse) has been determined. In addition, a useful index named the mean damage grade has been obtained according to [23]. This index represents the most likely damage state that will suffer the structure according to the seismic action. This value will range from 0 to 4.

3 RESULTS

This section presents the results obtained from the analyses carried out. Four capacity curves have been obtained, which are depicted in Figure 3. These have been named as AS (Ayamonte School) followed by the direction studied (X or Y) and the load pattern (proportional to the mass or to the first mode of vibration). Similar curves have been determined for each load pattern in both directions of the building. Therefore, the most unfavourable curves will be taken into account when obtaining the rest of the results (i.e. AS_X_mode and AS_Y_mode).

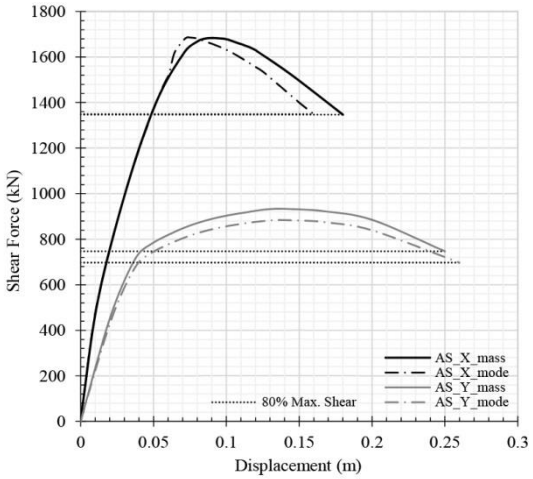


Figure 3: capacity curves in the X and the Y direction of the building.

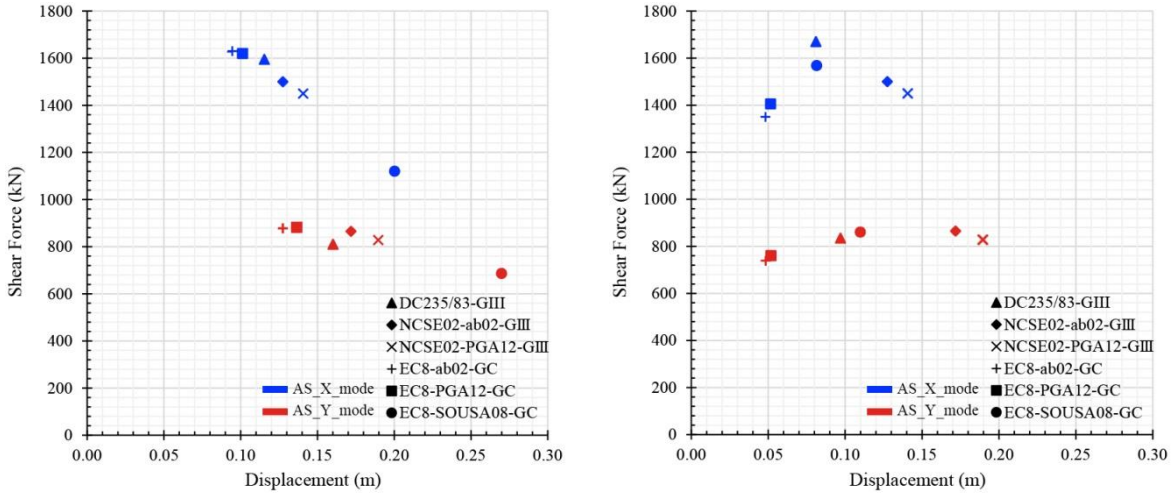
Once the pushover curves have been obtained, the performance points for the MDOF system have been determined for each response spectrum considered. The performance points are plotted in Figure 4.



(a) (b)

Figure 4: performance points obtained for each unfavorable load pattern considering Type 1 (a) and Type 2 (b) response spectra.

In Figure 5, the damage level probability is shown for each capacity curve selected. Only the results concerning the Type 1 response spectrum have been shown owing to the worse results obtained.

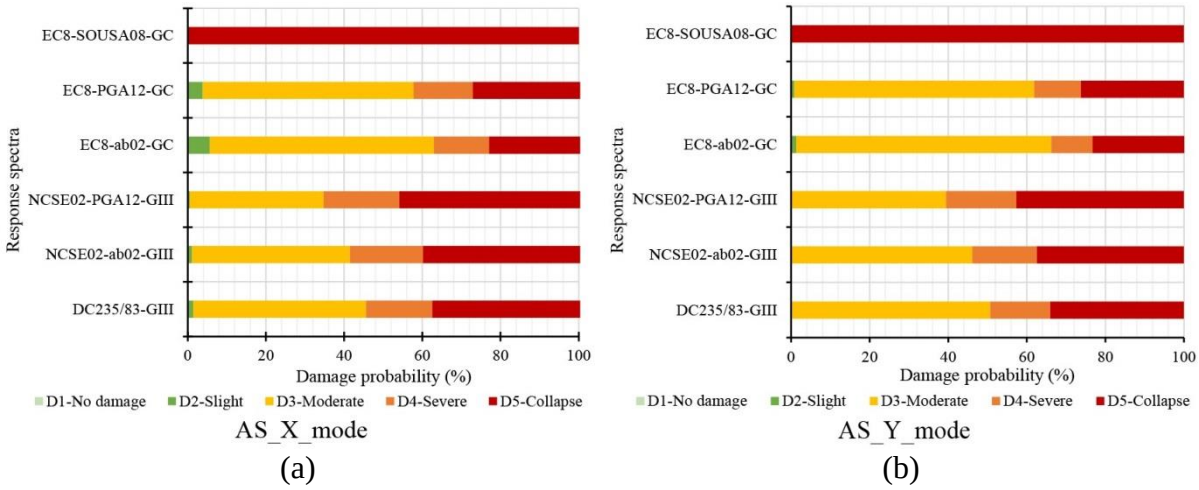


Figure 5: damage level probability for the capacity curves in the X (a) and Y (b) direction considering a load pattern based on the first vibration mode.

In Figure 6, the mean damage index is depicted for each capacity curve selected considering both types of response spectra.

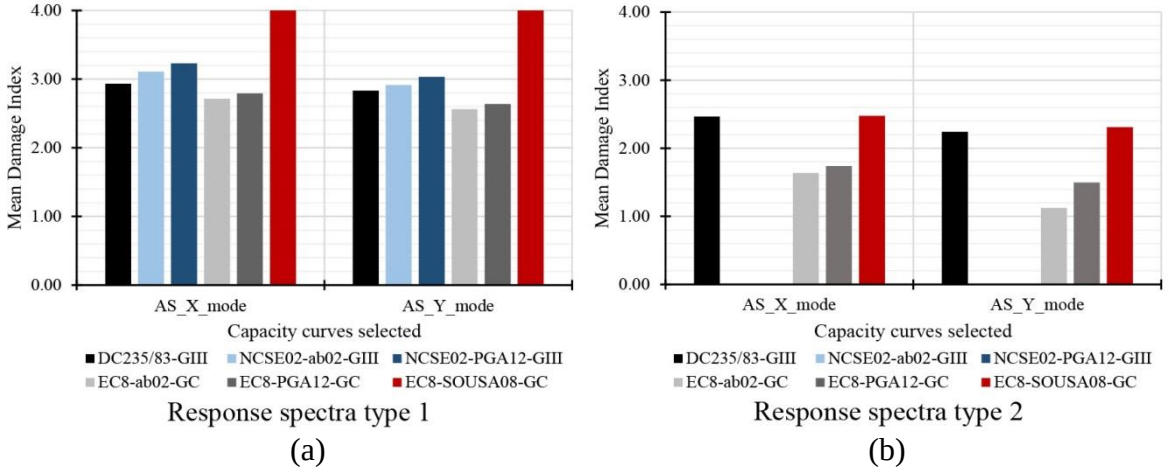

Figure 6: mean damage index for each capacity curve considering Type 1 (a) and Type 2 (b) response spectra.

Table 2 summarizes the SDOF ultimate displacements (d_u*) and the inelastic target displacements (d_t*) for the most unfavorable capacity curves considering each response spectrum.

Response spectrum	Type	Data	AS_X_mode	AS_Y_mode
Original building ultimate displacement		du*(m)	0.160	0.260
DC235/83-GIII	Type 1	dt*(m)	0.098	0.135
		du*/dt*	1.637	1.920
	Type 2	dt*(m)	0.069	0.082
		du*/dt*	2.332	3.171
NCSE02-ab02-GIII	Type 1	dt*(m)	0.108	0.145
		du*/dt*	1.482	1.789
	Type 2	dt*(m)	-	-
		du*/dt*	-	-
NCSE02-PGA12-GIII	Type 1	dt*(m)	0.119	0.160
		du*/dt*	1.343	1.622
	Type 2	dt*(m)	-	-

		du*/dt*	-	-
EC-8-ab02-GC	Type 1	dt*(m)	0.080	0.108

		du*/dt*	2.317	2.798

Table 2: SDOF ultimate and target displacements for each capacity curve and corresponding ratios of d_u*/d_t*.

4 ANALYSIS OF RESULTS

The analysis of the specific provisions established in each seismic code has revealed considerable differences regarding the seismic action level designation. This is mainly due to the seismic hazard assessment of each code. The NCSE-02 considers a poissonian approach. This represents the probability of occurrence of an event in a time or spatial framework. The Portuguese seismic hazard assessment is based on a Gumbel distribution. Contrary to the poissonian approach, this represents a distribution of maximum values of events. This results in higher values of ground acceleration in the case of Portugal since only maximum values are considered in its hazard assessment.

Moreover, the importance factor of school buildings varies its value for each code. The values in each code can differ from each other up to a 30%. This also leads to higher values of ground acceleration in the Portuguese codes.

The nonlinear static analyses have resulted in similar capacity curves obtained for each load pattern considered in the X and Y direction. The most unfavourable curves have been those proportional to the first vibration mode of the structure. The MDOF performance point values obtained for the X direction have been considerably higher than those obtained for the Y direction. Differences of up to 200% can be found comparing both types of response spectra. Furthermore, the performance points have considerably differed from each response spectrum type. The displacement obtained for the Type 2-spectra have been lower than those obtained for the Type 1.

Regarding the damage level probability, lower values of damage have been obtained in the X direction of the building. This is due to the higher structural capacity of the building in this direction. Considering the response spectra, higher values of damage have been obtained for the response spectra designed according to the NCSE-02.

In the case of the mean damage level, the damage state D3-severe damage (value of 3) has been exceeded by the models that considered the NCSE-02 response spectrum. However, the worst value has been obtained for the consideration of the Portuguese seismic values. In the case of the Type 2 response spectra, the D3 limit has not been reached.

Regarding the safety requirement d_u*/dt*>1, higher ratio values have been obtained for the Type 2 response spectra. Moreover, higher values of this ratio have been obtained for the Y direction. This is due to the higher ductility that the building presents in this direction.

It should be highlighted that in the case of the Type 1-response spectra, the worst performance point has been obtained for the EC-8-designed spectrum considering the Portuguese seismic action values. Moreover, the target displacement has been higher than the ultimate displacement. Consequently, this resulted in the collapse of the structure as the damage prob-

ability has shown. Furthermore, the EC-8 safety requirement $d_u^*/dt^*>1$ has not been accomplished.

5 CONCLUSIONS

The Algarve-Huelva is located at the southwestern Iberian Peninsula, close to the Eurasia-Africa plate boundary. This results in a considerable seismic hazard. In fact, this region is affected by far away earthquakes of long-return period with large-very large magnitude. Despite the fact that both regions would be equally affected by an earthquake, the mandatory seismic codes of each country are significantly different. In this work, the seismic action of Ayamonte (Huelva) and Vila Real de Santo António (Portugal) have been compared. Both towns are very close and located at both sides of the border. Moreover, they share the same geology. This analysis has been applied considering a RC primary school building located in Huelva. Primary school buildings have been selected to be analysed owing to the considerable amount of similar buildings and the seismic vulnerability of this typology.

Nonlinear static analyses have been carried out to determine the performance point and the damage level of the building considering different response spectra definitions: the Portuguese *Decreto Lei*; the NCSE-02 response spectrum considering the Ayamonte seismic hazard values and those obtained by the update of 2012; and the EC-8 response spectrum considering these former values and the Portuguese seismic action provisions for Vila Real established in the National Annex and in [13].

This work has concluded that considerable differences can be found on each seismic code provision particularly in the definition of the response spectra. This is due to the seismic hazard approaches followed in each code (i.e. average event distribution in the Spanish code and maximum values distribution in the Portuguese code). Moreover, the impact factor that amplifies the ground acceleration value differs from each other. Despite the fact that the EC-8 was proposed as a homogenization tool, the seismic action is obtained from the National Annexes whose values considerably differ from each other. Therefore, although the buildings are close and share a similar geology, different values of ground acceleration are obtained when considering the different codes.

The nonlinear static analyses have shown that the worst seismic performance is obtained when considering the Portuguese seismic action updated. In fact, the EC-8 safety requirement has not been accomplished for this seismic action. This is due to the unfavourable values considered in the Portuguese code. Moreover, higher values of damage have been obtained when considering the NCSE-02 response spectrum. This is due to the reduction of the Ayamonte ground acceleration value established in the 2012 Spanish update. This study leads to the conclusion that safety provisions may not be fulfilled if a less restrictive seismic code is taken into account. Therefore, as pointed out in numerous works, an agreement between codes should be made for border regions.

ACKNOWLEDGEMENTS

This work has been supported by the INTERREG-POCTEP Spain-Portugal programme and the European Regional Development Fund through the 0313_PERSISTAH_5_P project and the VI-PPI of the University of Seville by the granting of a scholarship. The grant provided by the *Instituto Universitario de Arquitectura y Ciencias de la Construcción* is acknowledged.

Abstract

This paper presents a predictive model for evaluating the central tendency and related record-to-record variability for the residual displacements of simple inelastic oscillators under seismic excitation. For this study, yielding single-degree-of-freedom systems were considered, with bilinear backbones and non-degrading hysteretic rule characterized by peak-oriented reloading stiffness. Systems with natural periods belonging to the 0.3 s to 2.0 s range and exhibiting post-yield hardening ratios ranging from 0 to 10%, were analyzed via incremental dynamic analysis to obtain the residual displacements as a function of the ductility demand. A set of fifty acceleration records was used for the dynamic analysis, coming from medium-to-large magnitude events, recorded at the closest distance to the rupture surface ranging from 3.5 km to 43.7 km on firm soil or rock and devoid of apparent directivity effects of interest for seismic response. The model fitted on these results, consists of two regression equations: one equation for the period elongation given ductility demand and another for the residual displacement ratio given period elongation and ductility demand.
In this context, the residual displacement ratio is defined as residual-to-peak inelastic displacement. Thus, the model allows to assess the joint conditional distribution of period elongation and residual displacement at fixed ductility levels. These results could be useful for seismic reliability assessment for structures accumulating damage, for example during seismic sequences, where the seismic fragility of a structure damaged during a mainshock earthquake comes into play for risk calculations during the ensuing aftershock sequence.

Keywords: residual displacements; sequence-based seismic reliability; state-dependent seismic fragility.

1 INTRODUCTION

Within the Performance-Based Earthquake Engineering (PBEE; [1]) paradigm, the probabilistic assessment of a structure's residual displacement is of interest, in addition to the peak (transient) deformation demand, because the former can be useful in modelling the performance of structures during a seismic sequence, when these structures have been already damaged by the mainshock earthquake. In fact, the residual displacement is a response parameter closely related with the remaining capacity of mainshock-damaged structures to withstand aftershock sequences [2,3]. In this context, the residual deformation was established over the last years as a useful index of the severity of inelastic response, complementary to maximum transient response. Moreover, its amplitude can be used to determine the technical and economic feasibility of repairing seismic damages because of the difficulty to reverse permanent displacements [4]. Thus, several previous studies were focused on individuating the parameters that primarily affect residual displacement, and a few investigations also presented simple predictive equations for residual displacements.

Some early observations about residual displacement demands were provided by Mahin and Bertero [5] who found that the permanent displacements of elastoplastic systems averaged more than forty-percent of the peak inelastic displacement demand with high level of variability (coefficients of variation associated with residual displacements close to unity).

An early residual displacement predictive procedure was provided by MacRae and Kawashima [6]. They studied residual deformation demands of bilinear single-degree-of-freedom (SDOF) systems with several values of post-yield stiffness ratio, under three ductility demands. They pointed out the influence of post-yield stiffness ratio on the amplitude of residual displacements introducing a method for estimating the average value of residual displacements only dependent on the post-yield hardening ratio and the ductility demand, without identifying a clear trend with the structural period of natural vibration. Moreover, they proposed residual displacement response spectra for bilinear oscillators with varying post-yield hardening ratio [7]. The dependence of residual displacements amplitude on ductility demand and mainly on post yielding stiffness was also confirmed by Borzi et al. [8].

Subsequently, Pampanin et al. [9] studied residual displacements normalized by peak inelastic displacement demand of four equivalent SDOF systems representative of reinforced concrete (RC) frame buildings. They considered three hysteretic models (evolutionary and non-evolutionary) and different post-yielding stiffness ratios. These authors observed that the residual deformation demand depended on the type of hysteresis, seismic intensity and post-yield stiffness ratio.

Ruiz-Garcia and Miranda [4,10] studied the influence of several factors on the residual displacement ratio C_r, which they defined as the ratio of residual-to-maximum elastic displacement. These factors included period of natural vibration, lateral strength ratio, site conditions, earthquake magnitude, distance to the source, post-yield stiffness ratio and unloading stiffness. In that investigation residual displacement ratios were computed for elastoplastic, bilinear SDOF systems with kinematic strain hardening and for SDOF systems with three stiffness-degrading hysteretic models. They observed C_r to strongly depend on the lateral strength and on period of natural vibrations mainly for periods shorter than about 1.0 s. They also highlighted that residual displacements ratios exhibit record-to-record variability that should also be accounted for. Moreover, a simplified equation to estimate the central tendency of residual displacement demands for elastoplastic systems was suggested in [4], as function of two independent variables, period of natural vibration and strength ratio.

A detailed study about the influence of the hysteretic law on residual displacements was performed by Liossatou and Fardis [11]. They used hysteretic models which represent the cyclic degradation of stiffness and strength that is typical of RC structures. The scatter in residual displacements was also quantified providing at different periods of natural vibration.

The objective of this study is to present a predictive model for the central tendency and related record-to-record variability of residual displacements for SDOF bilinear systems with non-degrading hysteretic rule, characterized by peak-oriented reloading stiffness. To this end, the constant-ductility residual displacement ratio is investigated, defined as the absolute value of the ratio of residual to peak transient displacement, $C_\mu = \left|\delta_{res}/\delta_{\max}\right|$, where δ_{res} and $\delta_{\max}$ preserve their sign. This ratio is calculated for various combinations of input motion, natural vibration period and post-yielding hardening ratio. In all cases, ductility demand μ (defined as the ratio of maximum response to yield displacement of the intact system, $\mu = \delta_{\max}/\delta_y$) is held constant by appropriately scaling the input motion. Because it is typical to define the damage state of a structure based on crossing maximum transient displacement thresholds (e.g., [12,13]), this constant-ductility approach could be useful in the context of simplified estimation of state-dependent seismic fragility [2,3,14]. The main result of the study is a predictive equation for C_μ, derived via two-stage regression [15].

The article is structured as follows: first the analysis methodology is outlined describing the properties of the analyzed systems and the organization of the analyses used to collect the data set. The next two sections are dedicated to the detailed description of the predictive model development, presenting first the model for residual displacement and secondly the model for period elongation. Finally, the evaluation of the predictive model effectiveness is presented along with some evaluation and discussion of the obtained results.

2. ANALYSIS METHODOLOGY

In order to collect the required data on which to base the predictive model, yielding single-degree-of-freedom systems with bilinear backbone and modified Ibarra-Medina-Krawinkler (IMK) hysteretic model [16] were analyzed. Figure 1a shows an example of bilinear backbone and hysteresis in dimensionless $\{R, \mu\}$ coordinates, where $R = Sa(T)/Sa(T)_y$ is the strength ratio, defined as the ratio of spectral acceleration intensity to its value causing yield or, equivalently, the ratio of the elastic force over the yield base shear of the system, and μ is the ductility demand. The backbone starts elastically and presents a following hardening segment with a slope α_h, representing the ratio of post-yield stiffness to elastic stiffness, which ends at the capping point ductility μ_c where the loss of strength begins. Figure 1a reports a descending branch too, defined by the post-capping slope α_c, the ratio of the negative post-capping stiffness to elastic stiffness, and the fracture ductility, μ_f, point corresponding to complete loss of strength. This latter branch was defined exclusively for keeping track of the capping points in the damaged post-shock state, whilst only considering target ductility demands lower than the capping ductility during the execution of nonlinear dynamic time-history analyses. Figure 1b shows the modified IMK hysteretic model with peak-oriented response (presented in detail in [17]). This hysteretic model is characterized by peak-oriented reloading stiffness; therefore, the direction of the loading path targets the maximum displacement on the opposite side once the horizontal axis is intersected in each reloading cycle. Although the model can include cyclic deterioration modes, in this study it was implemented without considering any degradation rules for strength and unloading stiffness.

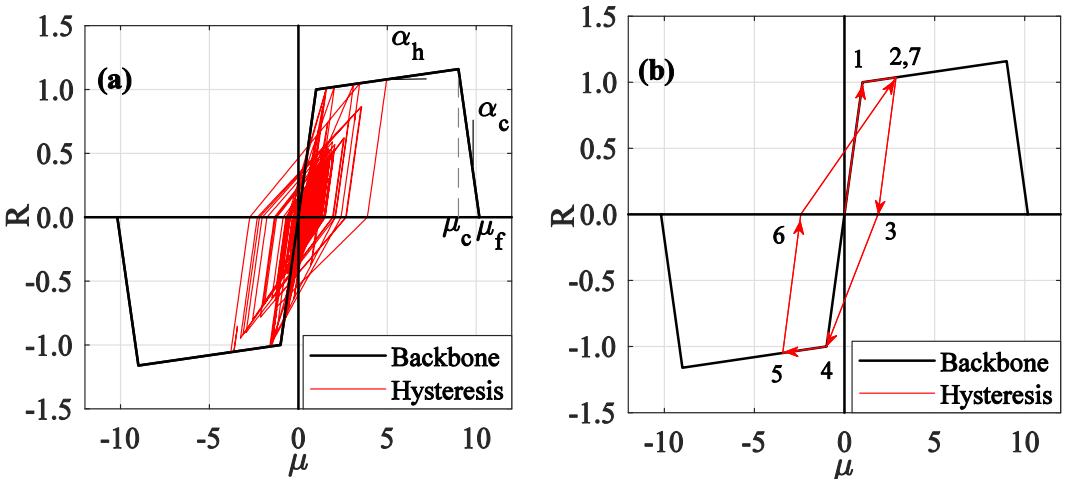

Figure 1: Backbone curve and non-degrading Modified Ibarra Medina Krawinkler (IMK) peak-oriented hysteretic model in dimensionless $\{R, \mu\}$ coordinates: backbone curve with defining parameters and an example of hysteresis for the case with $T = 1.0s$, $\alpha_h = 2.0\%$ and $\mu = 5.0$ (**a**); representation of IMK hysteretic model with peak-oriented response (**b**).

The residual displacements of the SDOF systems were computed using a set of analyses organized in two different phases. The first phase consists in the execution of *incremental dynamic analysis* (IDA) [18] fixing the target ductility μ, which defines the damage state reached by the structure during the earthquake. In this phase, the SDOFs are subjected to a suite of fifty earthquake ground motions selected from within the NESS dataset [19]. These ground motions were recorded on firm soil at a closest distance to the rupture surface (R_{RUP}) ranging from 3.5 km to 43.7 km and coming from seismic events with moment magnitude belonging to the 6.1-7.6 range. Furthermore, the selected records exhibit PGA ranging from 0.053 g to 1.43 g and are devoid of apparent directivity effects. IDA involves performing a set of nonlinear dynamic analyses using each record scaled in amplitude to increasing levels of intensity, represented by an intensity measure (IM), to reach or pass the limit of engineering demand parameter (EDP), the structural response corresponding to the level of ductility demand for each damage state. Thereby a scale factor (SF) for each accelerogram is evaluated to bring the response of the structural model to a fixed damaging level. The second phase consists in obtaining multiple realizations of the SDOF structure in post-mainshock damage state by performing non-linear dynamic analysis, using the records scaled by the SF calculated in the previous phase. Subsequently a *static pushover analysis* up to the collapse is performed for each realization, in both positive and negative direction of the load.

The performed analyses differ in the assumed values of ductility demand μ, period of natural vibration T and post-yield hardening ratios α_h of SDOF systems. Ductility demand assumed the following values $\mu = \{1.5, 2.0, 3.0, 4.0, 5.0, 6.0, 7.0, 8.0, 9.0\}$. The analyzed oscillators had a fixed backbone as shown in Figure 1. In detail, the bilinear backbone was defined assuming period, in seconds, $T = \{0.3, 0.6, 0.9, 1.0, 1.2, 1.5, 1.8, 2.0\}$, and hardening stiffness assuming the following percentage values with respect to the initial (elastic) one $\alpha_h = \{0.0, 0.5, 1.0, 2.0, 3.0, 4.0, 5.0, 10.0\}$. Setting the elastic stiffness and the period of natural vibration, the mass of the system for each single case was consequently computed. A viscous damping ratio $\xi = 5.0\%$ was used and kept constant throughout the time-history analyses.

The analyses were performed in order to study the variation of the backbone-defining parameters, following seismic damage. Large inelastic deformations during strong ground shaking leads SDOF systems with modified IMK hysteretic model to have residual displacements and elongation of natural vibration periods. The residual displacement at a certain ductility demand depends on the hysteretic characteristics of the system and it determines the remaining ductility capacity of the post-mainshock structure. The period elongation is caused by the reduction of the peak-oriented reloading stiffness which evolves according to the modified IMK hysteretic model reported in Figure 1b. Therefore, the structure from the natural vibration period T , in intact conditions, reaches by effect of the mainshock an elongated period T_{elon}. This elongated period is calculated from the post-shock reloading stiffness at the end of the dynamic analysis, k_{ps} as $T_{elon} = 2 \cdot \pi \cdot \sqrt{m/k_{ps}}$. Figure 2 shows the effects of seismic damage on the structural backbone for an analyzed case, where k_{ps} is evident from the slope of the pushover at the end of the excitation . In particular, Figure 2a shows the initial and post-mainshock backbones of a single SDOF system, highlighting the residual displacement and the elastic stiffness variation of the SDOF structure in its post-mainshock damage state, whereas in Figure 2b, the post-mainshock-damage-state realizations of the same SDOF structure under four accelerograms of the fifty-record set are shown, revealing the record-to-record variability.

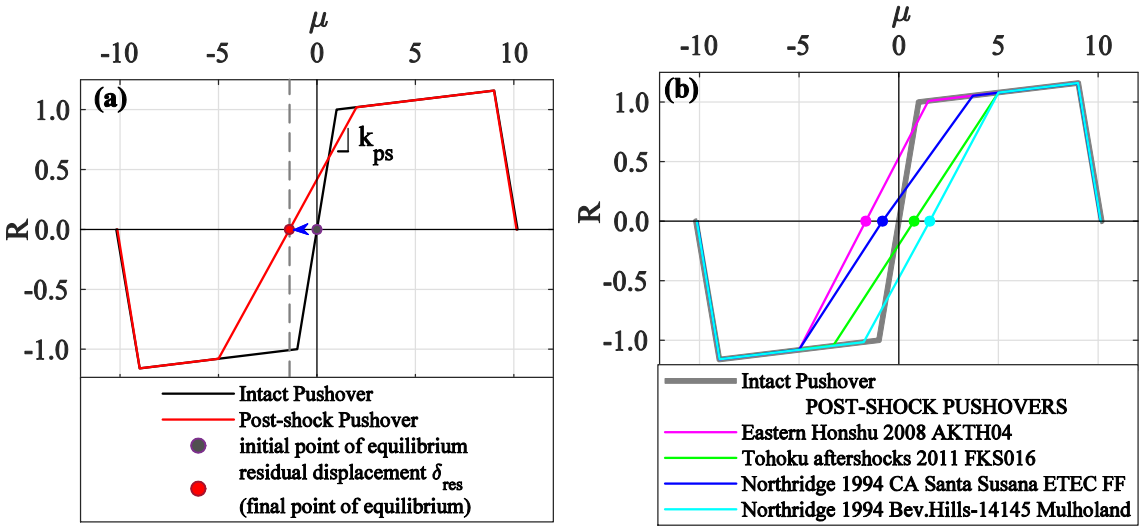

Figure 2: Examples of an SDOF structure's monotonic pushover (backbone) curve before and after the seismic damage in $\{R, \mu\}$ coordinates. Intact-structure backbone (dark line) and post-mainshock backbone (red line with pre-yield stiffness k_{ps} ,intersecting the zero-force horizontal axis at δ_{res}) for a generic analyzed case (**a**); post-mainshock backbones and residual displacements of an SDOF system with $T = 1.0s$ and $\alpha_h = 2.0\%$, evaluated for four different records scaled to cause ductility demand $\mu = 5.0$ (**b**).

3. PREDICTIVE MODEL FOR THE RESIDUAL DISPLACEMENT

During the investigation a total of 28800 elongated periods T_{elon} and constant-ductility residual displacement ratios C_μ were computed for peak-oriented bilinear systems, corresponding to fifty acceleration time histories, eight periods of natural vibration, nine levels of ductility demand and eight post-yield hardening ratios, and then processed to obtain the

predictive model. The highest C_μ value encountered among these results was 0.52. In subsequent elaborations, it was found useful to express these results in terms of the relation between the ratio of residual to peak transient displacement $\delta_{res}/\delta_{\max}$ (preserving the sign of both δ_{res} and $\delta_{\max}$ so that the ratio becomes negative when the two are in opposite directions) and $\ln(\Delta T/T)$, where $\Delta T = T_{elon} - T$ denotes the difference between the elongated post-mainshock period and the initial period. It was observed that $\delta_{res}/\delta_{\max}$ exhibits persistently high negative linear correlation with $\ln(\Delta T/T)$ for varying T, μ and α_h. In particular, values of the correlation coefficient between $\ln(\Delta T/T)$ and $\delta_{res}/\delta_{\max}$, ρ (see for example [20]), range from -0.50 to -0.99 with $\rho \le -0.7$ for the majority of analyzed cases (with $-0.5 < \rho < -0.7$ only in a few cases characterized by high ductility demands, $\mu \ge 7.0$, and long periods of natural vibration, $T \ge 1.8s$).

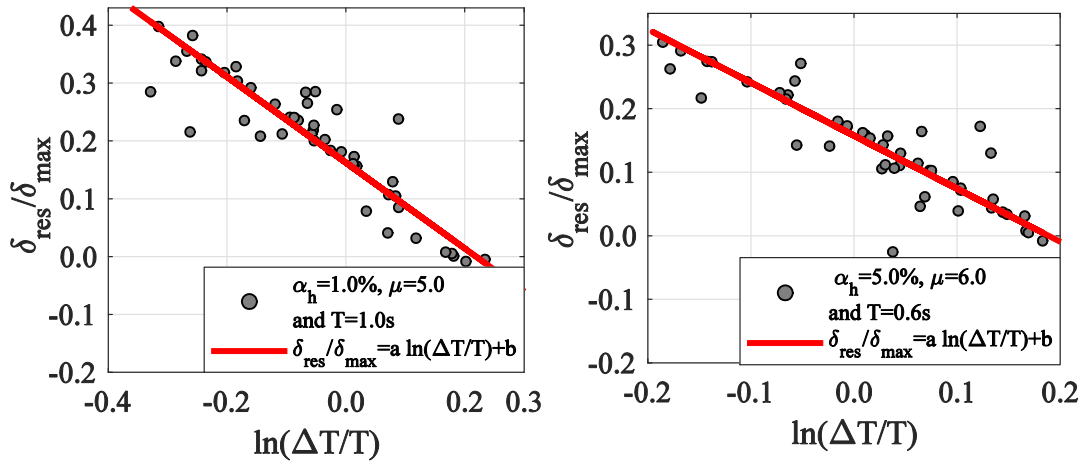

Figure 3: Examples of regression of $\delta_{res}/\delta_{\max}$ against $\ln(\Delta T/T)$ highlighting their (negative) linear correlation. Case of SDOF system with $\alpha_h = 1.0\%$, $T = 1.0s$ and $\mu = 5.0$ (left); case of SDOF system with $\alpha_h = 5.0\%$, $T = 0.6s$ and $\mu = 6.0$ (right).

This linear trend, examples of which are shown in Figure 3, motivates the adoption of a linear model for C_μ, whose slope and intercept are functions of the ductility demand μ and the post-yield hardening ratio α_h. The proposed model is given by Equation (1):

$$C_\mu = \left| \left[\beta_1 + \beta_2 \cdot (\mu - 1) + \beta_3 \cdot (\alpha_h + 1) \cdot (\mu - 1)^2 \right] \cdot \ln\left(\frac{\Delta T}{T} \right) + (\beta_4 + \beta_5 \cdot \alpha_h) \cdot (\mu - 1) + \beta_6 + \varepsilon \cdot \sigma_{C_\mu} \right| \quad (1)$$

where ε is the standard Normal variable and the parameters β_i, $i = \{1,2,...,6\}$ are coefficients estimated by means of robust regression of $\delta_{res}/\delta_{\max}$ against $\ln(\Delta T/T)$, μ, α_h using iteratively re-weighted least squares with bisquare weighting [20]. The standard deviation of the regression residual, σ_{C_μ}, was found to be non-constant, varying with T, μ and α_h (yet the residual can be assumed homoscedastic with $\ln(\Delta T/T)$ conditional on fixed values of the other independent

variables). Thus, σ_{C_μ} was also modelled analytically to account for this dependence (to follow). It should be mentioned that despite the perceived dependence of σ_{C_μ} on the oscillator's initial vibration period T, such dependence was not included in the expectation function of C_μ. In fact, according to the executed F-test [20] the null hypothesis that the slope of an additional linear term of T is zero, could not be rejected at the 5% significance level. Table 1 provides the parameter estimates for β_i appearing in Equation (1).

β_1	β_2	β_3	β_4	β_5	β_6
-0.1124	-0.1867	0.0094	0.1308	-0.6385	-0.3361

Table 1. Coefficient estimates in Equation (1).

Figure 4 shows the model for the mean of the constant-ductility residual displacement ratio for the cases with post-yield hardening ratio equal to 0.0% and 10.0%.

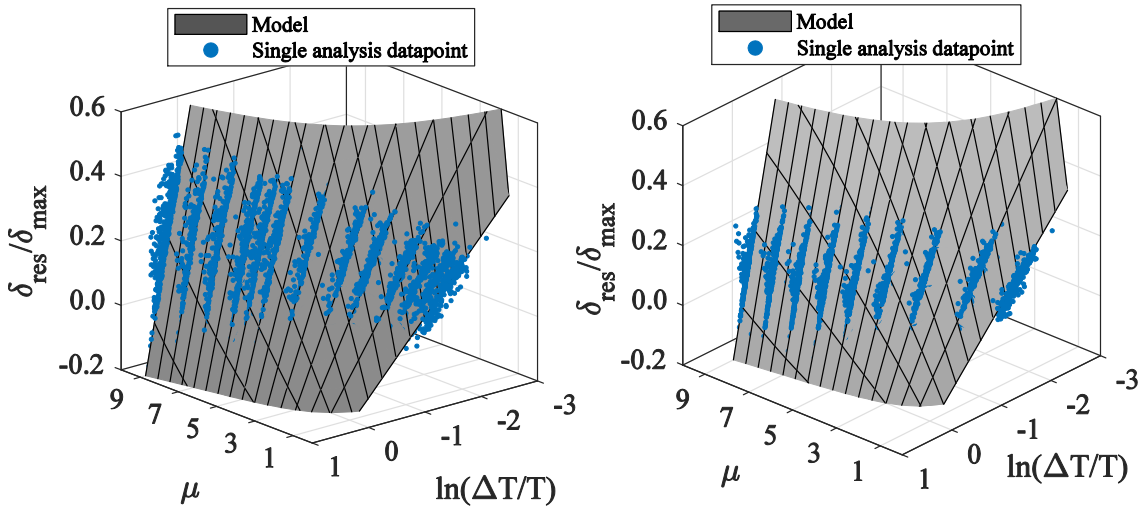

Figure 4: Central tendency of the model for the residual displacements. Case with $\alpha_h = 0.0\%$ (left); case with $\alpha_h = 10.0\%$ (right).

As already mentioned, non-constant variance of the residuals was dealt with by modelling σ_{C_μ} by means of least-squares curve-fitting of an analytical expression, with parameters γ_i, $i = \{1,2,...,7\}$, to the regression residuals for the various T, μ and α_h values, given in Equation (2):

$$\sigma_{C_\mu} = \begin{cases} \gamma_1 \cdot (\mu - 1) + \gamma_2 \cdot T \text{ , when } \alpha_h = 0 \\ \gamma_3 \cdot (\alpha_h + 1) \cdot (\mu - 1) + \gamma_4 \cdot T + \gamma_5 \cdot (\mu - 1)^2 + \gamma_6 \cdot (\mu - 1) \cdot T \cdot \alpha_h + \gamma_7 \cdot \alpha_h \text{ , when } \alpha_h > 0 \end{cases} \quad (2)$$

Due to the peculiar nature of increased response dispersion, as the post-yield stiffness of the systems goes to zero (due to the drifting effect observed for elastoplastic oscillators; e.g., [21]), Equation (2) provides separate equations for σ_{C_μ} in case of $\alpha_h = 0$ and $\alpha_h > 0$. Table 2 provides the fitted parameter values of γ_i for Equation (2).

Figure 5 shows the two model of standard deviation σ_{C_μ} in case of post-yield hardening ratio equal to 0.0% in Figure 5a and equal to 3.0 % in Figure 5b.

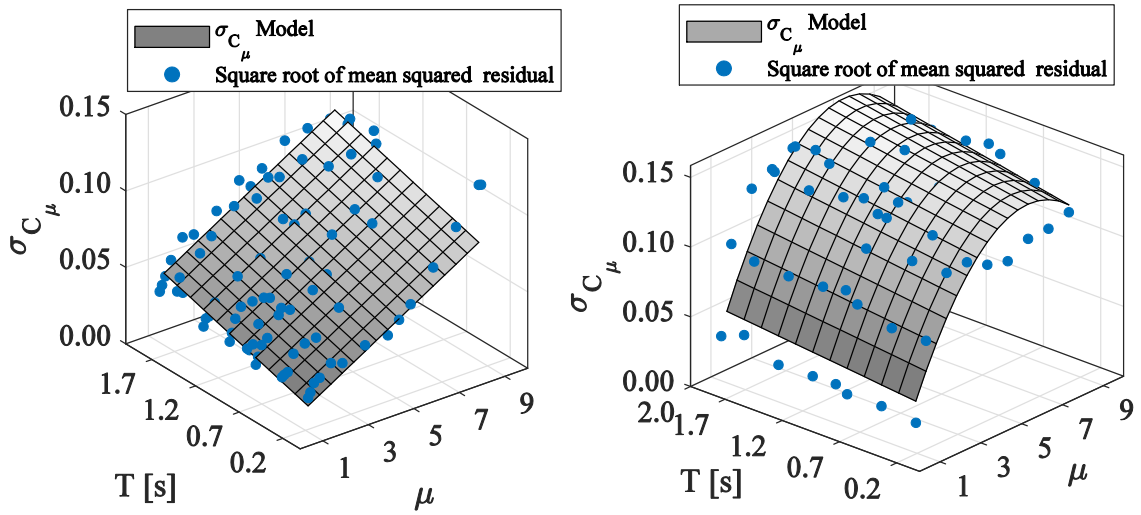

Figure 5: Models of standard deviation σ_{C_μ}. Case with $\alpha_h = 0.0\%$ (left); case with $\alpha_h = 3.0\%$ (right).

4. REGRESSION MODEL FOR PERIOD ELONGATION

The regression model for mean constant-ductility residual displacement ratios, given by Equation (1), is conditional on $\ln(\Delta T/T)$, which is also a random variable due to record-to-record variability. However, the results indicate that, given μ, α_h and T, $\ln(\Delta T/T)$ is conditionally independent of C_μ. Thus, in order to complete the predictive equation for residual displacements, an additional separate model for period elongation is needed to provide the conditional distribution of $\ln(\Delta T/T)$. The model for period elongation provides the period of the damaged structure T_{elon} at a fixed damage state represented by μ, given initial characteristics of the structure T and α_h. The analyses results were studied plotting in log-space the $\Delta T/T$ versus the ductility demand $(\mu-1)$, and assessing the dependence on independent variables T and α_h. The data showed a linear trend in log-space to each pair of T and α_h, therefore the model was realized fitting a straight line by ordinary least squares regression. The central tendency of $(\Delta T/T)$ resulted independent of the period of natural vibration T itself, whereas was strongly dependent on the post-yield hardening ratios α_h. Thus, the regression model proposed for period elongation uses only α_h and μ as predictor variables. A linear model was assumed, as reported in the following equation:

$$\ln\left(\frac{\Delta T}{T}\right)=\left(\theta_1\cdot\alpha_h+\theta_2\right)\cdot\ln\left(\mu-1\right)+\theta_3\cdot\alpha_h+\theta_4+\varepsilon\cdot\sigma_{\ln(\Delta T/T)}\ , \tag{3}$$

where ε was already defined as the standard Normal variable and $\sigma_{\ln(\Delta T/T)}$ represents the standard deviation of the regression residual, which was, also in this case, non-constant. It should be noted that, despite the Gaussian assumption for ε, for this type of hysteretic model and given μ and α_h, $\Delta T/T$ cannot exceed the value $\left(\Delta T/T\right)_{\max}$ given by Equation (4):

$$\left(\frac{\Delta T}{T}\right)_{\max}=\sqrt{\frac{2\mu-1+\alpha_h\cdot\left(\mu-1\right)}{1+\alpha_h\cdot\left(\mu-1\right)}}-1 \tag{4}$$

As reported in Equation (3), the slope and the intercept of the model for period elongation are only dependent on α_h. The coefficients $\theta_i, i=\{1,2,3,4\}$, were evaluated by curve fitting of the single regressions results performed for each value of α_h. A weighted regression, on account of the non-constant variance, was not deemed necessary because the ratio of the maximum to the minimum value of the mean squared error of the residuals did not exceed 1.5, as suggested in [15]. In Table 3 the values of the coefficients which characterize Equation (3) are reported.

θ_1	θ_2	θ_3	θ_4

Table 3. Coefficient estimates of Equation (3).

Figure 6 shows the model fitted against the analysis results of SDOFs with α_h equal to 1.0% and T varying in the entire range considered, as well as a 3D graph of the model for period elongation, highlighting the dependence of its central tendency on α_h and μ.

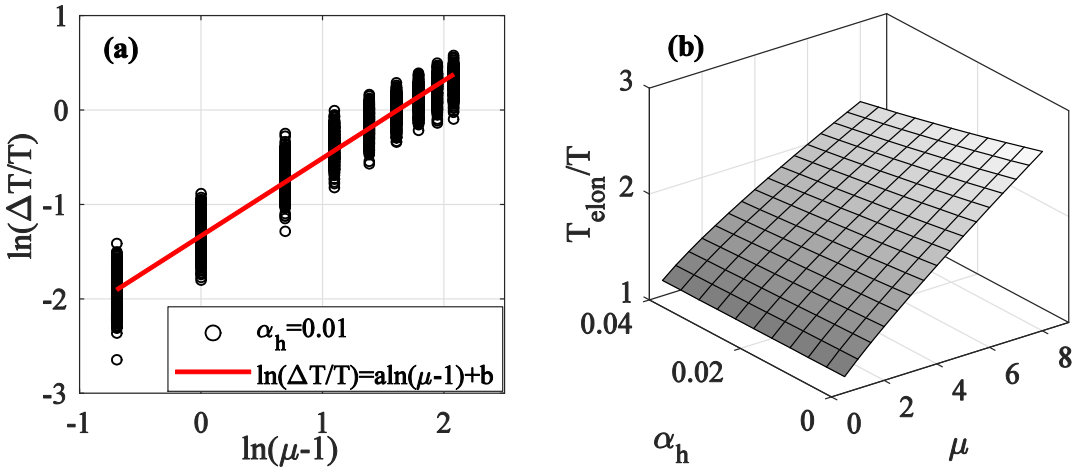

Figure 6: Central tendency of model for period elongation. Regression example of the form $\ln\left(\Delta T/T\right)=a\cdot\ln(\mu-1)+b$ used to define the model for period elongation evaluated in the case of post-yield hardening ratios α_h equal to 1.0% (**a**); Model for period elongation (**b**).

Finally, an analytical expression was proposed, to express the dependence of $\sigma_{\ln(\Delta T/T)}$ with the intact structure's period T and the hardening slope α_h, given by Equation (5) :

$$\sigma_{\ln(\Delta T/T)} = \xi_1 \cdot T + \xi_2 + \xi_3 \cdot \alpha_h + \xi_4 \cdot T^2 \tag{5}$$

Table 4 provides the values of the parameters ξ_i, $i = \{1,2,3,4\}$, appearing in Equation (5), estimated from curve-fitting against the regression residuals.

Figure 7 shows the model of the standard deviation $\sigma_{\ln(\Delta T/T)}$ as a function of the hardening slope α_h and the period of natural vibration T.

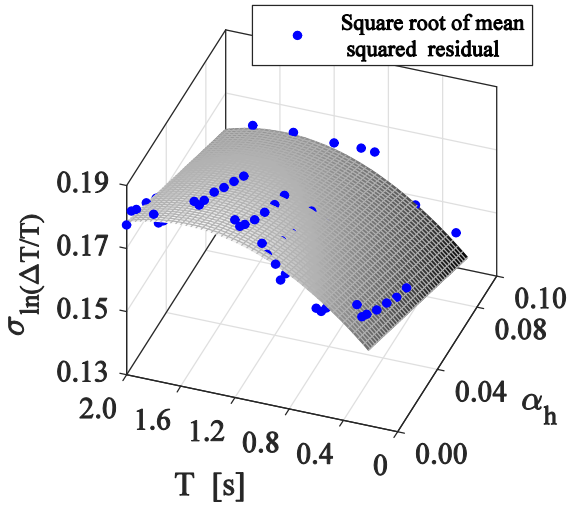

Figure 7: Model of standard deviation $\sigma_{\ln(\Delta T/T)}$.

5. PUTTING THE TWO COMPONENTS OF THE MODEL TOGETHER

Having completely defined both models, for period elongation and residual displacement, and recalling that period elongation was found conditionally independent of the residual displacement, it is possible to estimate the joint conditional distribution of the two random variables, given the ductility demand μ, the period T and the hardening slope α_h of the initial structure. Due to the fact that in Equation (1) C_μ is given by the absolute value of a regression model for $\delta_{res}/\delta_{\max}$, it is convenient to visualize its conditional joint distribution with relative period elongation T_{elon}/T by means of a Monte-Carlo sampling scheme. This entails fixing the values of T, α_h and μ, calculating the mean and standard deviation of $\ln(\Delta T/T)$ conditional to these values from Equations (3) and (5) and then extracting a random sample of $\ln(\Delta T/T)$ values from a normal distribution with that mean and $\sigma_{\ln(\Delta T/T)}$, truncated according to Equation

(4). Subsequently, the conditional mean and standard deviation of the ratio $\delta_{res}/\delta_{\max}$ is obtained for each sampled value of $\ln(\Delta T/T)$, from Equations (1) and (2), and a $\delta_{res}/\delta_{\max}$ value is randomly sampled from the corresponding normal distribution, truncated between -1 and 1. This amounts to random sampling of $\{\ln(\Delta T/T), \delta_{res}/\delta_{\max}\}$ from their joint conditional distribution. Finally, C_μ values are obtained by taking the absolute value of $\delta_{res}/\delta_{\max}$. An example of such a representation is reported in Figure 8a, that was constructed by sampling one thousand value-pairs from the joint distribution of $\delta_{res}/\delta_{\max}$ and $\ln(\Delta T/T)$. A representation of the marginal density of C_μ and its mean is also reported in Figure 8b, estimated during the same procedure.

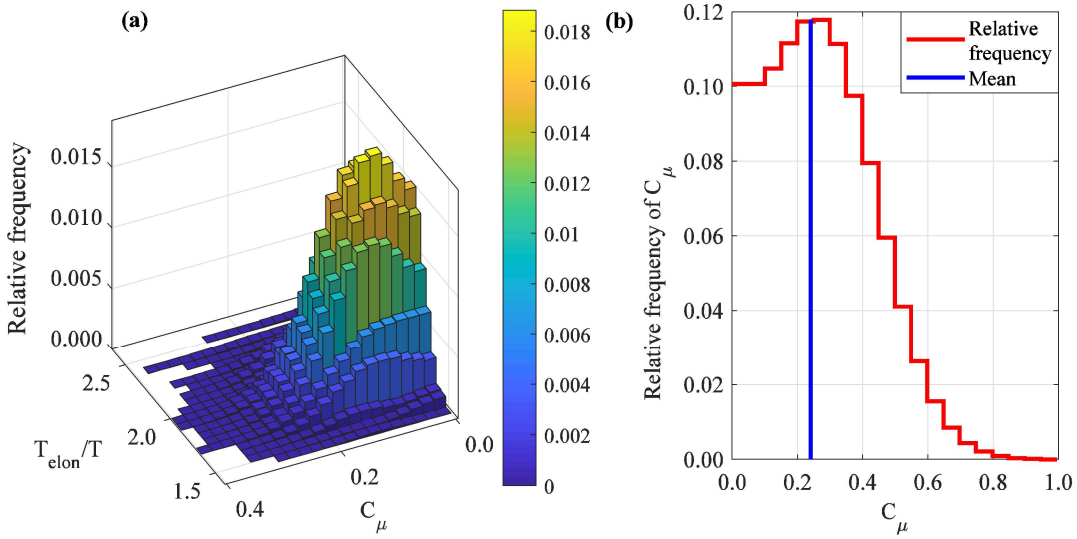

Figure 8. Sampling-based representation of the joint relative frequency of period elongation and residual displacement ratio (**a**), relative frequency of C_μ (**b**), for the case of ductility demand $\mu = 5.0$, post-yield hardening ratio $\alpha_h = 2.0\%$ and period of the initial structure $T = 0.9s$.

6. MODEL VALIDATION

To validate the predictive model a set of analyses for blind-testing the goodness-of-fit was performed. These analyses were organized in three groups: the first group was executed fixing the mass of SDOF systems and varying the elastic stiffness to achieve the required periods of natural vibration, whilst the analyses performed for the model evaluation, fixed the elastic stiffness and varied the mass to the same effect. The second group of analyses was executed levels of ductility demand and values of post-yield hardening ratio different from the ones used for fitting development the predictive model. The last group was performed using a different set of fifty records for IDA. To evaluate the accuracy of the predictive models in estimating elongated periods and residual displacements, the root mean square error (RMSE [20]) was computed for each group of analyses, according to Equation (6) .

$$RMSE = \sqrt{\frac{\sum_{i=1}^{n}(y_i - \bar{y})^2}{n}} \quad (6),$$

where $\bar{y}$ is the generic model of either $\ln(\Delta T/T)$ or C_μ, y_i is the data point from the i-th analysis and n is the total number of analyses run.

These RMSE values were employed to assess the goodness-of-fit for Equations (1),(3) in estimating mean C_μ and $\ln(\Delta T/T)$. In detail, the root mean square error measure was computed for the three groups of test data, comparing the results with the error evaluated on the entire data set used for fitting development the predictive model. Table 5 provides $RMSE_{\ln(\Delta T/T)}$ for the first and the second group of analyses defined by different values of μ and T.

Constant mass				Independent variable values (α_h, μ) not used in fitting the model			
T	μ	α_h	$RMSE_{\ln(\Delta T/T)}$	T	μ	α_h	$RMSE_{\ln(\Delta T/T)}$
0.3	4.0	0.02	0.024	0.3	4.3	0.07	0.020
0.6	4.0	0.02	0.016	0.6	4.3	0.07	0.013
2.00	4.0	0.02	0.008	2.00	4.3	0.07	0.002

Table 5. Values of $RMSE_{\ln(\Delta T/T)}$ for the first and the second group of validation analyses.

Table 6. provides $RMSE_{\ln(\Delta T/T)}$ for the third group of analyses executed fixing the ductility demand, the hardening slope and employing a new set of fifty acceleration records recorded on firm soil or rock and devoid of apparent directivity effects.

Using a different set of records			
T	μ	α_h	$RMSE_{\ln(\Delta T/T)}$
0.3	5.0	0.04	0.010
0.6	5.0	0.04	0.003
2.00	5.0	0.04	0.016
0.3	8.0	0.05	0.048
0.6	8.0	0.05	0.002
2.00	8.0	0.05	0.006

Table 6. Values of $RMSE_{\ln(\Delta T/T)}$ for the third group of validation analyses.

The values of $RMSE_{\ln(\Delta T/T)}$ previously reported are very close to the value evaluated on the data set used for fitting development the predictive model which is 0.024.

To evaluate the accuracy of the predictive model in estimating residual displacement, the error measure RMSE was computed for the three groups of test data. In particular, it was evaluated for C_μ as provided by the Equation (6). The values of RMSE for the three group of analyses are reported in Table 7 and Table 8. The values of $RMSE_{C_\mu}$ previously reported are very close to the value estimated on the data set used for fitting development the predictive model which is 0.056.

Constant mass				Independent variable values (α_h, μ) not used in fitting the model			
T	μ	α_h	$RMSE_{C_\mu}$	T	μ	α_h	$RMSE_{C_\mu}$
0.3	4.0	0.02	0.029	0.3	4.3	0.07	0.025
0.6	4.0	0.02	0.040	0.6	4.3	0.07	0.030

7. DISCUSSION AND CONCLUSIONS

The main purpose of this study was to present a predictive model for the central tendency and related record-to-record variability of residual displacements for bilinear single-degree-of-freedom systems (SDOF). To this end, a probabilistic model for the constant-ductility residual displacement ratio, C_μ, was introduced. The residual displacement ratio, defined as the absolute-value ratio of residual to peak transient displacement, was calculated for various combinations of input motion, natural vibration period and post-yielding hardening ratio, via nonlinear dynamic analysis designed to hold the ductility demand μ constant, by appropriately scaling the input motion. Thus, SDOF systems with non-degrading, peak-oriented hysteretic response, according to the modified *Ibarra-Medina-Krawinkler* model, were analyzed subjected to a set of fifty earthquake ground motions recorded on firm site conditions. From the data obtained during the dynamic analyses, it was observed that the residual displacement demand did not exceed 52% of the peak inelastic displacement demand and is mainly affected on post-yield hardening ratio. In fact, the SDOF systems with higher post-yield stiffness ratio exhibit smaller residual displacement ratios on average, in agreement with previous studies.

The two-part predictive model was derived via two-stage regression: the first-stage regression model provides a prediction for the post-shock elongated period and the second one accounts for the residual displacement of the system conditional to its elongated period. It was found that central tendency of constant-ductility residual displacement ratios depends on the ductility demand, the post-yield hardening ratio and ratio of post-shock elongated period to the initial period of natural vibration, while the non-constant variance of the residual displacement ratio mainly depends on the post-yield hardening slope of the structure in its initial (undamaged) condition. It was also found that the period elongation has a central tendency that only depends on post-yield hardening ratio and ductility demand, whereas the corresponding variance also exhibits some dependence on the structural period of natural vibration. Finally, it should be mentioned that the complete model proposed, allows to estimate the joint conditional

distribution of the two random variables: residual displacement and period elongation, given ductility, period and hardening slope.

Abstract

This study deals with seismic reliability-based design (SRBD) relationships in terms of behavior factors and displacement demands for softening structures equipped with double friction pendulum system (DFPS) bearings. An equivalent 3dof system having a softening post-yield slope is adopted to describe the superstructure behavior, whereas velocity-dependent laws are assumed to model the responses of the two surfaces of the DFPS. The yielding characteristics of the superstructures are defined for increasing behavior factors in compliance with the seismic hazard of L'Aquila site (Italy) and with NTC18 assuming a lifetime of 50 years. Considering several natural seismic records and building properties under the hypothesis of modelling the friction coefficients of the two surfaces of the DFPS as random variables, incremental dynamic analyses are performed to evaluate the seismic fragility and the seismic reliability of these systems. Finally, seismic reliability is assessed and seismic reliability-based design (SRBD) curves for the two surfaces of the double sliding devices are described.

Keywords: behavior factor, ductility demand, friction pendulum bearing, post-yield softening stiffness, seismic isolation, seismic reliability.

1 INTRODUCTION

A very effective technique for the seismic isolation[1] of building frames and infrastructure is represented by the sliding pendulum bearings [2]-[3] examined by several literature studies (e.g., [4]-[7]). Probabilistic analyses and reliability-based analyses have also been presented by [8]-[9] as well as reliability analysis and reliability-based optimization of base-isolated systems including the main uncertainties have been performed by [10]-[14]. A non-dimensionalization of the motion equations governing the dynamic response of equivalent two-degree-of-freedom (2dof) models equipped with friction pendulum system (FPS) isolators has been proposed by [15]. In the hypothesis that the friction coefficient and the earthquake main characteristics are the relevant random variables, seismic reliability analyses of a 3D base-isolated r.c. system have been developed in Castaldo et al. [16] and Palazzo et al. [17] to propose a method useful to design the isolator dimensions in plan. The life-cycle cost analysis (LCCA) of a r.c. 3D structure isolated by FPS bearings has been examined by [18] to evaluate the dependence on increasing isolation degrees. The approach for a seismic reliability-based design (SRBD) of elastic systems isolated by FPS has been generalized in Castaldo et al. [19] for a wide range of structural properties. A robustness analysis in reliability terms of a r.c. 3D building frame isolated by FPS devices in presented in [20] proposing the failure scenarios if a malfunction affects a seismic device together with the design solution. The literature studies of [21] and [22] proposed, respectively, the optimal values of the friction coefficient, on the one hand, as a function of the system properties and of the soil condition in order to minimize the superstructure response and, on the other, as a function of the ground motion characteristics by means of the ratio PGA/PGV (peak ground acceleration/velocity). In [23], a robust design optimization (RDO) of base isolation system considering random system parameters characterizing the structure, isolator and ground motion model, is performed by minimizing the weighted sum of the expected value of the maximum root mean square acceleration of the structure as well its standard deviation. In [24], an optimal design of frictional devices is proposed by applying a Pareto-type optimization approach.

The seismic performance of bridges or structures isolated with FPS or DFPS has been investigated in [25]-[31]. Specifically, [28]-[30]provide useful relationships, according also to experimental results, for the evaluation of the seismic response of structures isolated by DFPS together with the equations governing the dynamic behaviour of these devices. The principal benefit of the DFPS bearing is its capacity to accommodate substantially larger displacements compared to a traditional FP bearing of identical plan dimensions as discussed in [28]. In [26] and [31], the seismic performance of isolated bridge and liquid storage tanks are respectively investigated, considering different combinations of radii of curvature and friction coefficients.

As for the design of base-isolated systems under strong earthquake events, seismic code provisions [32]-[36] are based on low values of the strength reduction factor [32]-[36] or behavior factor [33]-[34] to ensure a safety level against the non linear dynamic amplification phenomenon (partial resonance) [37]. Precisely, NTC18 [34], Eurocode 8 [33] and the Japanese building code [35] provide a maximum behavior factor value of 1.5, without explicitly distinguishing between the ductility and overstrength factor terms, ASCE 7 [32] prescribes a value equal to 0.375 times the one for corresponding fixed-base systems and no larger than 2. In this context, Vassiliou et al. [38] obtained that the displacement ductility demand of the inelastic base-isolated structure is 3 times the strength reduction factor confirming that, for base-isolated structures, it is not possible to adopt the formulas relating the strength reduction factor R and the displacement ductility demand μ of Newmark and Hall [39] and of Miranda and Bertero [40]. Then, seismic reliability-based relationships between the ductility-dependent strength reduction factors and the displacement ductility demand, respectively, for

equivalent perfectly elastoplastic and softening structural systems equipped with FPS depending on the structural properties have been proposed in [41],[42].

Inspired by [41],[42], this study proposes reliability-based design regressions relating the behavior factors and the displacement ductility demands for softening structural systems (sensitive or not sensitive to the $P-\Delta$ effects) equipped with double friction pendulum system (DFPS) devices and considering a high seismic hazard site like L'Aquila (Italy). By means of an equivalent 3dof system, different elastic and inelastic structural system properties are investigated. Specifically, the yielding characteristics of the softening superstructures are designed in compliance with the life safety limit state and with the seismic hazard of L'Aquila site (Italy) assuming a lifetime of 50 years and increasing behavior factors [32]-[35]. The model developed by [4] is used to describe the non-linear velocity-dependent behavior of the two surfaces of the DFPS. The study is also based on the hypothesis of assuming the both friction coefficients of the two surfaces of the DFPS and the characteristics of the records as the relevant random variables. In detail, appropriate Gaussian probability density functions (PDFs) are adopted to characterize the aleatory uncertainties of the both sliding friction coefficients and, by means of the Latin Hypercube Sampling (LHS) method [43]-[45], the input data have been generated.

Then, several incremental dynamic analyses (IDAs) are performed for increasing seismic intensity levels in compliance with the site seismic hazard to derive the seismic fragility curves related to the different degrees of freedom of the equivalent (3dof) system. Finally, by means of the convolution integral between the fragility curves and the seismic hazard curves of L'Aquila site (Italy), in the hypothesis of a design life of 50 years for the equivalent base-isolated systems, the corresponding reliability curves are derived.

2 EQUATIONS OF MOTION FOR NON-LINEAR SOFTENING STRUCTURAL SYSTEMS WITH DOUBLE CONCAVE SLIDING BEARINGS

The equivalent model, herein employed and depicted in Fig. 1, is a 3dof system with a dof representative of the superstructure behaviour and two dofs representative of the responses of the two surfaces of the DFPS. The model takes into account the inelastic softening response of the superstructure and non-linear behaviours of the two surfaces of the DFPS [28].

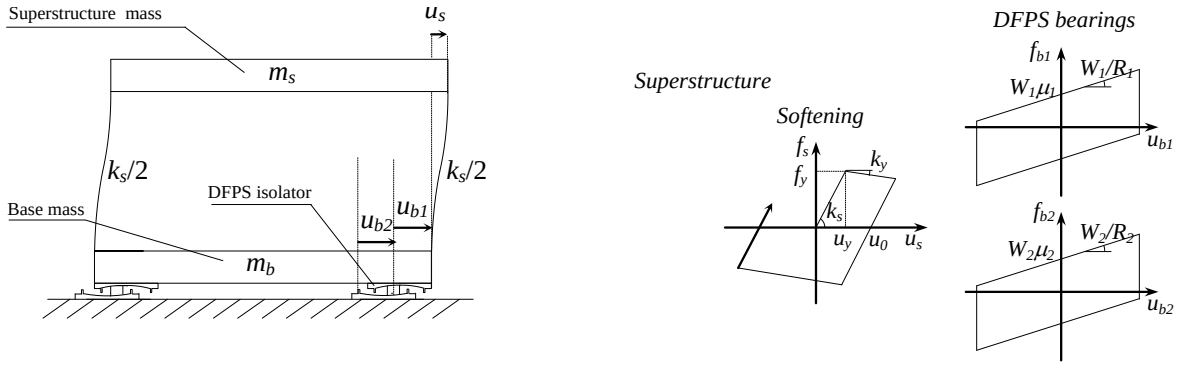

Figure1: 3dof model of an inelastic softening building frame isolated with DFPS.

Regarding the free body diagram of the DFPS, the bearing restoring force, considering only the horizontal component of the displacement on each surface, is:

$$f_{b,1} = \frac{W_1}{R_1} u_{b,1} + \mu_{d,1} W_1 \operatorname{sgn}\left(\dot{u}_{b,1}\right)$$
$$f_{b,2} = \frac{W_2}{R_2} u_{b,2} + \mu_{d,2} W_2 \operatorname{sgn}\left(\dot{u}_{b,2}\right) \quad (1)$$

where $W_1 = \left(m_b + m_s\right) g$ is the weight on the upper surface (surface 1) of the bearing, $W_2 = \left(m_b + m_s + m_d\right) g$ is the weight on the lower surface (surface 2) of the bearing, g is the gravity constant, R_1 and R_2 are the radii of curvature of the two surfaces of the device, $u_{b,1}$ denotes the displacement of the surface 1 with respect to the slider, $u_{b,2}$ represents the slider displacement with respect to the ground as well as $\mu_{d,1}$ and $\mu_{d,2}$ are the sliding friction coefficients of the two surfaces and sgn is the signum function of the sliding velocity for each surface. In this study, the upper surface (surface 1) is characterized by higher values of the friction coefficient and of the radius of curvature. Specifically, $\mu_{d,1}$ is selected as $4\mu_{d,2}$ and $R_1=2R_2$ [28]-[31]. The force of the bearing coincides with the force of each surface response $f_b = f_{b,1} = f_{b,2}$. For each surface, the friction coefficient is given as a function of the sliding velocity [4]-[6]:

$$\mu_{d,i} = f_{\max,\mathrm{i}} - \left(f_{\max,\mathrm{i}} - f_{\min,\mathrm{i}}\right) \exp\left(-\alpha \dot{u}_{b,i}\right) \quad \text{for } i = 1,2 \quad (2)$$

where $f_{\max,\mathrm{i}}$ and $f_{\min,\mathrm{i}}$ are, respectively, the friction coefficients at high and very low sliding velocities of the i-th surface, α is a constant set equal to 30 as well as the ratio $f_{\max,\mathrm{i}} / f_{\min,\mathrm{i}}$ equal to 3 for each surface [15]-[21],[41].

A bilinear constitutive law describes the inelastic softening behaviour of the superstructure, which responses in elastic phase if Eqn.(3) is satisfied and the restoring force $f_{s,i}$ is expressed by Eqn.(4):

$$\left|u_{s,i} - u_{0,i-1}\right| < y\left(u_{s,i}\right) \quad (3)$$

$$f_{s,i}\left(u_{s,i}\right) = k_s \left(u_{s,i} - u_{0,i-1}\right) \quad (4)$$

where $f_{s,i}$ is the restoring force at time instant i, $u_{s,i}$ is the superstructure deformation at the same instant, $u_{0,i-1}$ is the maximum plastic excursion at time instant $(i-1)$ and k_s is the elastic stiffness of the superstructure. The function $y(u_{s,i})$ is the yielding condition in function of the displacement and is non-univocally defined due to the translation of the elastic domain [46]. Defining u_y as the yield displacement, whose yield force is f_y, S denotes the ratio between the softening post-yield and the elastic stiffness [47]-[48], evaluated as:

$$S = \frac{k_y}{k_s} \quad (5)$$

The superstructure response is plastic if Eqn.(6) is satisfied and the restoring force applies according to Eqn.(7):

$$\left|u_{s,i} - u_{0,i-1}\right| \geq y(u_{s,i}) \quad (6)$$

$$f_{s,i}\left(u_s\right) = k_s (u_{s,i} - y(u_{s,i})) \operatorname{sgn}(u_{s,i} - u_{0,i-1}) \quad (7)$$

Therefore, the equations which describe the response of an inelastic 3dof system, isolated by DFPS devices, to the seismic input $\ddot{u}_g(t)$, without any viscous property for the DFPS, are:

$$\begin{aligned}
&m_s\ddot{u}_s + (m_s+m_b)\ddot{u}_{b,1} + (m_s+m_b+m_d)\ddot{u}_{b,2} + \frac{W_2}{R_2}u_{b,2} + W_2\mu_2\,\mathrm{sgn}\left(\dot{u}_{b,2}\right) = -(m_s+m_b+m_d)\ddot{u}_g \\
&m_s\ddot{u}_s + (m_s+m_b)\ddot{u}_{b,1} + (m_s+m_b)\ddot{u}_{b,2} + (m_s+m_b)\frac{g}{R_1}u_{b,1} + (m_s+m_b)g\mu_1\,\mathrm{sgn}\left(\dot{u}_{b,1}\right) = -(m_s+m_b)\ddot{u}_g \\
&m_s\ddot{u}_s + m_s\ddot{u}_{b,1} + m_s\ddot{u}_{b,2} + c_s\dot{u}_s + f_{s,i}(u_s) = -m_s\ddot{u}_g
\end{aligned} \tag{8}$$

where m_s, m_b and m_d are respectively the mass of the superstructure, of the isolation level and of the slider, c_s is the viscous damping factor of the superstructure. Dividing Eqn.(8a) by $m_s+m_b+m_d$ as well as Eqn.(8b) by m_b+m_s and Eqn.(8c) by m_s, defining the mass ratios as $\gamma_s = m_s/(m_s+m_b+m_d)$, $\gamma_b = m_b/(m_s+m_b+m_d)$ and $\gamma_d = m_d/(m_s+m_b+m_d)$ [49], the isolation $\omega_{b,i} = \sqrt{g/R_i}$ and structural $\omega_s = \sqrt{k_s/m_s}$ circular frequency, the structural damping ratio $\xi_s = c_s/2m_s\omega_s$, the non-dimensional equations apply:

$$\begin{aligned}
&\gamma_s\ddot{u}_s + (\gamma_s+\gamma_b)\ddot{u}_{b,1} + \ddot{u}_{b,2} + \omega_{b,2}^2 u_{b,2} + g\mu_2\,\mathrm{sgn}\left(\dot{u}_{b,2}\right) = -\ddot{u}_g \\
&\gamma_s\ddot{u}_s + (\gamma_s+\gamma_b)\ddot{u}_{b,1} + (\gamma_s+\gamma_b)\ddot{u}_{b,2} + (\gamma_s+\gamma_b)\omega_{b,1}^2 u_{b,1} + (\gamma_s+\gamma_b)g\mu_1\,\mathrm{sgn}\left(\dot{u}_{b,1}\right) = -(\gamma_s+\gamma_b)\ddot{u}_g \\
&\ddot{u}_s + \ddot{u}_{b,1} + \ddot{u}_{b,2} + 2\omega_s\xi_s\dot{u}_s + a_s(u_s) = -\ddot{u}_g
\end{aligned} \tag{9}$$

where $a_s(u_s) = f_s(u_s)/m_s$ is the dimensionless force of the superstructure that depends, respectively, on the stiffness k_s in the elastic phase and on the yielding condition in the plastic phase. Note that the elastic isolation period of vibration varies if the sliding movement occurs along surface 1 or surface 2 or along the both surfaces simultaneously [30]. Specifically, if the sliding movement is developed along only a surface, the isolation period depends only on the radius of curvature of the spherical surface R_i (i.e., typically the radius of the surface with the lower friction coefficient) and the bearing behaves like a simple FPS [19], whereas when the both surfaces are involved, the isolation effective period applies [30]:

$$T_b = 2\pi\sqrt{\frac{R_1+R_2}{g}} \tag{10}$$

The change of the vibration period shows the adaptive behavior to the seismic intensity that characterizes these devices [28]-[30]. It follows that the ratio between the variable isolation period and structural period of vibration, which defines the seismic isolation degree [52] cannot be a constant during an earthquake event. Moreover, when the both surfaces slide simultaneously the restoring force of the DFPS device can be evaluated as $\mu_e W_1$ neglecting the mass of the slider [28], where μ_e is the effective sliding coefficient given by:

$$\mu_e = \frac{\mu_{d,1}R_1 + \mu_{d,2}R_2}{R_1+R_2} \tag{11}$$

2.1 Inelastic properties of the superstructure

The inelastic behavior of the superstructure is assumed as an equivalent single dof system [50]-[51] having a softening post-yield stiffness. The behavior factor, *q*, and displacement ductility, μ, are defined, respectively, as:

$$q = \frac{f_{s,el}}{f_y} = \frac{u_{s,el}}{u_y} \tag{12}$$

$$\mu = \frac{u_{\mathrm{s,max}}}{u_y} \tag{13}$$

where $f_{s,el}$ and $u_{s,el}$ are, respectively, the peak elastic response values required to the superstructure, whereas $u_{\mathrm{s,max}} = \left|u_s(t)\right|_{\max}$ is the peak inelastic displacement during a ground motion.

For a softening systems (sensitive to the $P-\Delta$ effects), the behaviour factor *q* represents only the ductility-dependent strength reduction factor due the absolute absence of the overstrength capacities. It follows that the parameter *q* is consistent with both the code provisions [32]-[36] assuming a unitary overstrength factor, and with the one discussed in [41],[42].

3 UNCERTAINTIES RELEVANT TO THE PERFORMANCE ASSESSMENT

For the seismic reliability assessment of a building frame, within the structural performance (SP) evaluation method [53]-[55], specific correlations between the SP levels [56] and appropriate exceeding probabilities during its design life [57]-[58] as well as the relevant (aleatory and/or epistemic) uncertainties with the corresponding PDFs have to be defined. According to the PEER-like modular approach [59] and performance-based earthquake engineering (PBEE) approach [60]-[61], distinguishing the aleatory uncertainties related to the seismic input intensity from those corresponding to the characteristics of the record by means of an intensity measure (IM), this work evaluates and quantifies the seismic reliability of softening systems equipped with DFPS, located in L'Aquila site (Italy), assuming also the friction coefficients as other relevant random variables. Other aleatory uncertainties are not modelled since their effects can be neglected as discussed in [41],[62]. The epistemic uncertainties are not considered in this study.

Specifically, a Gaussian PDF truncated on both sides to 2% and 6% with a mean equal to 4% for the upper surface ($\mu_{d,1}$) and a Gaussian PDF truncated on both sides to 0.5% and 1.5% with a mean of 1% for the lower surface ($\mu_{d,2}$) are used to model, respectively, the sliding friction coefficients at large velocities of the two surfaces of the DFPS bearings [41]-[42]. These values are in compliance with [28]-[31] and chosen in order to obtain a mean value of the effective friction coefficient equal to 3% and, so to allow a comparison with the FPS analysed in [41]-[42]. Then, using the LHS technique [43]-[45], 15 sampled couples of the friction coefficients at large velocities are defined.

As for the uncertainty on the characteristics of the seismic records (record to record variability), according to PBEE approach [60]-[61] and similarly to [41]-[42], the spectral displacement $S_D(\xi_b, T_b)$, related to the equivalent effective period $T_b = 2\pi/\omega_b$ (Eq.(10)) and to damping ratio ξ_b [19],[41] is chosen as *IM* [64]-[66]. Considering ξ_b equal to zero [15],[41],[67], the corresponding IM is hereinafter denoted as $S_D(T_b)$ in the range from 0 m to 0.45 m according to the seismic hazard of L'Aquila site (Italy) [34]. The record-to-record variability is taken into account by means of 30 ground motion records, corresponding to 19 different earthquake events, selected form different national and international databases. A detailed description may be found in [41].

4 INCREMENTAL DINAMIC ANALYSES: RESULTS AND COMPARISON

The performance of systems isolated with DFPS is evaluated through incremental dynamic analyses (IDAs), considering several structural parameters combination and L'Aquila (Italy) as the reference site.

4.1 Design of the elastic and inelastic properties of the structural systems

An extended parametric analysis is carried out considering the following deterministic parameters: isolation degree I_d, varying between 2, 4, 6 and 8 with respect to the equivalent effective isolated period; the equivalent effective isolation period T_b, varying between 3s, 4s, 5s and 6s; the mass ratio γ_s, assumed equal to 0.6 and 0.8 with γ_d equal to 0.001 and so γ_b equal to 0.399 and 0.199; the behaviour factor q, ranging from 1.1 to 2, with a step of 0.1, according to the codes [32]-[35], and the post-yield softening stiffness ratio *S*, set equal to 0.03 [47]-[51]. It follows that 384 equivalent 3dof systems, with isolation damping ratio ξ_b and superstructure damping ratio ξ_s respectively equal to 0% and 2%, are properly defined. These abovementioned 384 equivalent 3dof systems derive from 32 different 3dof systems (with the different values of I_d, of T_b and of the mass ratio) by modifying the behavior factor In the hypothesis of $\mu_{d,1}$ and $\mu_{d,2}$ equal to 4% and 1%, respectively, and a ratio equal to 2 between R_1 and R_2 [28]-[31], the yielding characteristics of 32 3dof elastic systems, necessary to perform IDAs, are evaluated considering the average elastic responses to the 30 seismic inputs scaled to the *IM* value of the life safety limit state for L'Aquila site (Italy): the $IM = S_D(T_b)$ applies 0.311 m for T_b=3, 4, 5 s and 0.26 m for T_b =6 s (NTC18 [34]). In this way, the average values in terms of both yield strength $f_{y,\text{average}}$ and displacement $u_{y,\text{average}}$ of the superstructure have been computed in Matlab-Simulink [72] and, the yielding properties are finally defined for each value of *q*, according to Eqn.(14):

$$u_{y,average} = \frac{f_{y,average}}{k_s} = \frac{f_{s,el,average}}{k_s q} = \frac{u_{s,el,average}}{q} \tag{14}$$

4.2 Incremental dynamic analysis (IDA) curves

This section describes the responses of the 384 equivalent 3dof softening systems having different properties (i.e., I_d, T_b, γ_s, q, *S*) combined with the 15 sampled couples of the friction coefficients, to the 30 seismic inputs scaled to the different $IM = S_D(T_b)$, ranging from 0 m to 0.45 m. A total number of 450 numerical analyses has been performed for each *IM* level and parameter combination. The isolated non-linear softening systems are modelled in Matlab-Simulink [72], by employing the Runge-Kutta-Fehlberg integration algorithm to solve the coupled equations (Eqn.(9)) and determine the responses of each degree of freedom. For each structural system with a softening behaviour, the collapse condition assumed within the numerical analysis is reached when the response of the superstructure is equal to zero. The results of the non-linear IDAs have made it possible to estimate the collapsed system cases as well as the superstructure and isolation response parameters, expressed, respectively, in terms of displacement ductility demand μ and of displacements for the DFPS (i.e., peak value for each surface or peak value of their sum computed at each time instant). These response parameters are assumed as the engineering demand parameters (EDPs) and their peak values have been fitted with lognormal distribution [15],[16]-[21],[41],[60],[67], by estimating the sample

lognormal mean, $\mu_{\ln}(EDP)$, and the sample lognormal standard deviation $\sigma_{\ln}(EDP)$, or dispersion $\beta(EDP)$, through the maximum likelihood estimation technique, to determine the 50th, 84th and 16th percentile of each lognormal PDF [15]. Note that other uncertainties [73]-[78] as well as the influence of the infills [79]-[82] are not considered in this study.

Figures 2-6 show the IDA results related to softening structures. Only the results corresponding to some parameters (I_d =2 and 8, T_b =3s and 6s and mainly related to γ_s equal to 0.6) are reported due to space constraints.

Fig.s 2-3 show the IDA results regarding the isolation level EDP $u_{b,\max}$, which is the peak value of the sum of $u_{b,1}$ and $u_{b,2}$ in each time instant. This response parameter is important to design the elements and components at the isolation level and to estimate the maximum displacement of the isolation system. Therefore, the displacement $u_{b,\max}$ shown in Fig.s 2-3 is the maximum displacement recorded during the non-linear dynamic analysis, and generally is not concomitant with the maximum displacement recorded at each single surface.

Fig. 2 depicts the response of the EDP with a mass ratio equal to 0.8, whereas Fig. 3 and 4 illustrate the responses of the surface 1 and 2, respectively, with a mass ratio of 0.6. As for the isolation level EDP , the lognormal mean decreases by decreasing Tb (Fig. 2) and also for lower Id due to the lower values of the superstructure elastic stiffness.

As regards the softening superstructure, the statistics of the μ strongly increase for higher q (Fig.s 5-6).

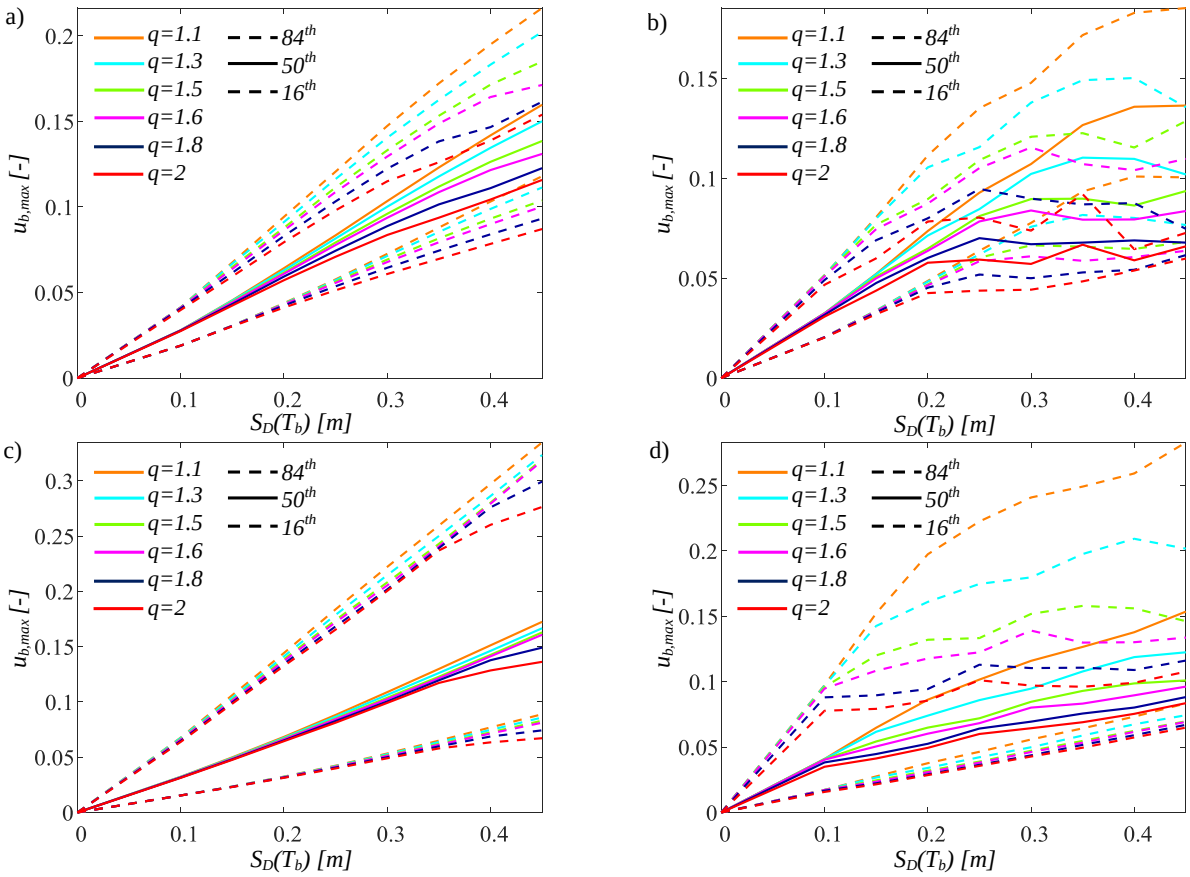

Figure 2: IDA curves of the isolation level with γ_s =0.8 for I_d=2, T_b=3 s, S=0.03 (a), I_d=2, T_b=6 s, S=0.03 (b), I_d=8, T_b=3 s, S=0.03 (c), I_d=8, T_b=6 s, S=0.03 (d).

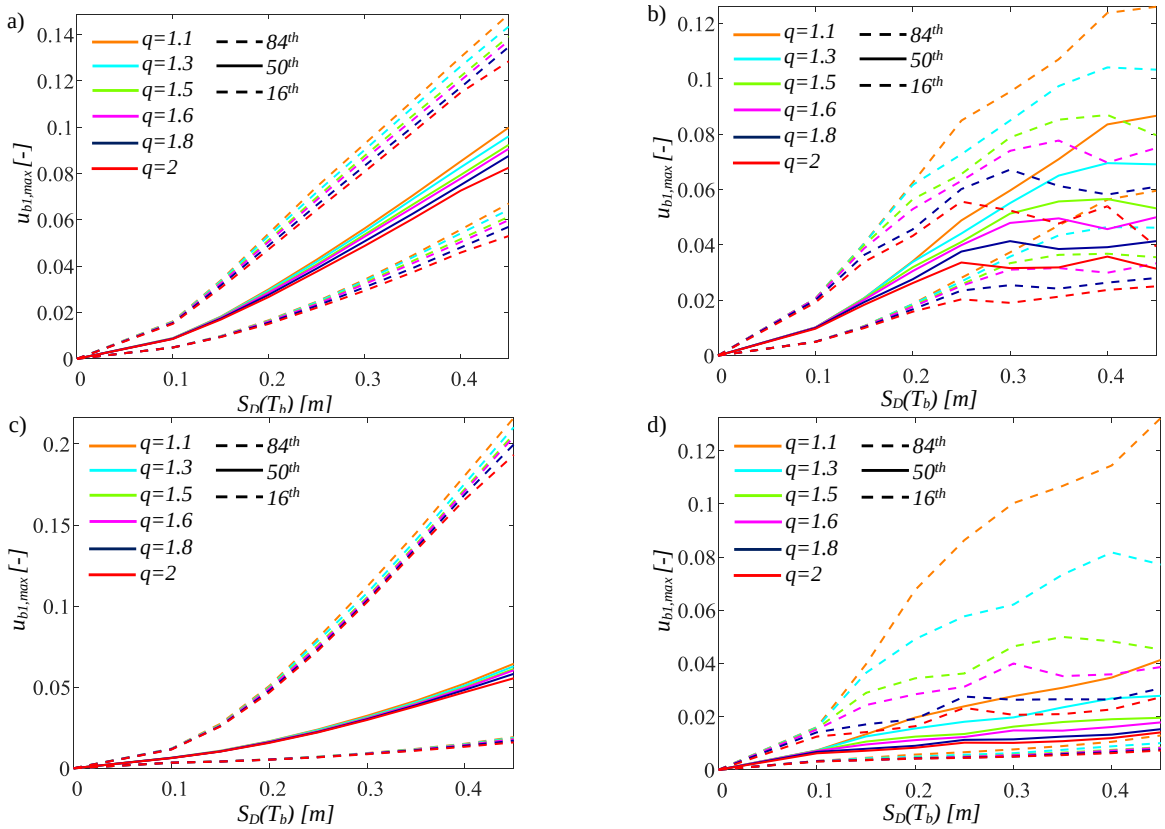

Figure 3: IDA curves of the sliding surface 1 with γ_s=0.6 for I_d=2, T_b=3 s, S=0.03 (a), I_d=2, T_b=6 s, S=0.03 (b), I_d=8, T_b=3 s, S=0.03 (c), I_d=8, T_b=6 s, S=0.03 (d).

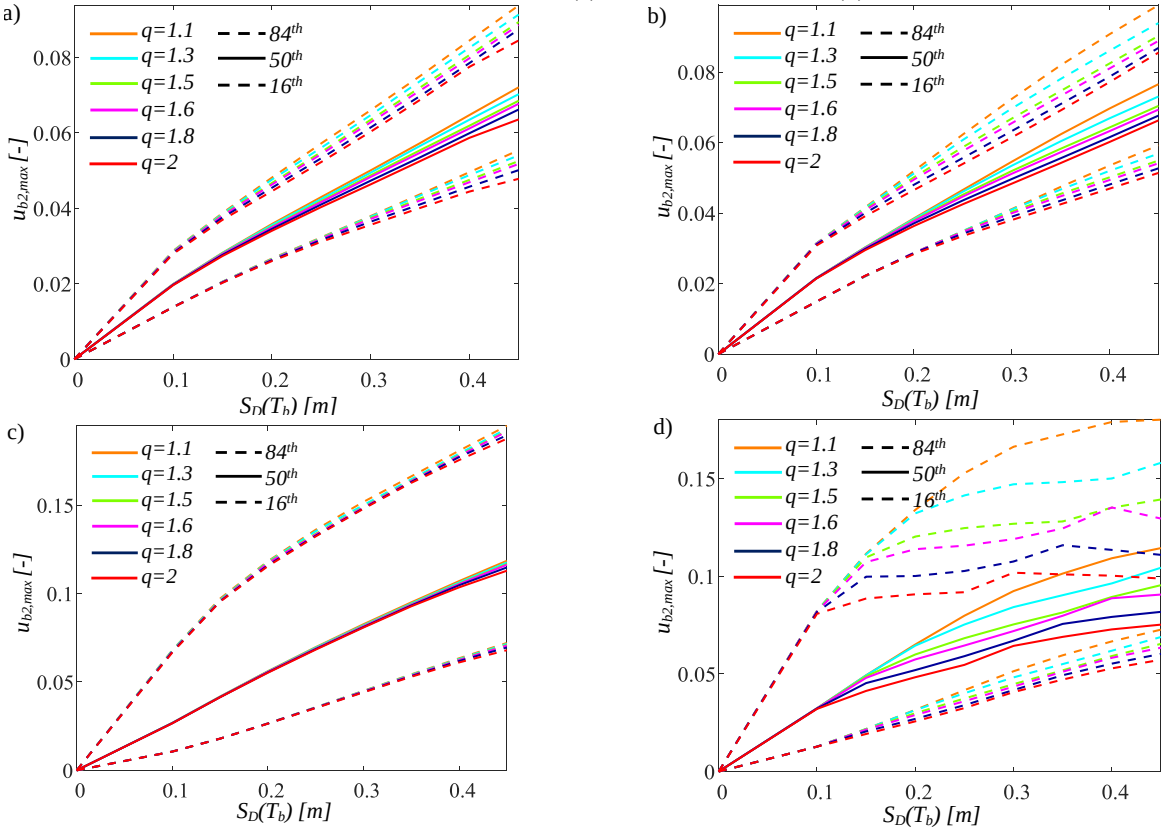

Figure 4: IDA curves of the sliding surface 2 with γ_s=0.6 for I_d=2, T_b=3 s, S=0.03 (a), I_d=2, T_b=6 s, S=0.03 (b), I_d=8, T_b=3 s, S=0.03 (c), I_d=8, T_b=6 s, S=0.03 (d).

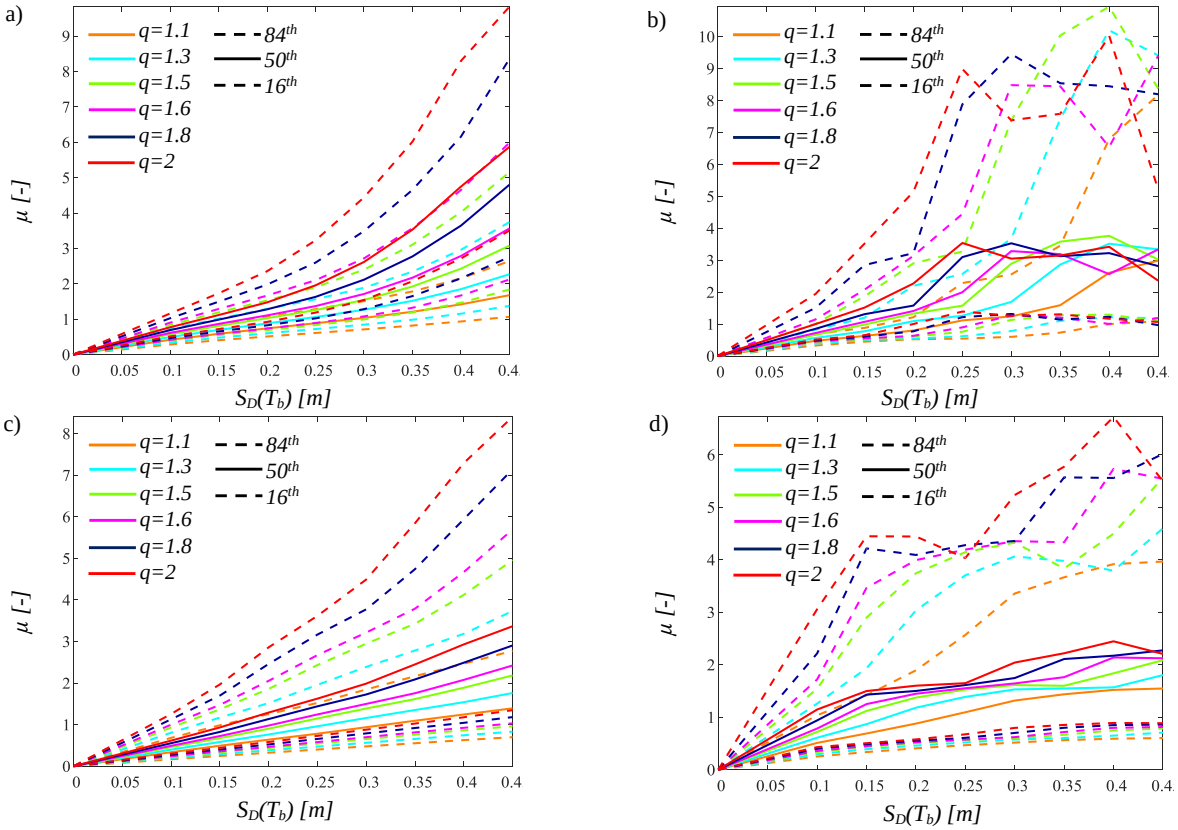

Figure 5: IDA curves of the superstructure with γ_s=0.6 for I_d=2, T_b=3 s, S=0.03 (a), I_d=2, T_b=6 s, S=0.03 (b), I_d=8, T_b=3 s, S=0.03 (c), I_d=8, T_b=6 s, S=0.03 (d).

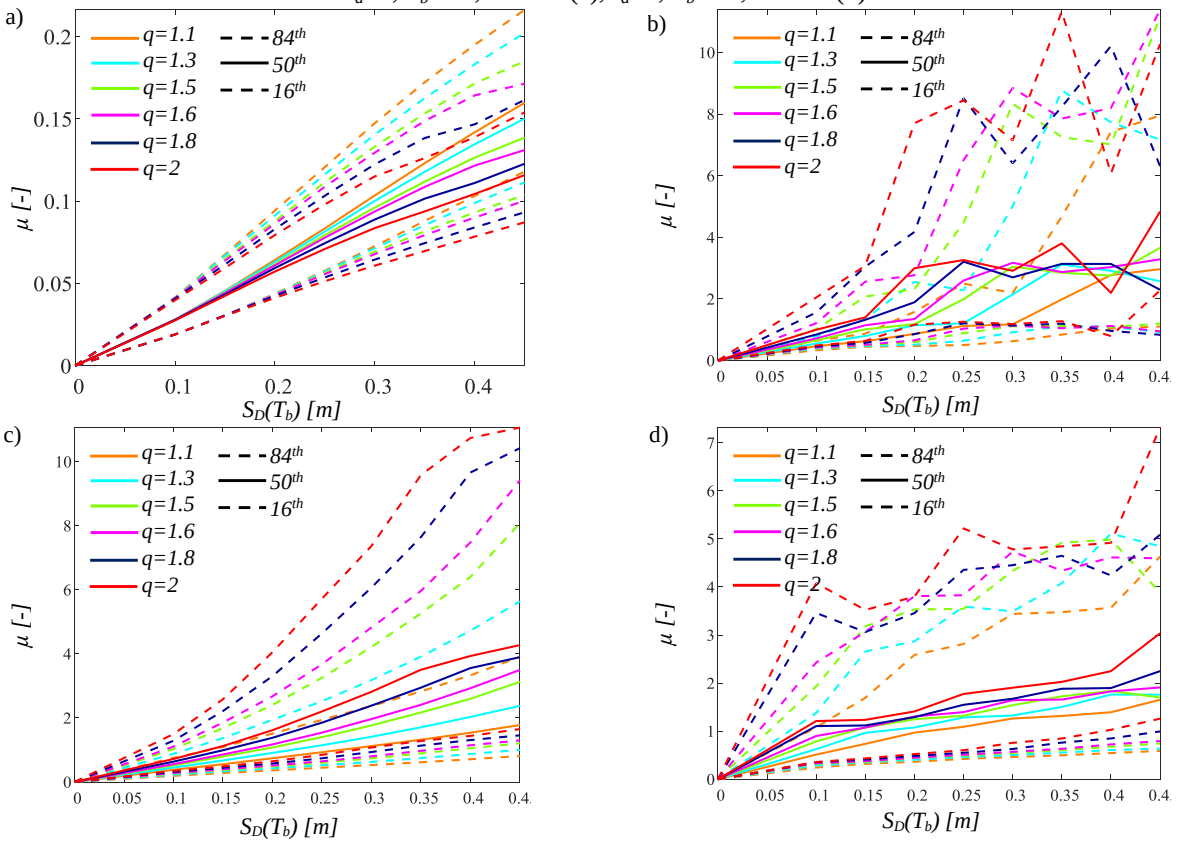

Figure 6: IDA curves of the superstructure with γ_s=0.8 for I_d=2, T_b=3 s, S=0.03 (a), I_d=2, T_b=6 s, S=0.03 (b), I_d=8, T_b=3 s, S=0.03 (c), I_d=8, T_b=6 s, S=0.03 (d).

It is worthy to note that the 50th, 84th and 16th percentiles illustrated in Figures 2-6 have been evaluated without considering the failure cases. From the IDA curves corresponding to the softening systems, it is possible to observe a number of dynamic collapses which increase in quite all the parameter combinations for increasing *IM* levels. The influence of the data related to the dynamic collapses has computed within the seismic fragility assessment as discussed later. Similarly, the influence of the other structural properties (i.e., γ, q and S) on both the DFPS and on the softening superstructures are properly discussed in the next section.

5 SEISMIC FRAGILITY CURVES

Defined the limit states, respectively, in terms of the radii in plan for the two surfaces of the DFPS device, $r_1[m]$ and $r_2[m]$, and of the displacement ductility for the superstructure, μ *[-]*, the seismic fragility, representative of the probabilities P_f exceeding the different limit states at each level of the *IM*, is evaluated. Tables 1-2 report, respectively, the failure probabilities in 50 years [54],[55] with the corresponding *LS* thresholds, related to the *LS*s provided by the codes [33]-[34]: the failure probability in 50 years [18],[54],[55] corresponding to the collapse *LS* [34] for the DFPS; whereas, the failure probability in 50 years [18],[54],[55] corresponding to the life safety *LS* [34] for the superstructure in compliance with the design. The limit state thresholds of Table 1 are also used to assess the fragility in terms of the overall displacement demand to the DFPS. For the both *LS*s, several thresholds are considered with the aim to provide reliable *LS* thresholds for these systems. For each parameter combination (384 equivalent 3dof systems), the probabilities P_f exceeding the different *LSs* at each *IM* level, are numerically computed and then fitted through lognormal distributions [19] with a R-square value higher than 0.8. For the softening systems, the number of both the collapse and not-collapse cases has been considered to estimate the seismic fragility for each parameter combination at each *IM* level by means of the total probability theorem [83], as follows:

$$P_{SL}(IM = im) = (1 - F_{EDP|IM=im}(LS_{EDP})) \cdot \frac{N_{not-collapse}}{N} + 1 \cdot \left(1 - \frac{N_{not-collapse}}{N}\right) \qquad (15)$$

where N is the total number of analyses at each *IM* level, and $N_{not-collapse}$ is the number of numerical simulations without any collapse. The first term of the sum in Eq.(15) represents the probability exceeding a *LS* corresponding to not-collapsing cases [83].

	$LS_{r,1}$	$LS_{r,2}$	$LS_{r,3}$	$LS_{r,4}$	$LS_{r,5}$	$LS_{r,6}$	$LS_{r,7}$	$LS_{r,8}$	$LS_{r,9}$	$LS_{r,10}$
r_i *[m] for i =1,2*	0.05	0.1	0.15	0.2	0.25	0.3	0.35	0.4	0.45	0.5
p_f*(50 years)=1.5·10*$^{-3}$										

Table 1: Limit state thresholds for the two surfaces of the DFPS with the associated exceeding probability.

	$LS_{\mu,1}$	$LS_{\mu,2}$	$LS_{\mu,3}$	$LS_{\mu,4}$	$LS_{\mu,5}$	$LS_{\mu,6}$	$LS_{\mu,7}$	$LS_{\mu,8}$	$LS_{\mu,9}$	$LS_{\mu,10}$
μ *[-]*	1	2	3	4	5	6	7	8	9	10
pf (50 years)=2.2·10^{-2}										

Table 2: Limit state thresholds for the superstructure with the associated exceeding probability.

Fig.s 7-9 depict the fragility curves (i.e., the exceeding probabilities P_f (complementary distribution functions (CCDFs))) versus the *IM* for softening structures. Precisely, the curves corresponding to the different structural properties of interest and related only to some *LS* thresholds ($LS_{r,4}$ and $LS_{\mu,3}$) and to I_d=8 and T_b=3s, are represented. Generally, the seismic fragility of each degree of freedom decreases for increasing the corresponding *LS* threshold.

Fig.s 7-8 illustrate the fragility curves regarding the response of two surfaces of DFPS. For the all limit states, the exceeding probabilities slightly increase for decreasing γ_s. Then, especially for high limit state thresholds, the fragility decreases by decreasing T_b, I_d and increasing q. Note that the probability exceeding a limit state is quite low for the single surface, with a lower probability for the surface 2 characterized by a lower friction coefficient with a lower radius of curvature, in compliance with the IDA results.

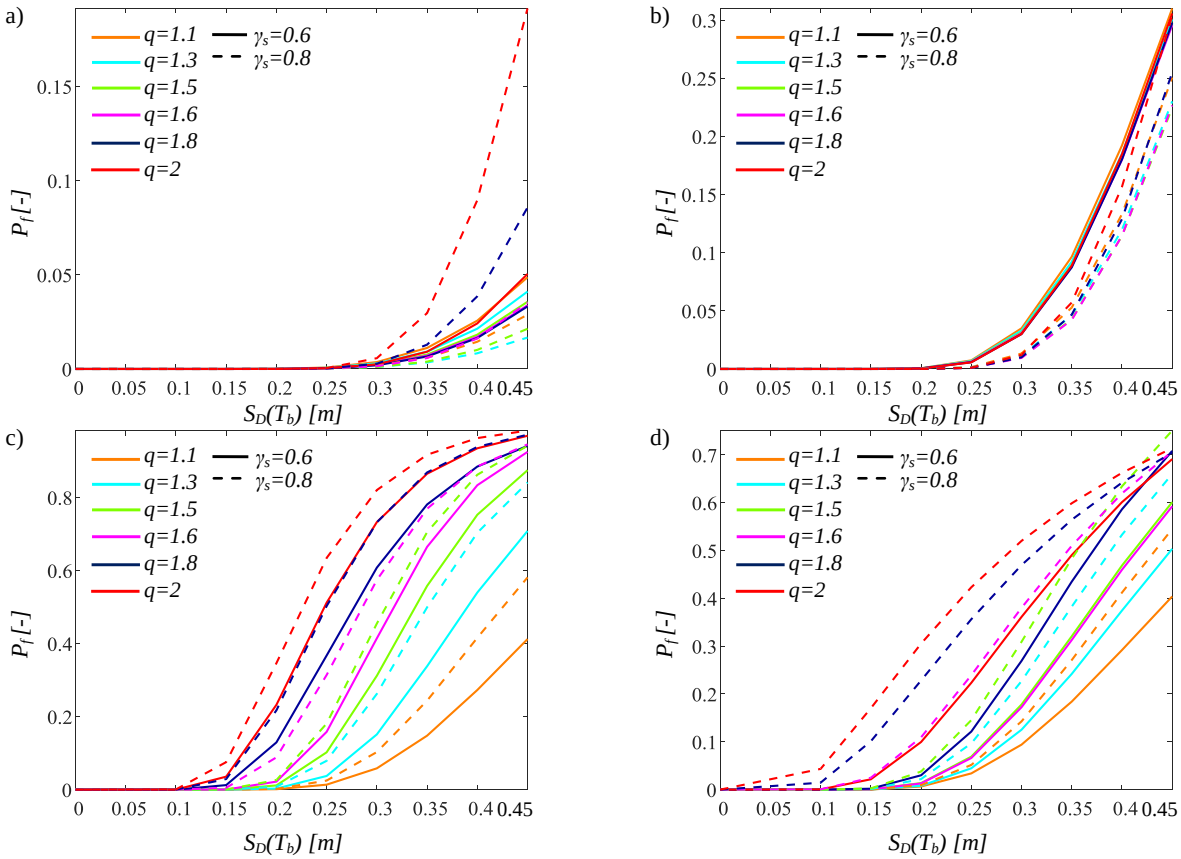

Figure 7: Seismic fragility curves of the sliding surface 1 related to $LS_{r,4}$=0.2 m, for I_d=2, T_b=3 s, S=0.03 (a), I_d=2 and T_b=6 s, S=0.03 (b), I_d=8 and T_b=3 s, S=0.03 (c), I_d=8 and T_b=6 s, S=0.03 (d).

The fragility curves of the nonlinear softening superstructures are shown in Fig. 9. The exceeding probabilities are slightly higher as γ_s increases but highly increase for increasing values of q. Conversely, higher values of T_b for fixed I_d lead to a decrease of the seismic fragility because an increase of the period T_s means an increase of the correlated yielding displacement as well as lower values of T_b for fixed I_d lead to higher values of the seismic fragility. In fact, the coupling between I_d and T_b is a very important parameter because it defines T_s and the corresponding yielding displacement.

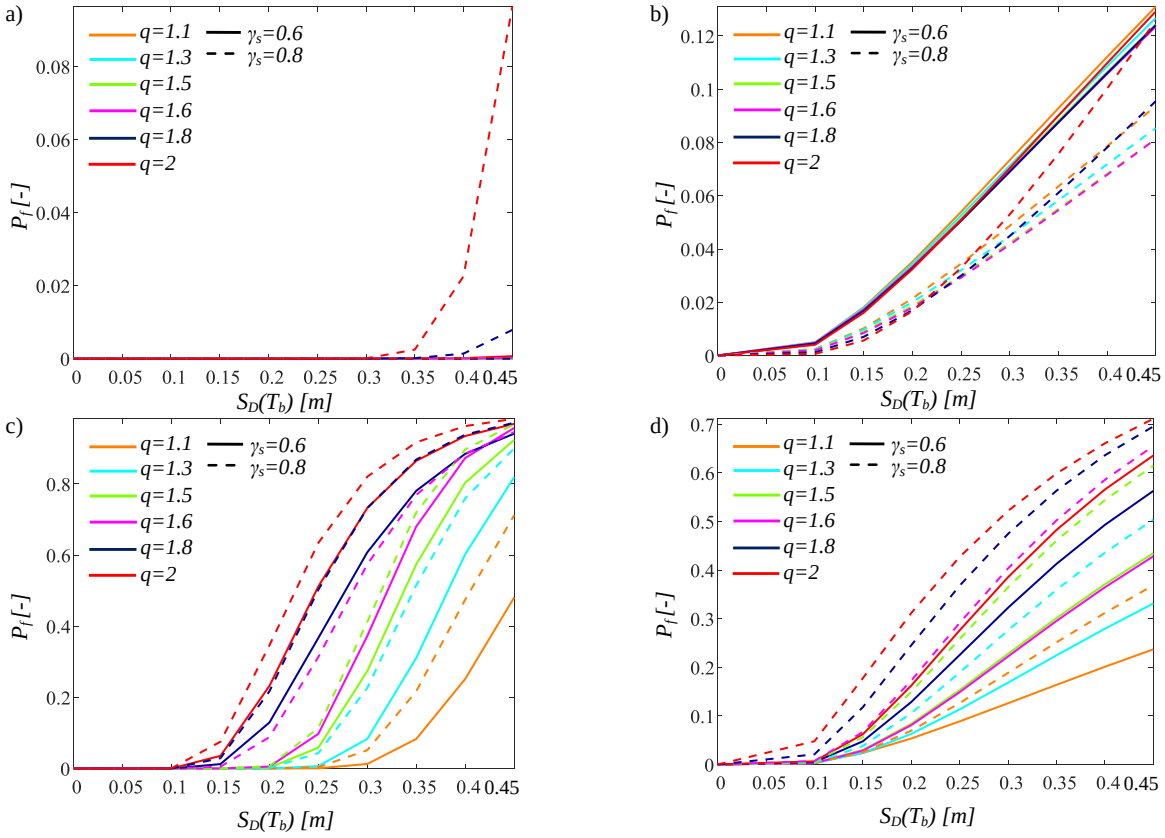

Figure 8: Seismic fragility curves of the sliding surface 2 related to $LS_{r,4}$=0.2 m, for I_d=2, T_b=3 s, S=0.03 (a), I_d=2 and T_b=6 s, S=0.03 (b), I_d=8 and T_b=3 s, S=0.03 (c), I_d=8 and T_b=6 s, S=0.03 (d).

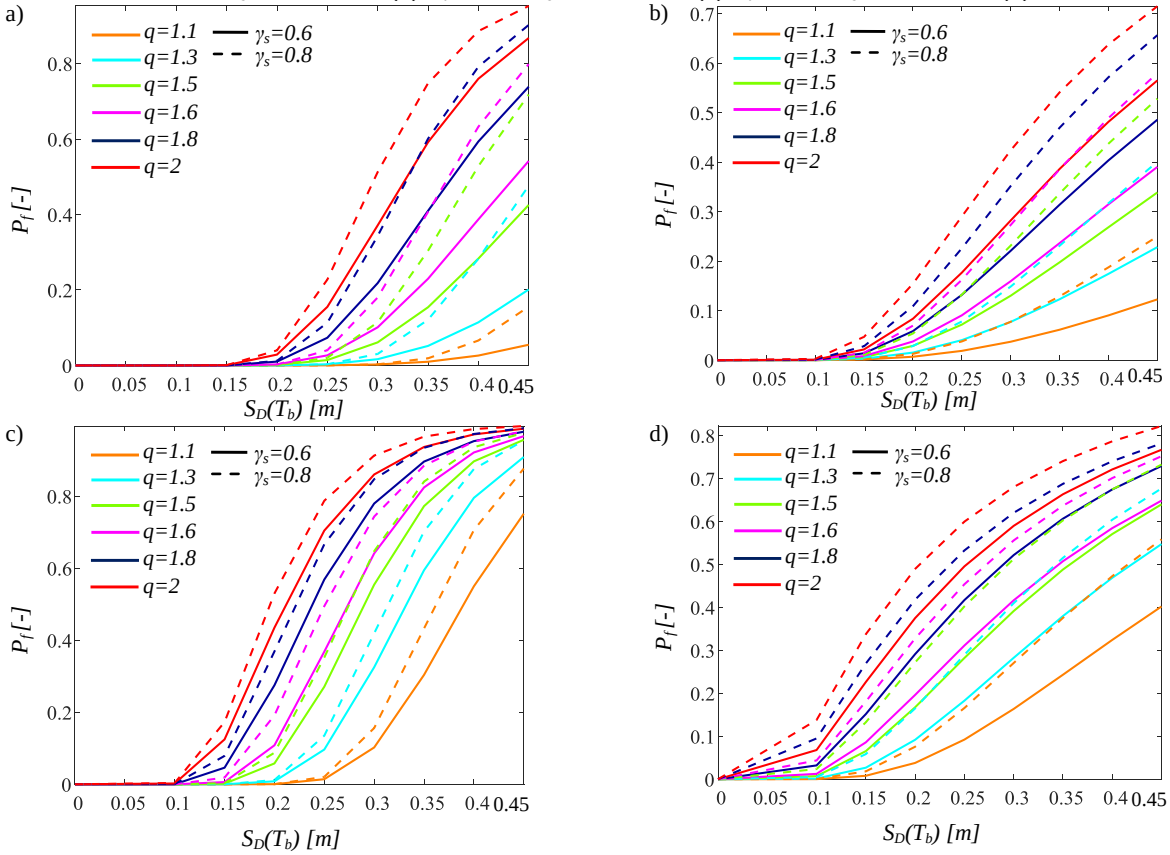

Figure 9: Seismic fragility curves of the superstructure related to $LS_{\mu,3}$=3, for I_d=2, T_b=3 s, S=0.03 (a), I_d=2 and T_b=6 s, S=0.03 (b), I_d=8 and T_b=3 s, S=0.03 (c), I_d=8 and T_b=6 s, S=0.03 (d).

Therefore, as also discussed in [41]-[42], in the case of systems with low T_s, the ensuing dynamic amplification can cause disproportioned superstructure responses and, so a high seismic fragility derives.

The post-yield softening stiffness ratio S strongly and negatively influences the superstructure seismic fragility leading to a very high displacement ductility demand. Comparing the results with the outcomes of [42], for the softening systems higher values of T_b lead to a higher probability exceeding a limit state, especially for the superstructure. This important difference is due to the lower effectiveness the DFPS in comparison to the FPS because at low *IM* and at the beginning of each seismic record, the sliding occurs along only one surface having lower friction coefficient with the consequence that both the energy dissipated and the actual equivalent isolation period are lower.

6 SEISMIC PERFORMANCE OF INELASTIC STRUCTURES WITH DFPS

The convolution integral between the previously achieved seismic fragility curves and the seismic hazard curves expressed in terms of the same *IM*, $S_D(T_b)$, related to the reference site (L'Aquila (Italy)), allows the evaluation of the mean annual rates exceeding the limit states for each parameter combination. Then, by using a Poisson distribution, the seismic reliability of the all softening structures isolated by DFPS in the time frame of interest (e.g., 50 years) have been computed.

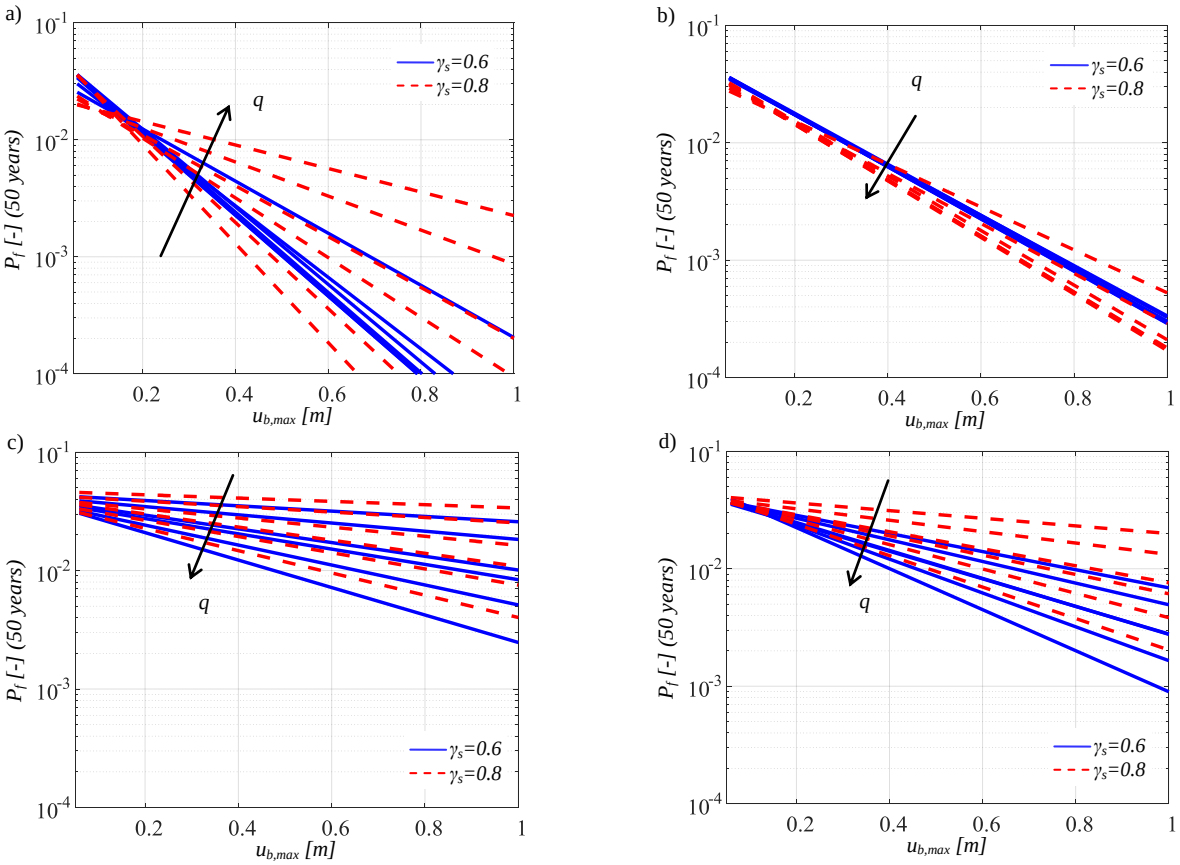

Figure 10: Seismic reliability curves of the isolation level related to I_d=2, T_b=3 s, S=0.03 (a), I_d=2 and T_b=6 s, S=0.03 (b), I_d=8 and T_b=3 s, S=0.03 (c), I_d=8 and T_b=6 s, S=0.03 (d). The arrow denotes the increasing direction of q.

In this work, the seismic hazard of L'Aquila site (Italy), soil class B, with geographic coordinates 42°38'49''N and 13°42'25''E, has been considered, as widely described in [41].

As for the DFPS devices, the seismic reliability evaluation makes it possible to define SRBD curves to design the dimensions in plan of each surface of these devices and the overall dimension of the isolation level as a function of the expected reliability level and of the structural properties.

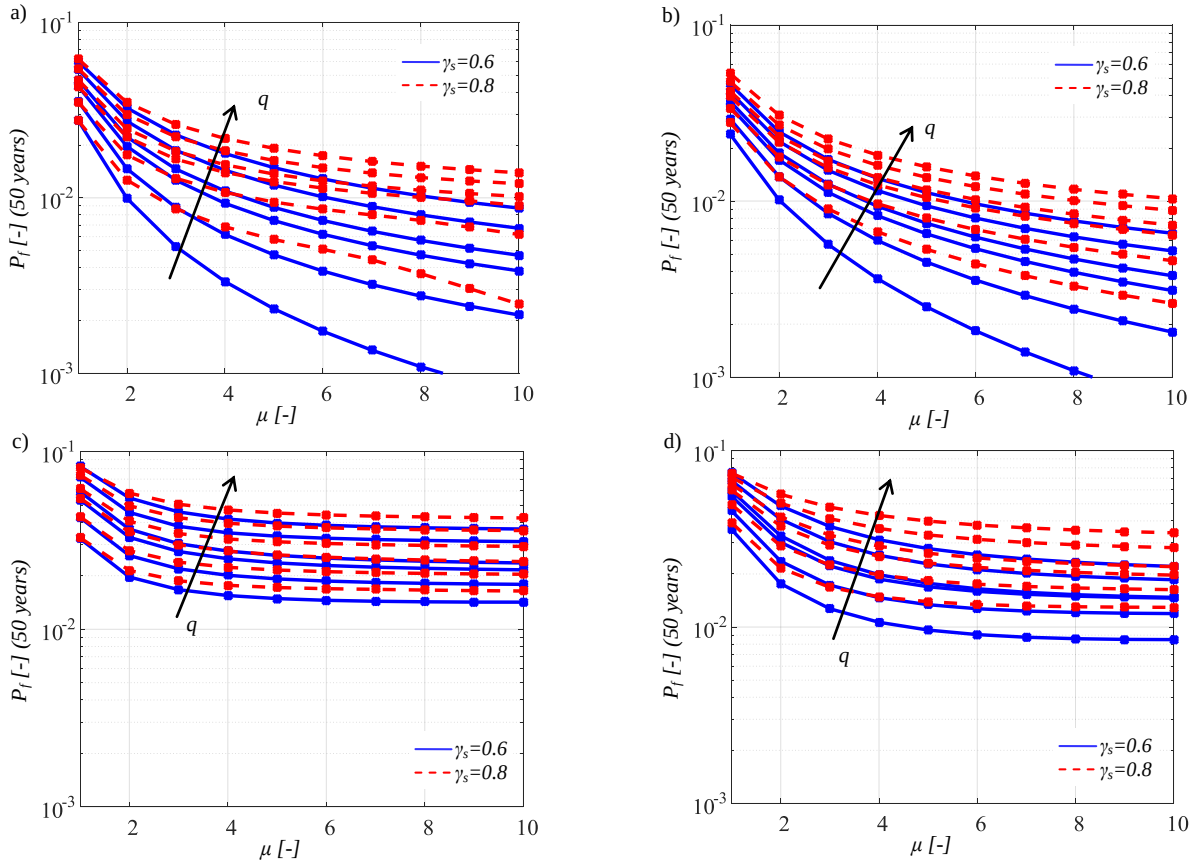

Figure 11: Seismic reliability curves of the superstructure level related to I_d=2, T_b=3 s, S=0.03 (a), I_d=2 and T_b=6 s, S=0.03 (b), I_d=8 and T_b=3 s, S=0.03 (c), I_d=8 and T_b=6 s, S=0.03 (d). The arrow denotes the increasing direction of q.

Fig. 10 depicts the linear regressions, representative of the seismic reliability of the overall dimension of the isolation level, in the semi-logarithmic space for softening systems. The value of R-square is higher than 0.8 demonstrating the robustness and the effectiveness of the kind of the regressions selected within the different statistic approaches [84]-[89]. The exceeding probability of $P_f = 1.5 \cdot 10^{-3}$ can be assured for a global dimension larger than 1 m, in the case of low I_d and γ_s, depending on the behaviour factors. The overall dimension of the isolation level estimated with the above described curves, can also be useful to define the radius in plan of each surface of the DFPS. In fact, SRBD curves of each surface, evaluated and not represented due to space constrains, highlighted that around 1/3 of the global dimension can be attributed to the surface 2 (having a lower friction coefficient with a lower radius of curvature) and 2/3 to the surface 1 for low T_b, whereas for high T_b, these ratios become 1/4 and 3/4, respectively. This aspect is a very important design feature because if high displacements are required to the isolation level, especially for softening systems, they are divided between the two sliding surfaces reducing the geometric encumbrance of the itself device and of the structural elements directly connected as also highlighted in [28]-[30].

Fig. 11 shows the results, representative of the SP curves of the softening superstructure in 50 years, in the logarithmic scale for the different *LS* thresholds in terms of μ and for the dif-

ferent structural properties. The seismic reliability of the superstructure increases for low values of γ_s, I_d, q and for high values of T_b. Comparing the results with the outcomes achieved by [42], the seismic reliability of systems equipped with DFPS, with different friction coefficients for the two surfaces, is slightly lower respect the systems equipped with simple FPS due to the reasons previously explained for the fragility assessment.

7 CONCLUSIONS

This study describes the seismic reliability-based performance of softening structural systems equipped with double concave sliding devices isolators on varying the elastic and inelastic building properties, seismic intensity levels with the hypothesis of the friction coefficients and of the characteristics of the seismic records assumed as the relevant random variables. By means of an equivalent 3dof system with a non-linear velocity-dependent model for the two surfaces of the DFPS, incremental dynamic analyses are carried out considering several natural seismic records, the seismic hazard of L'Aquila site (Italy), increasing behavior factors and different post-yield stiffness ratios. Then, the seismic fragility curves are derived for the softening superstructure and for the isolation level taking also into account the dynamic failure cases. After that, assuming a design life of 50 years, seismic reliability-based design (SRBD) curves are proposed useful to design the radii in plan of the two surfaces as well as the maximum demand to the DFPS. The results have highlighted the negative effects of the post-yield stiffness as well as the possibility to reduce the encumbrance of the devices and of the structural elements directly connected because the seismic demand is divided on the two surfaces. This aspect is a very important design feature of the DFPS representing an its advantage.

Abstract

The work evaluates the optimal properties of friction pendulum system (FPS) bearings for the seismic protection of bridge piers under earthquake excitations having different frequency characteristics representative of different soil conditions in order to reduce the seismic vulnerability of infrastructures. A two-degree-of-freedom model is adopted to describe, respectively, the response of the infinitely rigid deck isolated by the FPS devices and the elastic behavior of the pier. By means of a non-dimensional formulation of the motion equations, a wide parametric analysis for several structural parameters is carried out. Seismic excitations, modelled as time-modulated filtered Gaussian white noise random processes having different intensities and frequency contents, are considered. Specifically, the filter parameters, which control the frequency contents, are properly calibrated to reproduce stiff, medium and soft soil conditions, respectively. Finally, the optimum values of the sliding friction coefficient able to minimize the pier displacements with respect to the ground are derived as a function of the structural properties, of the seismic input intensity and of the soil condition.

Keywords: Bridge, Seismic Isolation, Soil Condition, Performance, Optimal friction coefficient.

1 INTRODUCTION

Seismic isolation of bridges makes it possible to uncouple the deck from the horizontal components of the earthquake motion, leading to a substantial reduction of the deck acceleration and, consequently, of the forces transmitted to the pier [1]-[4]. In the last years, friction pendulum system (FPS) devices have often been preferred to other isolators for their capability of providing an isolation period independent of the mass of the supported structure, their capacity to assure high dissipation and recentering, and their longevity and durability properties [5]-[12]. In [13], with reference to an equivalent two-degree-of-freedom (2dof) model for base-isolated building frames, a non-dimensionalization of the motion equation considering different isolator and system properties has been proposed. Contextually, other studies have been focused on the seismic response of bridge isolated with sliding pendulum isolators highlighting the advantages [14]-[15]. Moreover, other works have been more oriented to develop design approaches for the isolators and to identify the optimal isolator properties. In this context, the seismic reliability-based design (SRBD) approach has been proposed and widely discussed in [16]-[22] as a new methodology useful to provide design solutions for seismic devices taking into account the main uncertainties relevant to the problem. Jangid [23], assuming a stochastic model of the earthquake ground motion, considered the seismic performance of a bridge equipped with FPS devices, characterized by a Coulomb behavior, illustrating that there exists an optimal value of the friction coefficient for which the pier base shear and deck acceleration can be minimized. Other works (e.g., [24]-[26],[27]) concerning isolated bridges have also demonstrated that soft soil condition leads to a higher demand in terms of displacements and shear forces by negatively influencing the isolated systems. In [28], the optimal values of the friction coefficient taking into account the influence of the ground motion characteristics by means of the ratio between the Peak Ground Acceleration (PGA) and the Peak Ground Velocity (PGV) have been proposed.

This work investigates the influence of soil characteristics in terms of frequency content on the seismic performance of bridges isolated with FPS isolators to define the optimal sliding friction coefficients. The two-degree-of-freedom model, as employed in [14],[29] is used for this purpose as an equivalent model representative of the dynamic behaviour of a single-column bent viaduct to describe, respectively, the seismic response of the infinitely rigid deck isolated by the FPS devices and of the elastic behavior of the pier. In compliance with the non-dimensionalization of the motion equations presented for base-isolated building frames in [13], in this study, a non-dimensionalization of the motion equations for isolated bridges is proposed in order to carry out a wide parametric analysis considering different values of the structural properties and three different sets of artificial ground motion records. These latter ones are modelled as non-stationary stochastic processes and generated through the power spectral density method [30], with different frequency contents corresponding to stiff, medium and soft soil conditions [31], respectively. Specifically, for each set of the random excitations, numerical simulations are executed to estimate the influence of the characteristic system and isolator properties on the response parameters relevant to the structural performance. Then, the optimal values of the sliding friction coefficient, able to minimize the pier displacements relative to the ground, are defined as a function of the structural parameters, of the seismic input intensity and of the soil condition.

2 NON-DIMENSIONAL MOTION EQUATIONS FOR ISOLATED BRIDGES

Assuming an equivalent 2dof model, the motion equations governing the response of a bridge equipped with single concave FPS devices (Figure 1), subjected to the seismic input $\ddot{u}_g(t)$, apply:

$$\begin{aligned} &m_d\ddot{u}_d(t)+m_d\ddot{u}_p(t)+c_d\dot{u}_d(t)+f_b(t)=-m_d\ddot{u}_g(t) \\ &m_p\ddot{u}_p(t)-c_d\dot{u}_d(t)+c_p\dot{u}_p(t)+k_pu_p(t)-f_b(t)=-m_p\ddot{u}_g(t) \end{aligned} \quad (1a,b)$$

where u_d denotes the displacement of the deck relative to pier, u_p the pier displacement relative to the ground, m_d and m_p respectively the mass of the deck and of the pier bridge, k_p and c_p respectively the pier stiffness and inherent viscous damping coefficient, c_d the bearing viscous damping factor, t the time instant, the dot differentiation over time, and $f_b(t)$ indicates the FPS force, that can be evaluated as:

$$f_b(t)=k_du_d(t)+\mu(\dot{u}_d)m_dg\,\mathrm{sgn}(\dot{u}_d) \quad (2)$$

where $k_d=W/R=m_dg/R$, g is the gravity constant, R is the radius of curvature of the FPS, $\mu(\dot{u}_d(t))$ the sliding friction coefficient, which depends on the bearing slip velocity $\dot{u}_d(t)$, and *sgn*(·) denotes the sign function. It follows that, similarly to base-isolated structures [13], the fundamental vibration period of an isolated bridge, $T_d=2\pi\sqrt{R/g}$, corresponding to the pendulum component, is independent of the deck mass and related only to the radius of curvature *R*.

According to [8]-[10], the sliding friction coefficient of teflon-steel interfaces can be expressed as:

$$\mu(\dot{u}_d)=f_{\max}-Df\cdot\exp(-\alpha|\dot{u}_d|) \quad (3)$$

where $f_{\max}$ and $f_{\min}=f_{\max}-Df$ represent, respectively, the maximum value of sliding friction coefficient attained at large velocities and the value at zero velocity. In this study, it is considered that $f_{\max}=3f_{\min}$ with the exponent α equal to 30 [13]. Considering the maximum value of the sliding friction coefficient, the effective stiffness of the FPS bearings $k_{eff}=W(1/R+f_{\max}/u_d)$ as well as the corresponding effective isolated period $T_{\mathrm{d},eff}$ [32],[33] (Fig. 1) can be computed depending on the displacement demand. Note that Eqn.(1) does not consider the effects of the higher modes due to flexibility of the pier and is verified if only the horizontal component of the bearing displacement is considered [18] (i.e., high radii of curvature *R*). Furthermore, the equivalent 2dof model [14],[29] can be assumed representative of the dynamic behaviour of a single-column bent viaduct as long as the bridge is straight and consists of a large number of equal spans, of piers with equal height/stiffness and considering a superstructure (deck) that can be assumed to move as a rigid body [34].

Let us introduce the time scale $\tau=t\omega_d$ in which $\omega_d=\sqrt{k_d/m_d}$ is the fundamental circular frequency of the isolated system with infinitely rigid superstructure, and the seismic intensity scale a_0, expressed as $\ddot{u}_g(t)=a_0\ell(\tau)$ where $\ell(\tau)$ is a non-dimensional function of time describing the seismic input time-history, the following non-dimensional equations can be obtained and herein proposed for isolated bridges:

$$\begin{aligned} &\ddot{\psi}_d(\tau)+\ddot{\psi}_p(\tau)+2\xi_d\dot{\psi}_d(\tau)+\psi_d(\tau)=-\ell(\tau)-\frac{\mu(\dot{u}_d)g}{a_0}\mathrm{sgn}(\dot{\psi}_d) \\ &\ddot{\psi}_p(\tau)-\frac{1}{\lambda}\left[2\xi_d\dot{\psi}_d(\tau)+\psi_d(\tau)+\frac{\mu(\dot{u}_d)g}{a_0}\mathrm{sgn}(\dot{\psi}_d)\right]+2\xi_p\frac{\omega_p}{\omega_d}\dot{\psi}_p(\tau)-\frac{\omega_p^2}{\omega_d^2}\psi_p(\tau)=-\ell(\tau) \end{aligned} \quad (4a,b)$$

where $\omega_p = \sqrt{k_p / m_p}$ and $\xi_p = c_p / 2m_p\omega_p$ represent respectively the circular frequency and damping factor of the pier bridge; $\omega_d = \sqrt{k_d / m_d} = \sqrt{g / R}$ and $\xi_d = c_d / 2m_d\omega_d$ are respectively the circular frequency and the isolator damping factor of the FPS isolator; $\lambda = m_p / m_d$ [14],[29],[32] the mass ratio. The non-dimensional parameters $\psi_d = \dfrac{u_d\omega_d^2}{a_0}$ and $\psi_p = \dfrac{u_p\omega_d^2}{a_0}$ describe the dynamic response of the deck and the pier, respectively. From Eqn.(4), it is possible to observe that the five non-dimensional Π terms [13],[35]-[36] that govern the system non-dimensional response are:

$$\Pi_\omega = \frac{\omega_p}{\omega_d}\,,\ \Pi_\lambda = \lambda\,,\ \Pi_\mu\left(\dot{\psi}_d\right) = \frac{\mu\left(\dot{u}_d\right)g}{a_0}\,,\ \Pi_{\xi_d} = \xi_d\,,\ \Pi_{\xi_p} = \xi_p \qquad \text{(5a,b,c,d,e)}$$

where Π_ω represents the isolation degree [32],[37], Π_λ is the mass ratio as previously defined, Π_{ξ_p} and Π_{ξ_d} are related to the inherent viscous damping of the pier and the isolator, respectively, Π_μ denotes the isolator strength which depends on both the friction coefficient $\mu\left(\dot{u}_d\right)$ and the seismic intensity. Since the sliding friction coefficient is a velocity-dependent parameter, Π_μ is considered as follows [13]:

$$\Pi_\mu^* = \frac{f_{\max}\,g}{a_0} \qquad (6)$$

From Eqn.s(4)-(6), note that only the non-dimensional terms Π_{ξ_d}, Π_{ξ_p}, Π_ω, Π_λ, Π_μ^*, the function $\ell(\tau)$, describing the frequency content and time-modulation of the seismic input, and the time scale parameter ω_d influence the non-dimensional seismic response of the bridge system isolated by FPS.

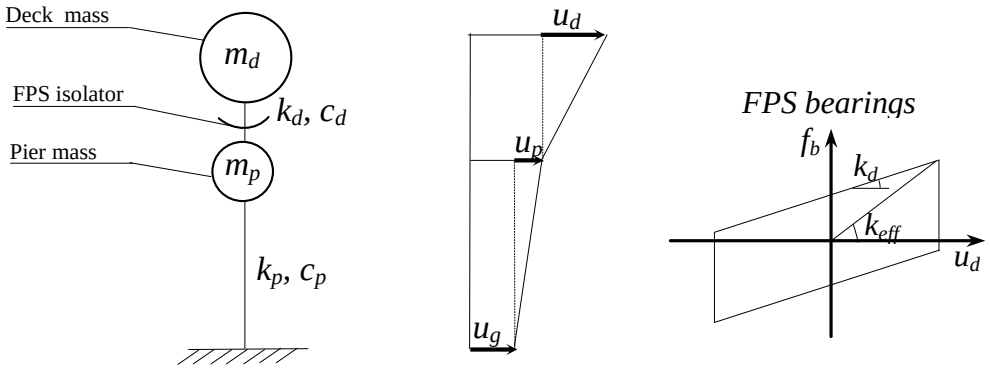

Figure 1: 2dof model of a bridge isolated by FPS bearings.

3 UNCERTAINTIES RELATED TO THE SEISMIC INPUT

This section describes the stochastic model employed for the generation of the artificial ground motions in order to reproduce the uncertainty in terms of frequency characteristics for different soil conditions as well as the uncertainty corresponding to the seismic intensity.

3.1 Random excitations

The "record-to-record" variability in terms of the dynamic characteristics of different seismic inputs related to stiff, medium and soft soil conditions, respectively, is herein described by means of three corresponding wide groups of artificial records having different frequency contents. These artificial inputs are modelled as time-modulated filtered Gaussian white noise random processes [30],[38] within the power spectral density (PSD) method [39] by adopting the Kanai-Tajimi model [40]-[41], modified by Clough and Penzien [42],[26],[43]-[53], as follows:

$$S_f(\omega) = \frac{\omega_g^4 + 4\xi_g^2\omega_g^2\omega^2}{(\omega_g^2 - \omega^2) + 4\xi_g^2\omega_g^2\omega^2} \cdot \frac{\omega^4}{(\omega_f^2 - \omega^2) + 4\xi_f^2\omega_f^2\omega^2} S_0 \qquad (7)$$

in which S_0 is the amplitude of the bedrock excitation spectrum, modeled as a white noise process; ω_f and ξ_f are the Clough-Penzien filter parameters assumed as deterministic values, set equal to $\omega_f = 1.6$ (rad/s) and $\xi_f = 0.6$; ω is the circular frequency, assumed varying in the range 0 and 50 rad/s; ω_g and ξ_g represent the fundamental circular frequency and damping factor of the soil, respectively, assumed as uniformly distributed independent random variables with appropriate ranges of variation [31],[54] as follows: ω_g varies in the range 5π-9π rad/s (high frequency/short period) with ξ_g =0.6-1 for stiff soil condition, ω_g is assumed ranging between 3π rad/s and 5π rad/s (intermediate frequency/ period) with ξ_g =0.4-0.6 for medium soil condition, and, finally, ω_g ranges from π to 3π (low frequency/high period) with ξ_g =0.2-0.4 for soft soil condition. Specific sampling techniques [47]-[52] are used to sample the data. Assuming the same duration [55],[56] equal to 31.25 s, longer than 25s as provided from [57], the Shinozuka-Sato function [58] is adopted as time-modulating function in order to define non-stationary stochastic processes for each set corresponding to each soil condition. Specifically, 100 artificial (non-stationary stochastic processes) records, generated through the Spectral Representation Method [30] and reflecting the wide uncertainty in terms of frequency content for each soil type [31],[54],[59] are defined for each soil condition.

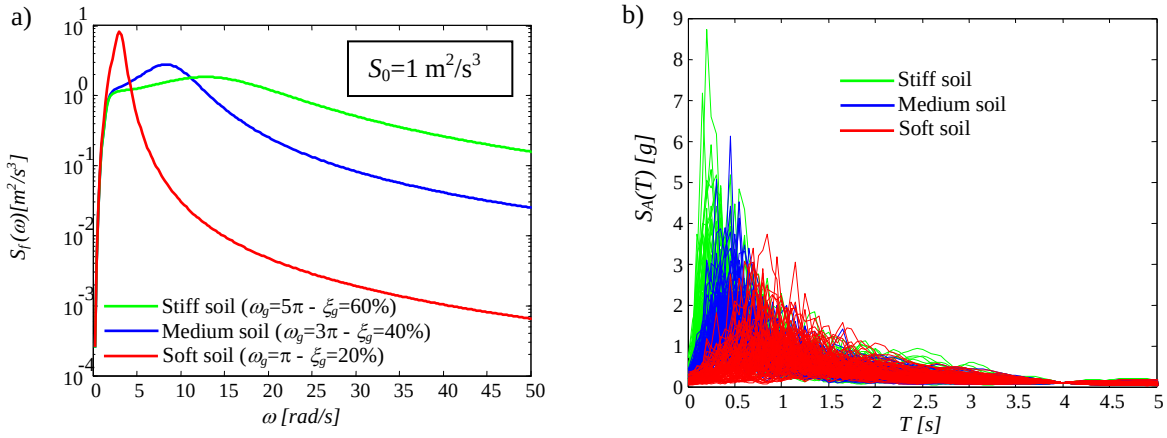

Figure 2: PSD functions corresponding to stiff, medium and soft soil conditions (a); Pseudo-acceleration response spectra for the 300 records scaled to the common seismic intensity measure $S_A(T)$ = 0.1 g, for T=4s (b).

Note also that, for each set of artificial records a high number of random excitations is defined in order to highly reduce the standard errors of the statistics of the response parameters [18]. As an example, Fig.s 2(a)-(b) show, respectively, the sampled PSD functions and the elastic pseudo-acceleration response spectra of the 300 artificial records, scaled to the common *IM* value $S_A(T)$ = 0.1g, for a period T = 4s.

3.2 Intensity measure

In order to take into account the uncertainty related to the seismic intensity, the intensity scale factor, a_0, of Eqn.(4), represents the seismic intensity measure (*IM)* in the context of the performance-based earthquake engineering (PBEE) [60],[61]. In this study, the abovementioned *IM* is denoted by the spectral pseudo-acceleration, $S_A\left(T_d,\xi_d\right)$, corresponding to the isolated period of the bridge $T_d = 2\pi/\omega_d$ with the damping ratio $\Pi_{\xi_d} = \xi_d$. Note that, in the analyses herein developed, the damping ratio ξ_d is set equal to zero [13],[23],[63] and the corresponding *IM* is hereinafter denoted as $S_A\left(T_d\right)$.

4 PARAMETRIC STUDY

This section describes the results of the parametric study carried out on the system of Figure 1 to evaluate the seismic performance of bridge isolated with FPS bearings for different structural properties and soil conditions. The first subsection describes the response parameters relevant to the seismic performance, whereas the final subsection illustrates the parametric study results. More details may be found in [62].

4.1 Non-dimensional response parameters relevant to the seismic performance assessment

The following response parameters relevant to the seismic performance assessment of isolated bridges are considered: the peak deck displacement relative to the pier $u_{\mathrm{d,max}}$, the peak pier displacement $u_{\mathrm{p,max}}$. These latter ones can be defined in non-dimensional form, as expressed in Eqn. (4), as:

$$\psi_{u_d} = \frac{u_{\mathrm{d,max}}\omega_d^2}{S_A\left(T_d\right)} = \frac{u_{\mathrm{d,max}}}{S_d\left(T_d\right)} \;,\; \psi_{u_p} = \frac{u_{\mathrm{p,max}}\omega_d^2}{S_A\left(T_d\right)} = \frac{u_{\mathrm{p,max}}}{S_d\left(T_d\right)} \tag{8a,b,c,d}$$

For each soil condition (i.e., set of the 100 ground motion records), Eqn. (4) is repeatedly solved computing a set of samples for each response parameter. As also described in [13]-[22],[63]-[64], the response parameters are modeled in probabilistic terms by means of a lognormal distribution. Specifically, the generic response parameter *D* (i.e., the extreme values ψ_{u_d}, ψ_{u_p} of Eq. (4)) can be fitted by a lognormal distribution estimating the sample geometric mean, $GM\left(D\right)$, and the sample lognormal standard deviation $\sigma_{\ln}\left(D\right)$, or dispersion $\beta\left(D\right)$, defined, respectively:

$$GM\left(D\right) = \sqrt[N]{d_1 \cdot \ldots \cdot d_N} \tag{9}$$

$$\beta\left(D\right) = \sigma_{\ln}\left(D\right) = \sqrt{\frac{\left(\ln d_1 - \ln\left[GM\left(D\right)\right]\right)^2 + \ldots\ldots + \left(\ln d_N - \ln\left[GM\left(D\right)\right]\right)^2}{N-1}} \tag{10}$$

in which d_i is the *i*-th sample value of *D*, and *N* represents the total number of samples. The *k*th percentile of the generic response parameter *D* can be evaluated as:

$$d_k = GM(D)\exp[f(k)\beta(D)] \tag{11}$$

where $f(k)$ is a function that assumes the following values $f(50)=0$, $f(84)=1$ and $f(16)=-1$ [65], for the 50th, 16th and 84th percentile, respectively.

4.2 Parametric study results for each soil condition

In this section, the results of the parametric study developed using the proposed non-dimensionalization, for the different structural properties and for each set of 100 records, are illustrated and discussed. According to several studies [1]-[2],[4],[14]-[15],[29],[66]-[70], the parameters $\Pi_{\xi_d}=\xi_d$ and $\Pi_{\xi_p}=\xi_p$ are assumed respectively equal to 0% and 5%, the isolation period T_d varies in the range between 2s and 4s, the pier period T_p ranges from 0.05s to 0.2s, $\Pi_\lambda=\lambda$ varies between 0.1 and 0.2, Π_μ^* ranges between 0 (no friction) and 2 (very high friction) [13]. Other uncertainties [71]-[76] are not considered. Indeed, a high value for the upper bound of Π_μ^* is considered in order to take also into account the very low values of the *IM* at high isolated periods (i.e., T_d=4s) depending on the seismic hazard [57]. For each parameter combination, the differential motion equations, i.e., Eqn. (4), have been repeatedly solved adopting the Bogacki-Shampine integration algorithm available in Matlab-Simulink [77]. After that, for each normalized response parameter, the geometric mean, *GM*, and the dispersion, β, have been evaluated through Eqns. (9) and (10) and are plotted in Figs. 5-12 for each soil type. Each figure contains several meshes, corresponding to the different Π_λ. The results for deck and pier displacements related to the all pier periods are reported.

Figs. 5-8 plot the results concerning the normalized deck displacement ψ_{u_d}, related to different pier period values. $GM\left(\psi_{u_d}\right)$ is quite perfectly equal to unit for $\Pi_\mu^*=0$ and T_p = 0.05 because of the very reduced influence of the pier behaviour. For $\Pi_\mu^*\neq 0$, and $GM\left(\psi_{u_d}\right)$ increases slightly for increasing T_d because of the period elongation. Obviously, $GM\left(\psi_{u_d}\right)$ decreases significantly as Π_μ^* increases while it is not heavily influenced by Π_λ. For soft soil condition and low Π_μ^* values, the decrease of $GM\left(\psi_{u_d}\right)$ for increasing Π_μ^* is more gradual, while, for high Π_μ^* values $GM\left(\psi_{u_d}\right)$ increases in the case of stiff soil, especially, for high T_p values due to the pier influence. The dispersion $\beta\left(\psi_{u_d}\right)$ for high T_d increases for increasing values of Π_μ^*, as a result of the reduction of the efficiency of the *IM* employed in the study for each soil condition. Moreover, with reference to soft soils, the values of $\beta\left(\psi_{u_d}\right)$ also result to be the highest for low or high values of both T_d and Π_μ^*. Obviously, in the reference situation corresponding to $\Pi_\mu^*=0$ and T_p=0.05s, the dispersion is zero for all the values of T_d and of Π_λ considered and for all the soil conditions. The mass ratio Π_λ does not affect significantly the response dispersion, especially in the case of high T_p values.

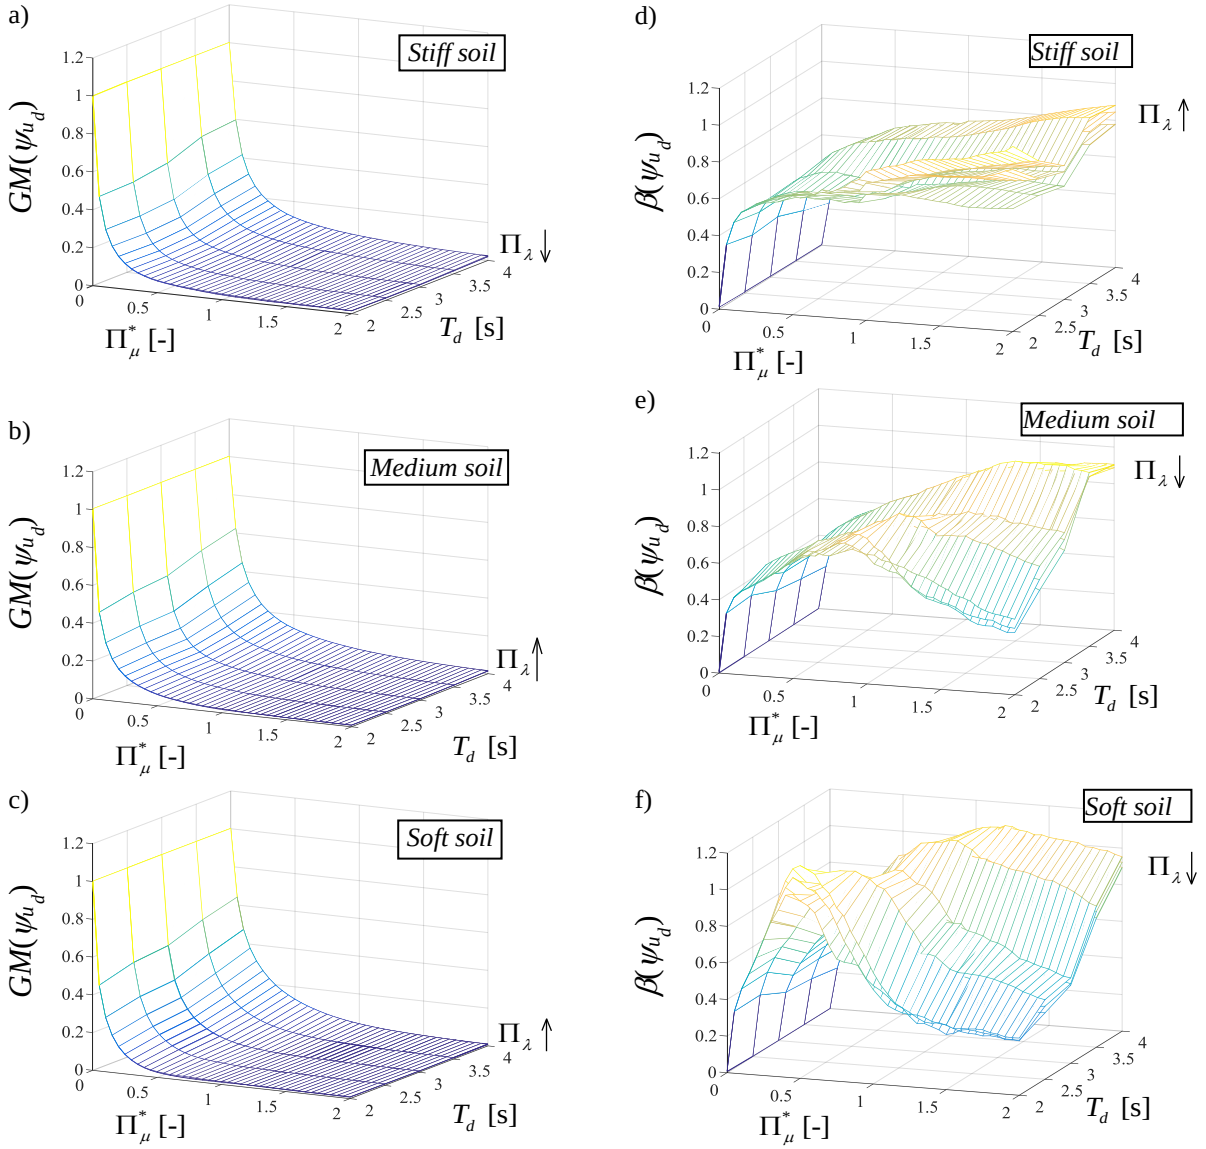

Figure 5: Normalized deck displacement vs. Π^*_μ and T_d for T_p =0.05s and each soil condition: median value (a,b,c) and dispersion (d,e,f) for different values of Π_λ. The arrow denotes the increasing direction of Π_λ.

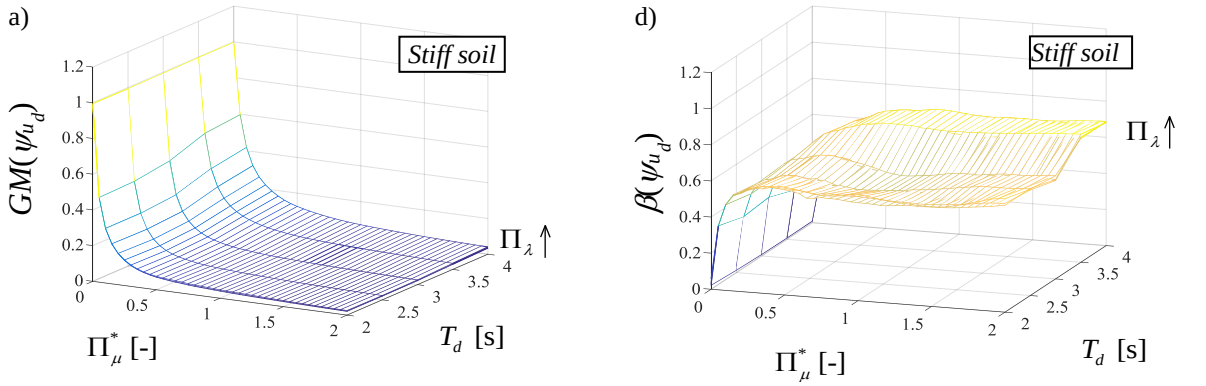

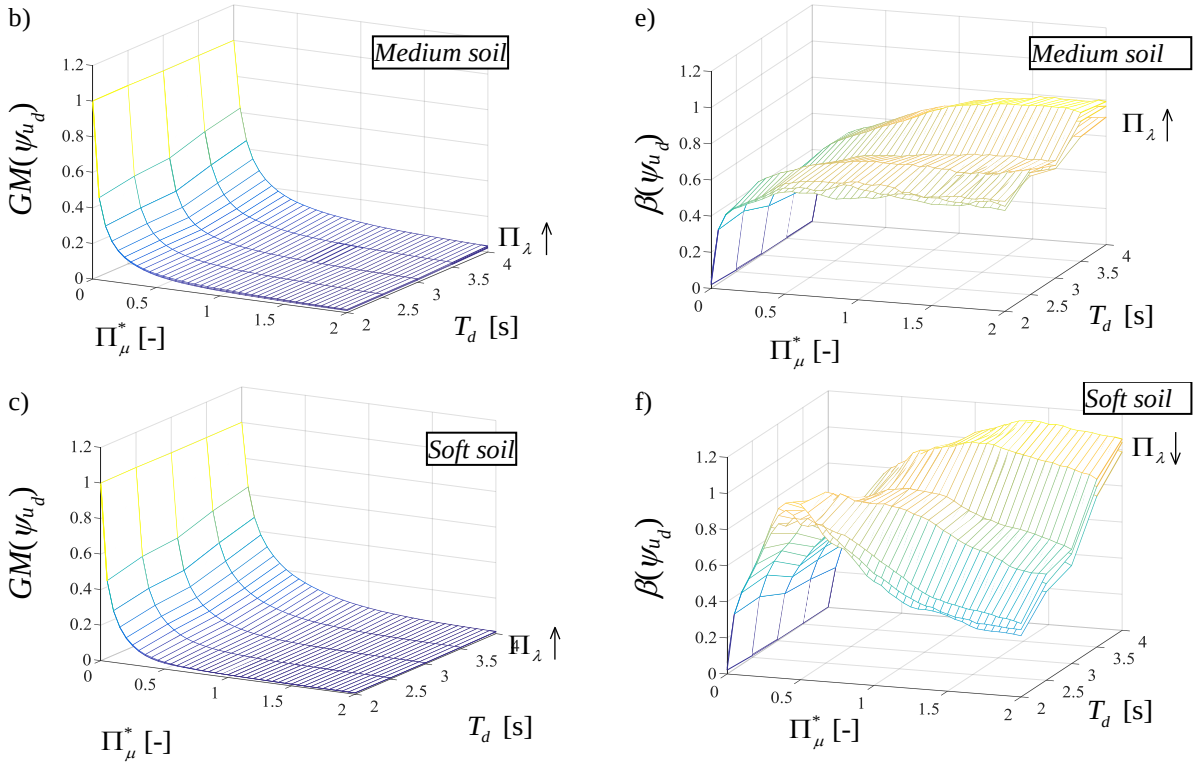

Figure 6: Normalized deck displacement vs. Π^*_μ and T_d for T_p =0.1s and each soil type: median value (a,b,c) and dispersion (d,e,f) for different values of Π_λ. The arrow denotes the increasing direction of Π_λ.

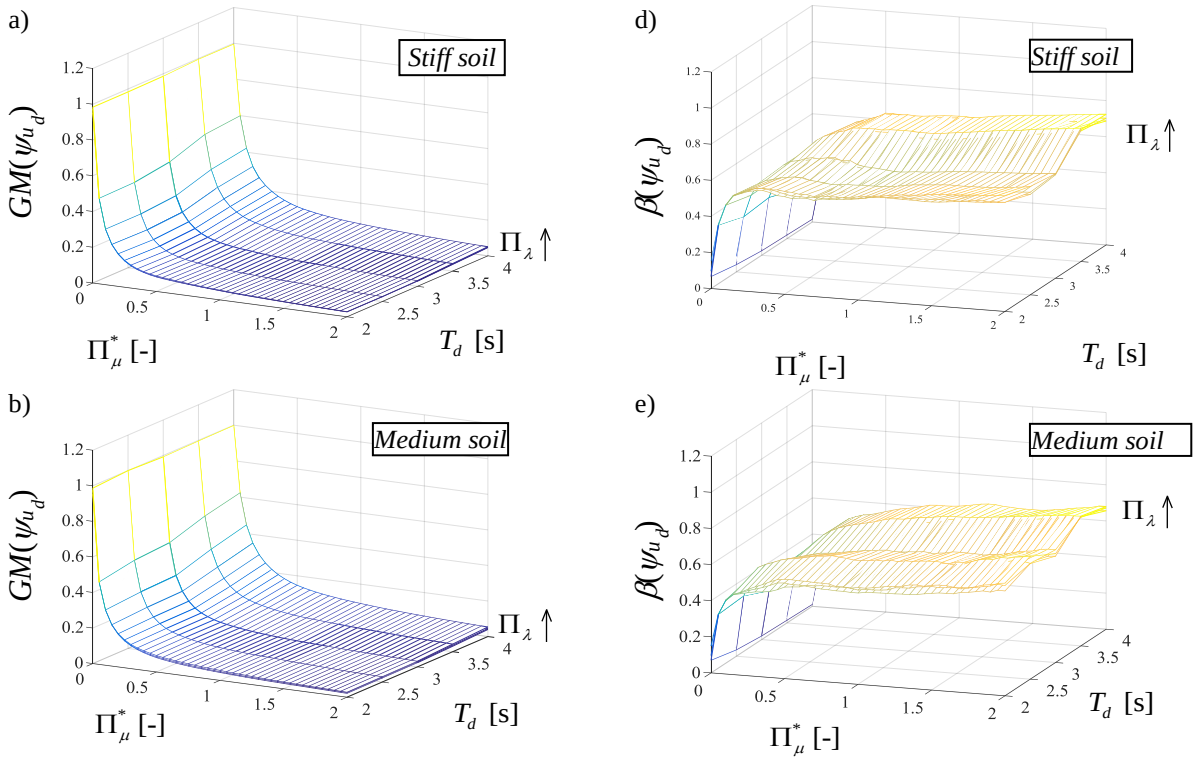

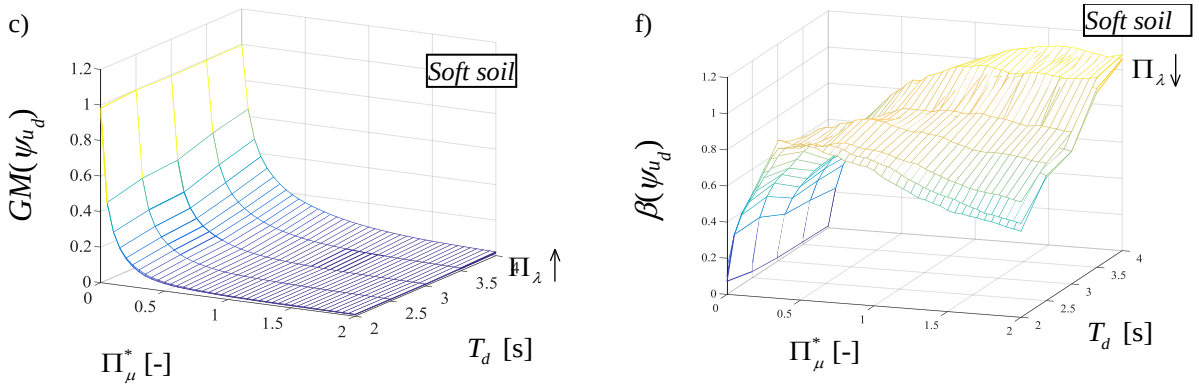

Figure 7: Normalized deck displacement vs. Π^*_μ and T_d for T_p =0.15s and each soil type: median value (a,b,c) and dispersion (d,e,f) for different values of Π_λ. The arrow denotes the increasing direction of Π_λ.

The above described peak values of both $GM\left(\psi_{u_d}\right)$ and $\beta\left(\psi_{u_d}\right)$ in the case of soft soil condition are high due to the resonance effects which mainly affect the effective frequency charactering the dynamic behaviour of the frictional bearings and the dominant frequency of the corresponding random excitations.

Figs. 8-12 show the response statistics of the normalized pier displacements ψ_{u_p}. $GM\left(\psi_{u_p}\right)$ decreases for increasing values of T_d and of Π_λ as well as for decreasing values of T_p, whereas it first decreases and then increases for increasing values of Π^*_μ. Thus, this means that there exists an optimal value of the normalized friction coefficient Π^*_μ such that the pier displacement is minimized for each soil condition. This optimal value is in the range between 0.1 and 0.3 and depends on the values of T_p, T_d, Π_λ and on the soil condition. Differently to the case of base-isolated systems, there is not a particular and specific trend of the optimal friction coefficients from stiff to soft soil condition, as discussed later in detail. There is a further increase in the value of $GM\left(\psi_{u_p}\right)$ from soft soil to stiff soil due to resonance effects, especially, for lower values of T_d. The values of the dispersion $\beta\left(\psi_{u_p}\right)$ are very low for low Π^*_μ values due to the high efficiency of the *IM* used in this work, and attain their peak for values of Π^*_μ close to the optimal ones. The other system parameters have a reduced influence on $\beta\left(\psi_{u_p}\right)$ compared to the influence of Π^*_μ. For the soft soil condition, the dispersion $\beta\left(\psi_{u_p}\right)$ strongly increases for increasing values of Π^*_μ for low isolation period and for higher pier periods because of the resonance effects which mainly affect the effective frequency of the frictional bearings and the dominant frequency of the corresponding random excitations.

As observed in similar studies [13],[23],[78]-[81], the existence of an optimal value of the friction coefficient derives from a combination of different effects. Indeed, an increase of the sliding friction coefficient leads to higher isolator strengths (and thus higher values of the equivalent stiffness, with a lowering of the corresponding effective fundamental vibration period (Fig.1)) and higher forces towards the deck. This also leads to an increase in the forces transmitted to the pier bridge due to inertial effect, relative to deck mass, on the pier.

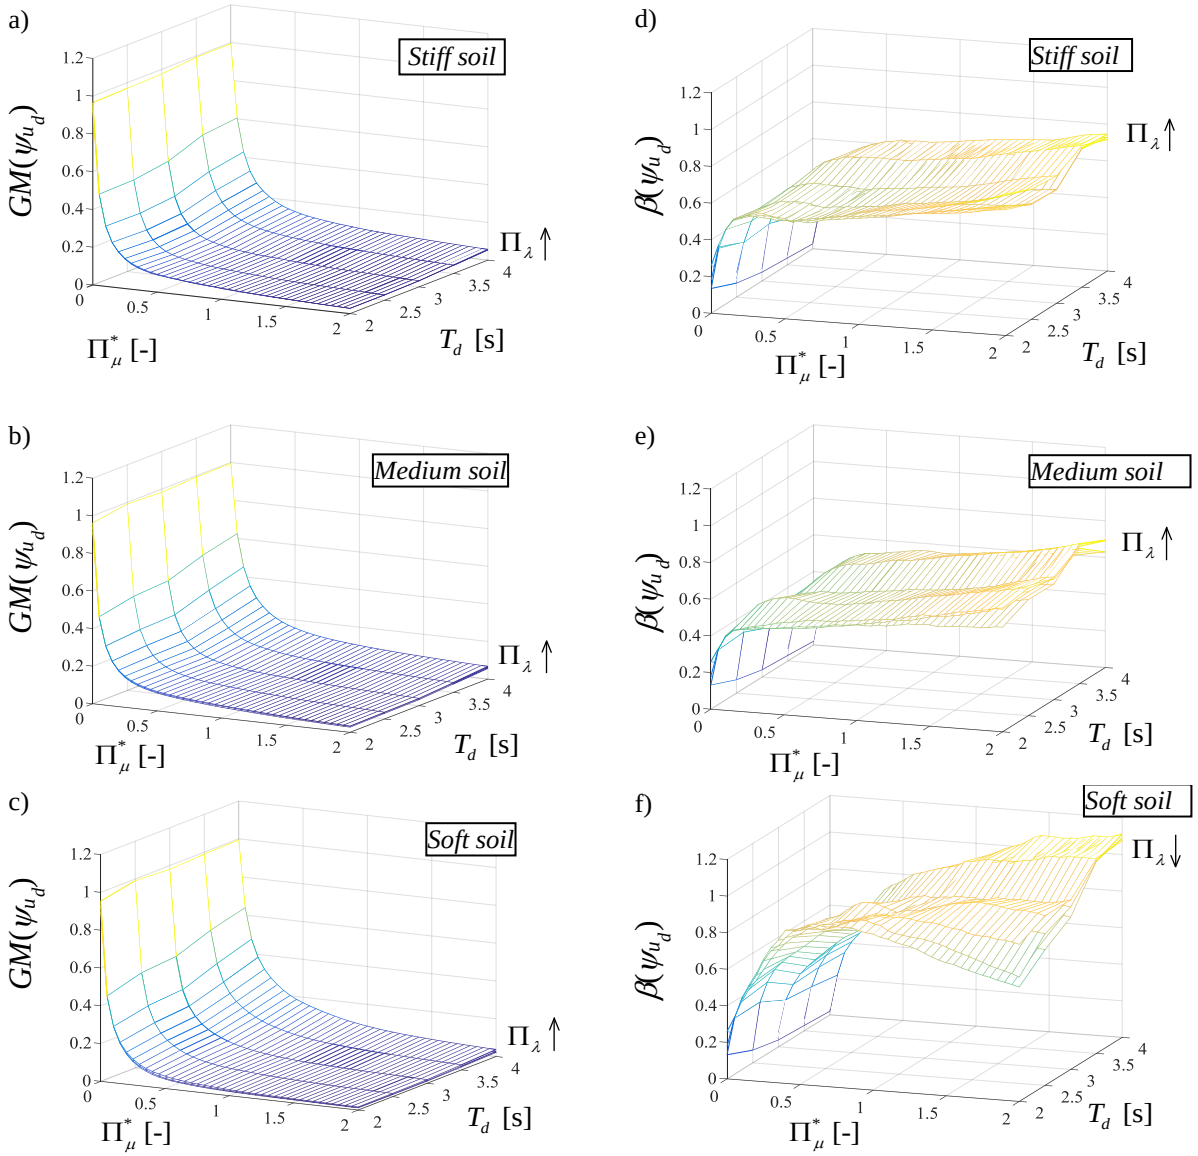

Figure 8: Normalized deck displacement vs. Π^*_μ and T_d for T_p =0.2s and each soil type: median value (a,b,c) and dispersion (d,e,f) for different values of Π_λ. The arrow denotes the increasing direction of Π_λ.

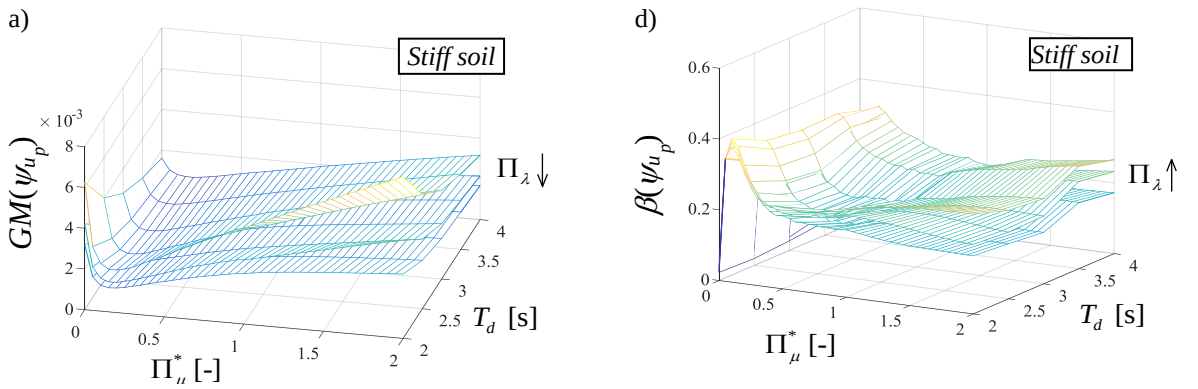

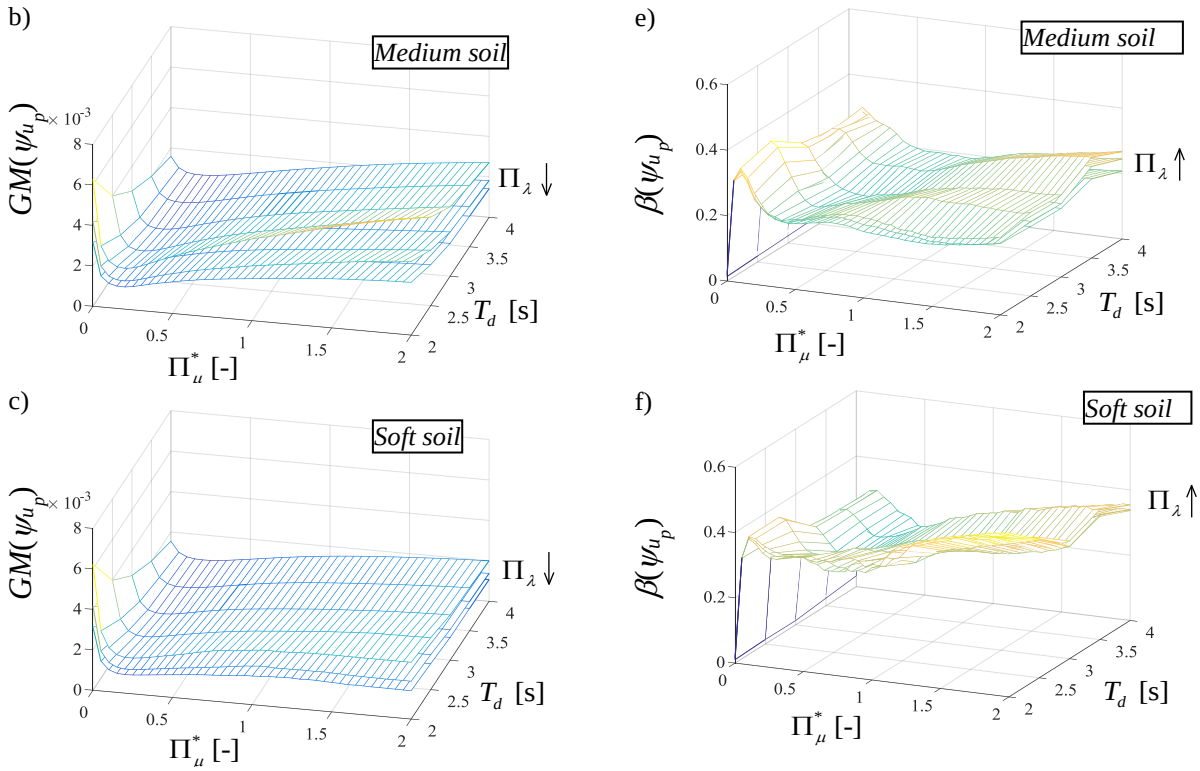

Figure 9: Normalized pier displacement vs. Π^*_μ and T_d for T_p =0.05s and each soil condition: median value (a,b,c) and dispersion (d,e,f) for different values of Π_λ. The arrow denotes the increasing direction of Π_λ.

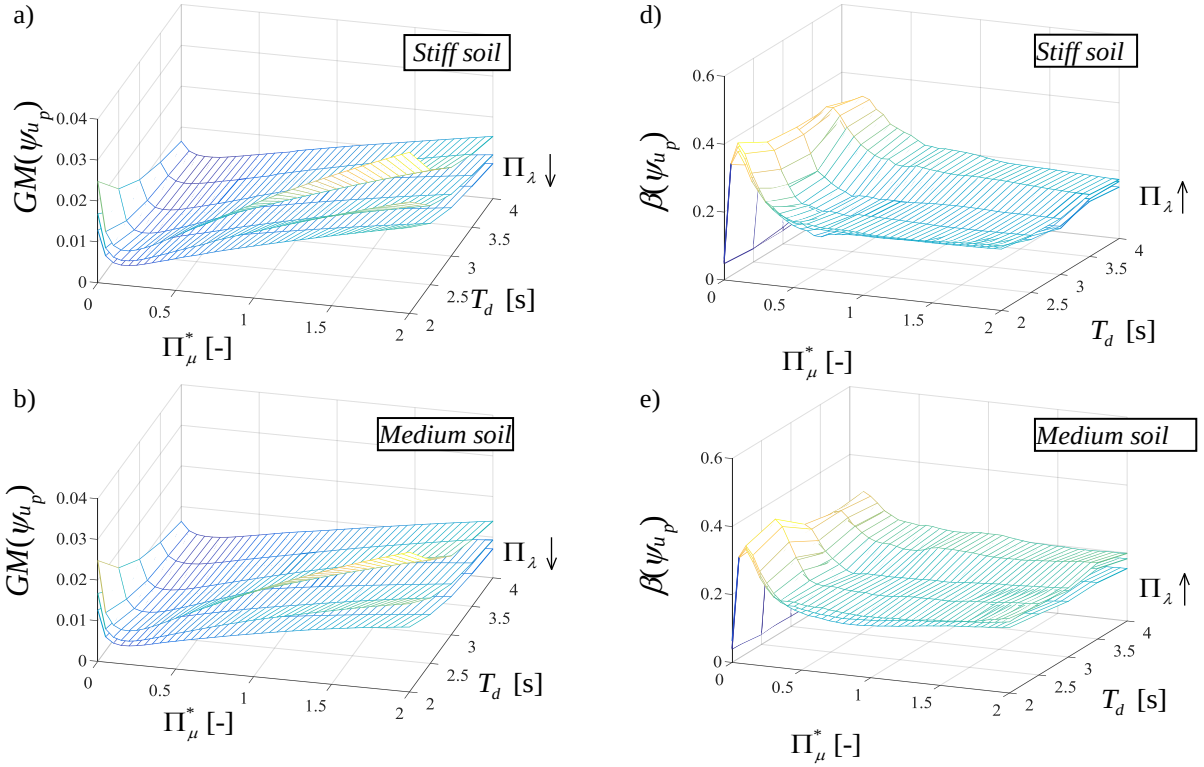

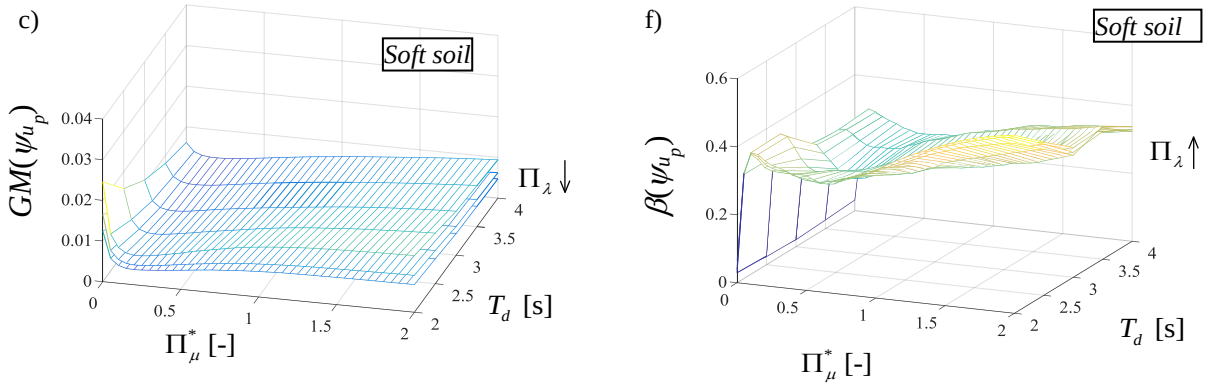

Figure 10: Normalized pier displacement vs. Π^*_μ and T_d for T_p =0.1s and each soil condition: median value (a,b,c) and dispersion (d,e,f) for different values of Π_λ. The arrow denotes the increasing direction of Π_λ.

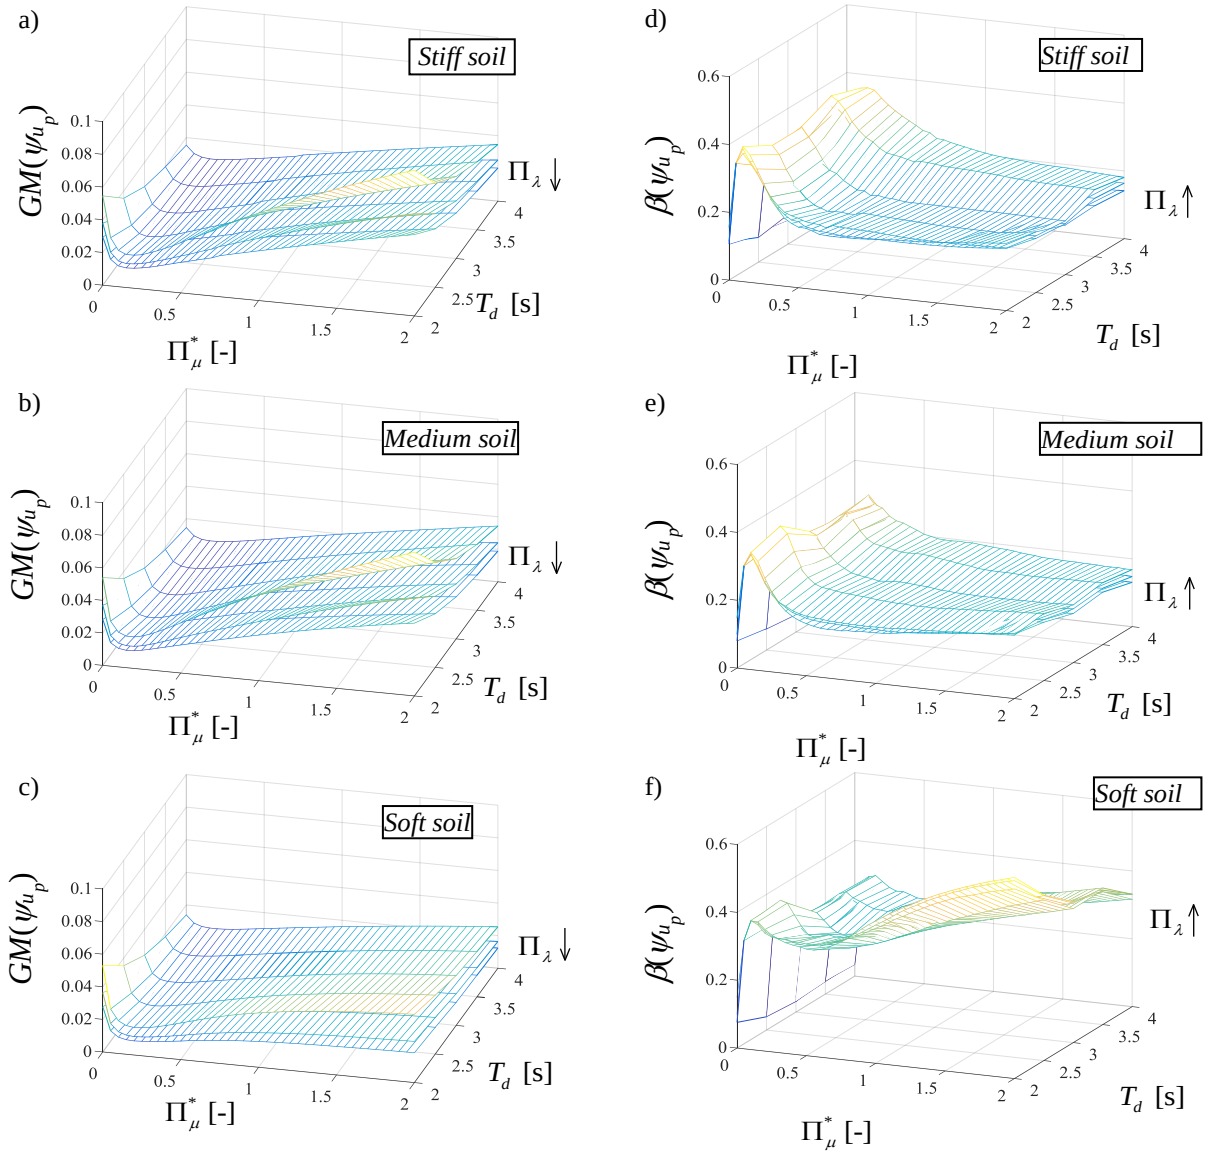

Figure 11: Normalized pier displacement vs. Π^*_μ and T_d for T_p =0.15s and each soil condition: median value (a,b,c) and dispersion (d,e,f) for different values of Π_λ. The arrow denotes the increasing direction of Π_λ.

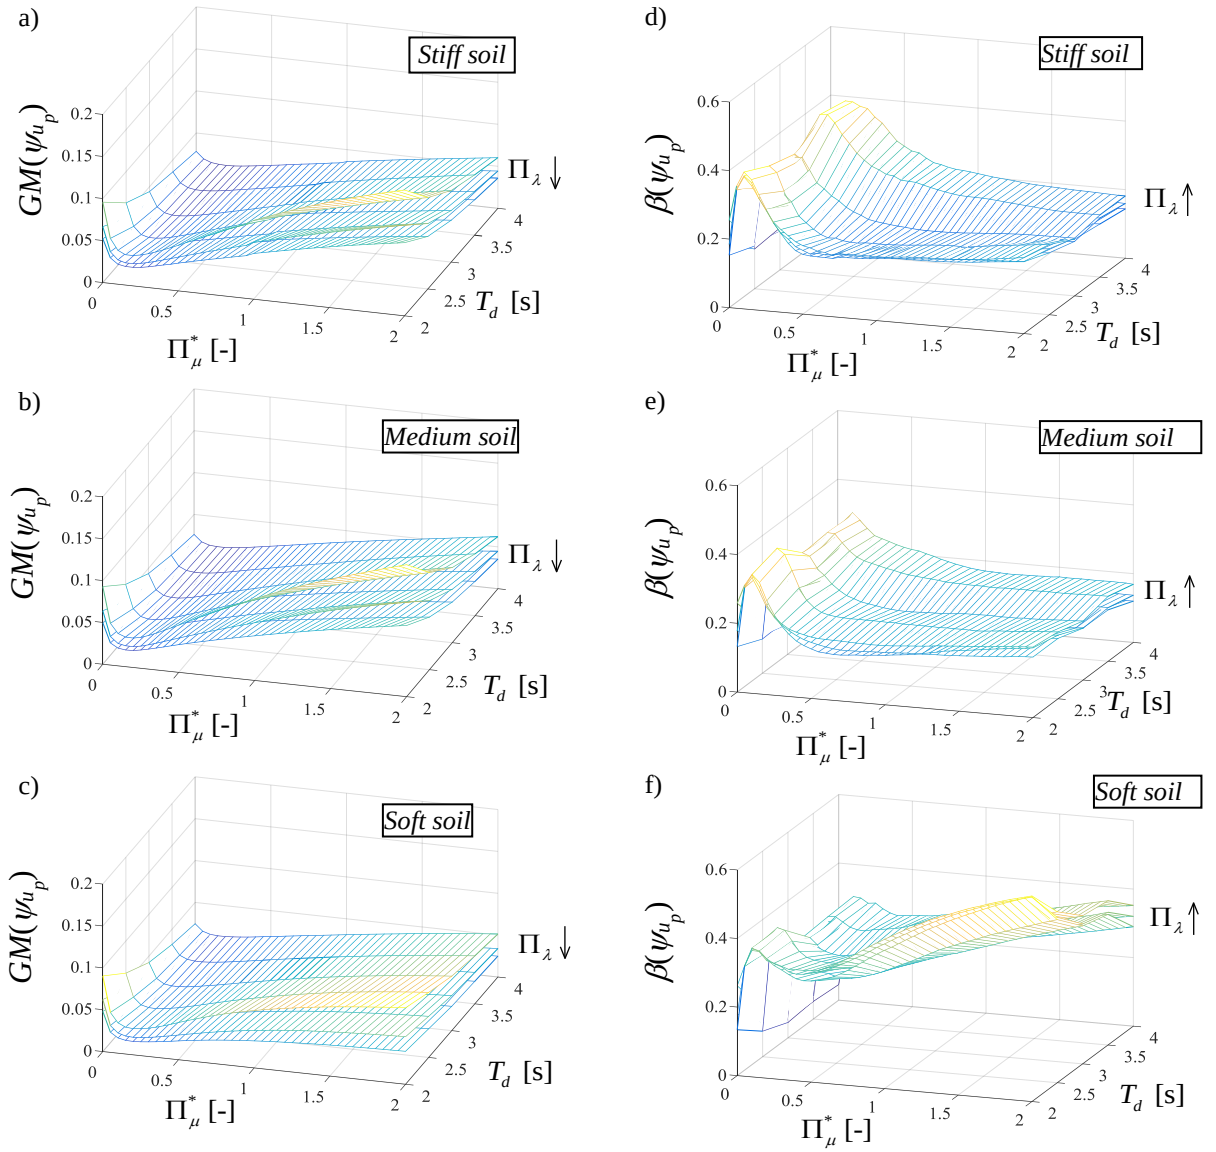

Figure 12: Normalized pier displacement vs. Π^*_μ and T_d for T_p =0.2s and each soil condition: median value (a,b,c) and dispersion (d,e,f) for different values of Π_λ. The arrow denotes the increasing direction of Π_λ.

However, the forces transmitted to the substructure also depend on the bearing displacements, which decrease as the friction coefficient increases. An increase of the forces transmitted to the substructure generally increases the substructure displacements. Contextually, another effect is the increase in terms of energy dissipation (equivalent damping), which reduces the substructure displacements. The balance between these effects defines the optimal friction coefficient of the FPS devices.

5 OPTIMAL SLIDING FRICTION COEFFICIENTS FOR ISOLATED BRIDGES DEPENDING ON SOIL CONDITIONS

From the results defined in the previous section, for each parameter combination (i.e., Π_λ, T_d and T_p) and soil condition, the optimal values of the normalized sliding friction coef-

ficient, $\Pi^*_{\mu,\text{opt}}$, that minimize the median (50$^{\text{th}}$ percentile) normalized pier displacements ψ_{u_p} have been computed and are illustrated in Fig. 13. Minimizing the pier displacements relative to the ground represents a notable design requisite for the safety of bridges in order to assure an adequate seismic protection. In fact, an inelastic response of the pier can lead to a disproportionately large displacement response that could also be amplified in the case of the resonance effects. Figure 13 shows the variation of $\Pi^*_{\mu,\text{opt}}$ with Π_λ and T_p for T_d = 2s (Figure 13a,b,c) and T_d = 4s (Figure 13d,e,f), for the three soil conditions.

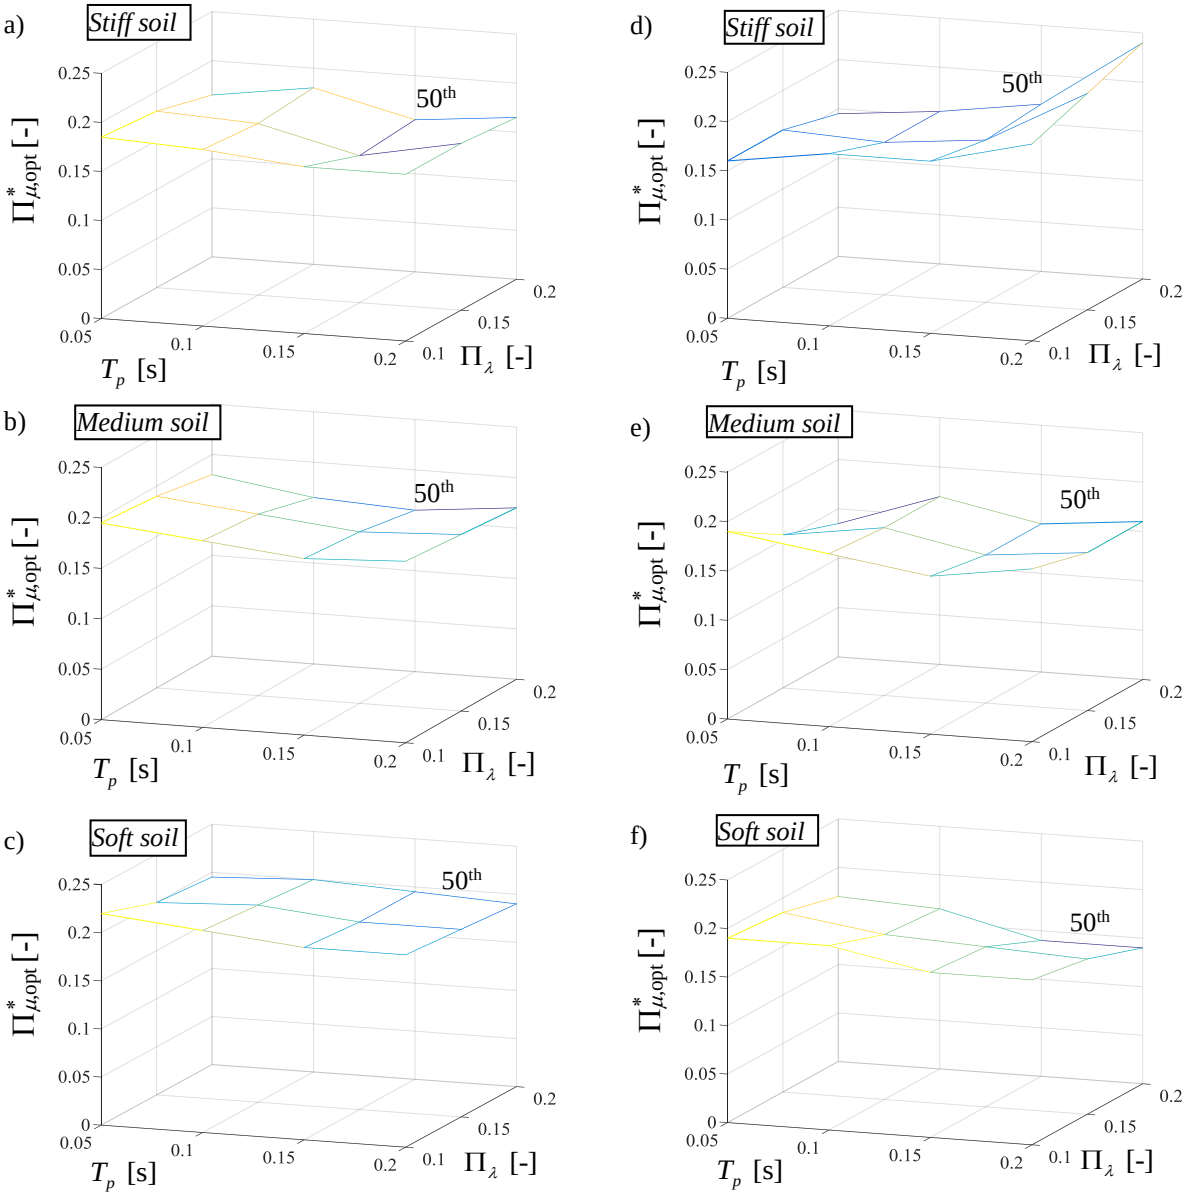

Figure 13: Optimal values of normalized friction that minimize the 50$^{\text{th}}$ percentile of the normalized pier displacements vs. Π_λ and T_p for each soil type and for T_d =2s (a,b,c) and T_d =4s (d,e,f).

According to [23], the optimal values of the (normalized) sliding friction coefficient slightly increase for decreasing T_d, especially for low T_p and for each soil condition. It is also observed that, for low T_d, $\Pi^*_{\mu,\text{opt}}$ generally decreases by increasing Π_λ and T_p. This trend is reversed with increasing of T_d and soil stiffness, when it is necessary to dissipate more energy, due to the resonance effects.

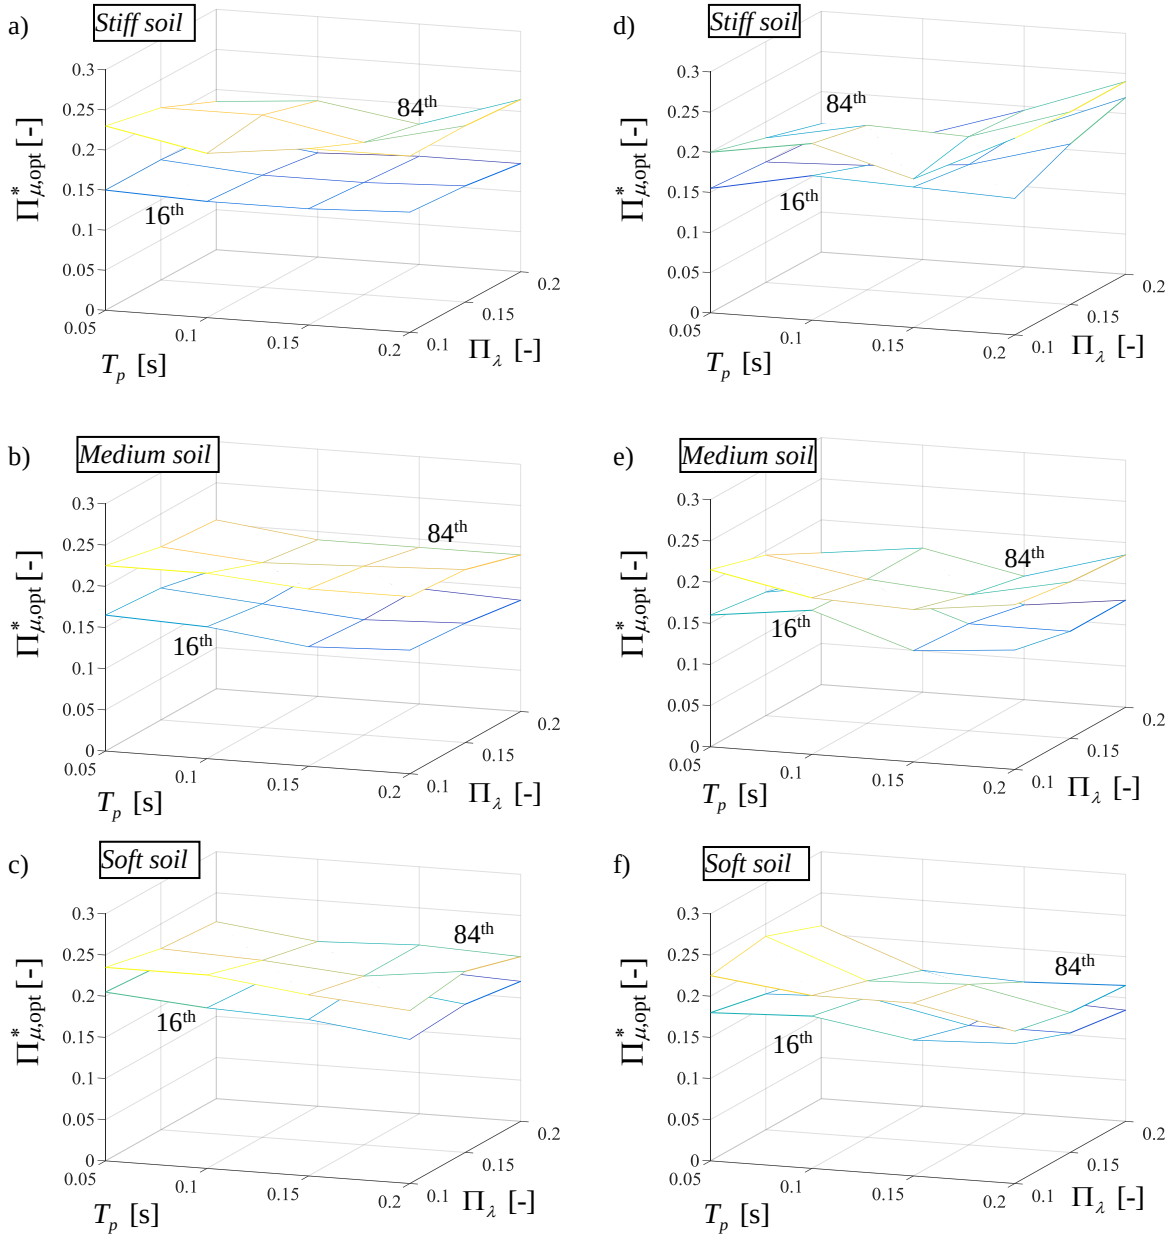

Figure 14: Optimal values of normalized friction that minimize the 84th and 16th percentiles of the normalized pier displacements vs. Π_λ and T_p for each soil type and for T_d =2s (a,b,c) and T_d =4s (d,e,f).

As previously discussed, it is also possible to observe that higher values of the optimum friction coefficient are required, especially for low isolated periods, for soft soil condition in order to reduce the bearing displacements and, consequently, the forces transmitted to the pier

as well as to increase the energy dissipation (equivalent damping). A reversal of this trend occurs for high values of both the isolation period and pier period, when it is necessary to dissipate more seismic energy input due to the resonance effect that affects the pier for stiff soil condition. In order to assure a high safety level, it might be of interest to define the values of $\Pi^*_{\mu,\text{opt}}$ that minimize others response percentiles [63]. Fig. 14 shows the optimal values of normalized friction that minimize the 84$^{\text{th}}$ and 16$^{\text{th}}$ percentiles of the normalized pier response for the different values of Π_λ, T_p, T_d = 2s (Fig. 14a,b,c), T_d = 4s (Fig. 14d,e,f) and for the three soil conditions. The trend is similar to the case of the 50$^{\text{th}}$ percentile. Regression expressions as statistics equations [82]-[87] to estimate the optimal friction coefficient may be found in [62].

6 CONCLUSIONS

This paper describes the seismic performance of elastic bridge pier equipped with friction pendulum system (FPS) bearings in order to define the optimal isolator friction properties as a function of the structural properties and of the soil characteristics in terms of frequency content, corresponding to stiff, medium and soft soils, respectively. Assuming an equivalent two-degree-of-freedom model, representative, respectively, of the dynamic behaviour of a single-column bent viaduct, describing a continuous and infinitely rigid deck with an elastic pier, and the velocity-dependent FPS isolator behaviour, a non-dimensionalization of the motion equations is herein proposed. For each soil type, the uncertainty in the seismic inputs is taken into account by means of a set of 100 artificial non-stationary stochastic records, obtained through the power spectral density method, with different frequency content. By means of the proposed non-dimensionalization, a wide parametric analysis is developed for several isolator and pier properties, and for different soil conditions, by monitoring the response parameters of interest.

With reference to the deck response, the geometric mean of the normalized deck displacement increases slightly for increasing isolation period because of period elongation and it decreases significantly as normalized friction increases while it is not heavily influenced by the mass ratio. The dispersion for high isolation period increases for increasing values of normalized friction. The mass ratio does not affect significantly the response dispersion, especially for high pier periods. There are resonance effects for soft soil condition and low normalized friction values, and for stiff soil condition and high normalized friction values, particularly, for higher values of the pier period.

With reference to the pier response, the geometric mean of the normalized displacement decreases for increasing values of isolation period and of mass ratio as well as for decreasing values of pier period, whereas it first decreases and then increases for increasing values of normalized friction. Thus, there exists an optimal value of normalized friction coefficient such that the pier displacement is minimized for each soil condition. This optimal value varies in the range between 0.1 and 0.3 depending on the system parameters and the soil type. The values of the dispersion are generally very low. The other system parameters have a reduced influence on the dispersion compared to the influence of the normalized friction. There are resonance effects for the stiff soil condition with increasing normalized friction values, particularly, for higher values of pier period and lower isolation period values.

Abstract

Large-scale seismic experimental facilities play a relevant role and provide essential contribution to the performance-based earthquake engineering. In such a context, recent advances in experimental data acquisition methodologies in large laboratories can open new perspective to the evaluation of structural performance of tested mockups under seismic load. In particular, the application of 3D motion capture systems to shaking table testing provides a unique tool for recording relative displacements of a large number of measurement points. The analysis of 3D relative displacements during dynamic tests allows to evaluate the structure deformations and to monitor the cracks formation and evolution, which can lead to the formulation of damage indices. Also, the failure mechanism could be easily visualized and analyzed by monitoring the cumulative relative displacements between markers. In addition, in-plane and out-of-plane deformations of walls could be monitored during each seismic test, providing accurate information on the torsional and bending effects. A case study is presented about a full-scale model of a masonry cross vault of the mosque of Dey, Algiers, tested at the ENEA Casaccia shaking table. The cross vault was subjected to a seismic sequence based on the 21-May-2003 earthquake recorded at Keddara station. The results obtained through the processing of the data from 67 markers located on the vault showed the potentialities of the methodology.

Keywords: Damage Detection, Shaking Table Tests, 3D Motion Capture, Deformations, Crack, Masonry Structures.

1 INTRODUCTION

In the general context of performance-based earthquake engineering (PBEE), as developed by the Pacific Earthquake Engineering Research [1], several steps are considered in order to achieve the complete methodology. One of these steps is the damage analysis, in which a damage measure (DM) representing a damage state of a structural or non-structural element is associated with one or more engineering demand parameters (EDPs). As a final step, the loss analysis of constructions that have undergone a seismic event, enables to estimate repair costs, repair duration (downtime), and human losses. For the damage assessment of structures through numerical analyses (e.g. FEM etc.) many parameters and indices have been developed and validated by correlation with damage observed on-the-field, e.g. by comparison with the damage grades, as defined by reference guidelines and regulations, such as the European Macroseismic Scale EMS-98 [2], widely adopted by national standards, such as the Italian regulation [3].

Even if numerical methods are nowadays consolidated and widely used for structural and damage analyses, the study of damage occurrence/evolution and seismic performance of structures must be considered a more general objective that still needs laboratory experimentation and data collection. In this direction, the damage assessment in full-scale shaking table tests through non-destructive tests (NDTs) and measurements of the dynamic behavior of tested mock-ups have a remarkable importance [4].

The present paper focuses on pointing out a methodology for the construction of a simplified damage index based on the application of 3D motion capture systems to shaking table testing. This kind of measurement systems represent a unique tool for recording relative displacements of a large number of measurement points through simple markers located on the tested mock-up [5]. Analyzing the 3D relative displacements between markers during dynamic tests, the deformations and the cracks can be detected and measured, opening to the possibility of formulating damage indices from experimental seismic experiments.

The methodology is illustrated and applied to a case study representative of a typical full-scale historic masonry mock-up of a cross vault of the mosque of Dey, Algiers. The 67 markers located on the vault mock-up were processed and damage indices computed, showing the potentialities of the methodology.

2 DAMAGE INDICES

A variety of damage indices (DIs) can be built on the base of different kinds of properties (structural or dynamic) and at different scale (local or global), as described in the literature [6]. Also fatigue effects may be taken into account, defining cumulative indices [7]. In general, damage indices are typically normalized on a scale of 0 to 1, where zero represents the undamaged state and unity represents the final collapse state of the structure. Most of such indices have been built and consolidated through extensive theoretical and experimental studies on reinforced concrete buildings, which are very common construction typology in many parts of the world. On the other hand, reinforced concrete structures are designed with somewhat simple schemes and have a more homogeneous and controllable behavior in comparison to historic masonry constructions. Moreover, they commonly present large cracking damage before the most common hysteretic one. Thus, the definition of proper and effective DIs for historic masonry structures is a very complex topic [8].

Damage indices can be used to describe the condition of a structure after an earthquake by relating its values with the level of damage states. To this purpose, correlations between DIs and Macroseismic Scale EMS-98 grades have been proposed. The one illustrated in Table 1 developed for reinforced concrete buildings in Croatia [9] is one of the most recent examples.

DI value	Description of structural damage	Damage grade (EMS-98)
$0 < DI \leqslant 0.3$	Insignificant	1°
$0.3 < DI \leqslant 0.5$	Moderate	2°
$0.5 < DI \leqslant 0.8$	Severe	3°
$0.8 < DI \leqslant 1.0$	Heavy	4°
$DI > 1.0$	Collapse	5°

Table 1: Correlation between DI values and EMS-98 damage grades [9].

Specific approaches for historic masonry buildings, such as ancient churches, have been developed by [10], in which the role of damage and collapse mechanisms, as well as the characteristics of the different macroelements, are taken into account. The following subsections will focus on the most used DIs to assess the overall damage degree of a structure subjected to shaking table tests.

2.1 Damage indices based on deformations and energy

Many indices were developed since the years 1980s by a variety of authors as deformation-based indices starting from simply attempting to extend the ductility concept to repeated loading [7]. Other authors focused on the energy absorption during hysteretic loops as a measure of damage [7]. In fact, more complete models were developed as combined indices of both concepts. This is the case of one of the most widely used damage index that was proposed in 1984 by [11] as a linear combination of the maximum displacement and the dissipated energy. It can be formulated as follows:

$$I_D = \frac{d_m}{d_u} + \beta_e \frac{\int \mathrm{d}E}{F_y d_u} \tag{1}$$

where d_u is the ultimate displacement at monotonic loading, d_m is the maximum displacement corresponding to the point of maximum capacity, β_e is the parameter representing the cyclic loading, dE is the incremental dissipated hysteretic energy and F_y is the longitudinal reinforcement yielding force. On the one hand, the simplicity and the calibration of the above model through a large amount of experimental observations of damage make I_D a very consolidated index. On the other hand, a major problem is the determination of d_u and, especially, of β_e. In particular, empirical studies and related regression equations in the literature yielded quite small values of β_e, so that the energy term provides a limited contribution, often negligible with respect to the deformation term [7].

The above indices are usually calculated for each structural macroelement or floor in multistory buildings (local indices), then a weighted average value is computed to estimate the global damage. Weighting systems are often based on subjective assessments and criteria, e.g. through considerations on the different collapse mechanisms and the relevance of heavy localized damage. The contribution of local energy absorption to the overall damage state as a more objective criteria for weights determination was also proposed by several authors [7].

2.2 Global damage indices based on stiffness reduction

Damage indices based on the dynamic properties of a building are widely accepted as the main indicators of the global state of health of the overall structure [12]. They are usually built as a function of the modal parameters of the structure. In particular, they calculate the change in the fundamental frequency (or frequency shift), on the basis of the consolidated observation that damage processes induce a measureable decrease of the system's stiffness. A common formulation of this type is the following:

$$DI_f = 1 - \frac{f_d^2}{f_0^2} \tag{2}$$

where f_0 is the initial fundamental frequency of the undamaged structure and f_d is the fundamental frequency of the damaged structure. Several methods of modal analysis, such as the Experimental Modal Analysis (EMA) based on the computation of the Frequency Response Function (FRF), or other modal identification methods [13], can be used to estimate the modal frequencies of the studied structure.

2.3 Construction of a global damage index based on markers displacements

A global damage index based on the 3D displacements of markers recorded by a motion capture system [14] during shaking table tests is explored in the following. In fact, the energy absorption in shaking table tests is of difficult assessment. However, its contribution is generally limited, if not negligible, in comparison to the plastic deformation term. Therefore, it is here explored the possibility of providing rough indication through a simplified index based uniquely on measured displacements. A general model for the index was assumed as:

$$DI_m = f(\Sigma\Delta\delta, a, b) \tag{3}$$

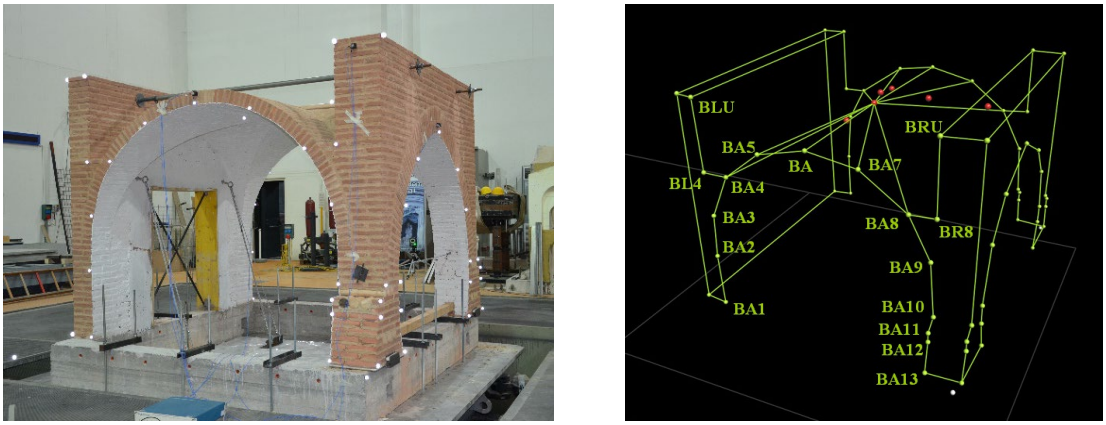
where f is a function of the cumulative residual relative displacements $\Sigma\Delta\delta$ between markers at the end of each seismic test, as an estimate of accumulated plastic deformations, while a and b are empirical coefficients to be determined through correlation with experimental results of a consolidated global damage index. In the following, the DI_f described in the previous subsection will be taken as reference index for such correlation. The function f can be determined *a priori* or it can be chosen among several functions by best correlation criteria. In the following, the application of the method is illustrate with a case study. Obviously, the larger amount of experimental cases are used for statistical correlation, the more representative and consolidated is to be considered the constructed index.

3 CASE STUDY

3.1 Shaking table tests

As a case study, the shaking table tests executed on a mock-up representing one of the 10 cross vaults of the Mosque of Dey were considered. The tested cross vault is shown in Figure 1(a). It is one brick layer in thickness and its dimensions are 350 x 360 cm^2 square plan, with a total height of 565 cm. More structural details on the Mosque of Dey can be found in [15-16]. The structural properties and characteristics of the tested mock-up are described in detailed in [17]. The mock-up was initially tested with two steel longitudinal bars linking transversal walls, functioning as tie-rods. Successively, the two ties were removed to verify the specimen resistance up to collapse.

The historic Algerian masonry reproduced for the vault is a poor masonry made up of baked clay bricks of size 3.5 x 12 x 25 cm^3 with weak 2.5-cm-thick joints.



(a) (b)

Figure 1: Tested specimen with markers in white (a) and 3D markers reconstruction (b).

Characterization tests on seven mortar samples extracted from buildings of the Citadel of Algiers, dating back to the same period of construction of the mosque, indicated that clay, finely bricks, gravel, sand, lime, and pozzolana in varying proportions are the main components. The bricks were assembled according to ancient master builders' technique, similar to local historical cross vaults. Figure 1 shows the positions of the 67 retro-reflecting markers tracked by a 3D motion capture system based on a constellation of high-frequency and high-resolution cameras located around the shaking table [18]. In Figure 1(a) the markers appear white, as they reflect the photo camera flash light. The 3D reconstruction of markers positions is achieved through geometrical triangulation algorithms by the acquisition software and mock-up wireframe is displayed by connecting markers, as illustrated in Figure 1(b). The system overall accuracy is in the order of 0.01-0.1 mm in terms of RMS error of markers position [19]. Markers motion data were acquired at 200 Hz of sampling frequency.

Seismic sequence on shaking table was based on the NS component of the ground motion recorded at Keddara station during the 21-May-2003 earthquake occurred in the province of Boumerdes and the eastern part of Algiers with 6.8 Magnitude [20]. The seismic signal was normalized to the site of the Citadel of Algiers according to the uniform hazard response spectrum (UHRS) method and was applied in the direction transversal to the tie-rods. The seismic sequence started with a test at 0.05 g of nominal peak ground acceleration (PGA). Succeeding tests were performed increasing the PGA of 0.05 g at each step. Also low-intensity white-noise tests were performed for the dynamic identification of the mock-up.

4 RESULTS

In Table 2 the results obtained with the different regression models utilized for the construction of the damage index DI_m are shown.

DI_m model	Regression eq.	R^2
$a \log(\Sigma\Delta\delta) + b$	$0.17 \log x + 0.78$	0.942
$a(\Sigma\Delta\delta) + b$	$0.58 x + 0.26$	0.908
$a(\Sigma\Delta\delta)^b$	$0.78 x^{0.159}$	0.832
$a e^{b(\Sigma\Delta\delta)}$	$0.25 e^{1.29 x}$	0.754

Table 2: Different models utilized for construction of damage index DI_m and corresponding correlation coefficients R^2 with stiffness damage index DI_f.

After regression analysis with the stiffness damage index DI_f as defined in eq. 2, as a reference damage estimator, the correlation coefficients R^2 was considered to assess the effectiveness of each proposed model. The best results were found with the logarithmic model, which showed very high correlation (R^2 of 0.942) with DI_f. It must be noted that all regression models gave quite good correlations (R^2 higher than 0.75), even if the contribution of energy absorption was neglected. On the other hand, most of the experimental points in Figure 2 are concentrated at low levels of damage (DI < 0.3). Consequently, the found regression equation is not be considered highly representative of all possible damage states of the structure. In fact, the mock-up suddenly collapsed with little warning, hardly visible to the naked eye, at test with 0.25 g of PGA, corresponding to 0.318 g of peak table acceleration (PTA), showing a quite fragile behavior. However, the methodology seemed effective to catch the behavior of the tested structure and easily applicable to further experiments to increase the model representativeness for different collapse mechanism and structural typologies.

In Figure 3 the in-plane relative displacements between top and bottom of the façade before and during collapse at test at 0.25 g of PGA are shown. Final collapse was activated at time equal to about 10 s of the time history with the catastrophic out-of-plane overturning of the façade and the consequent development of a four-hinge mechanism of the vault.

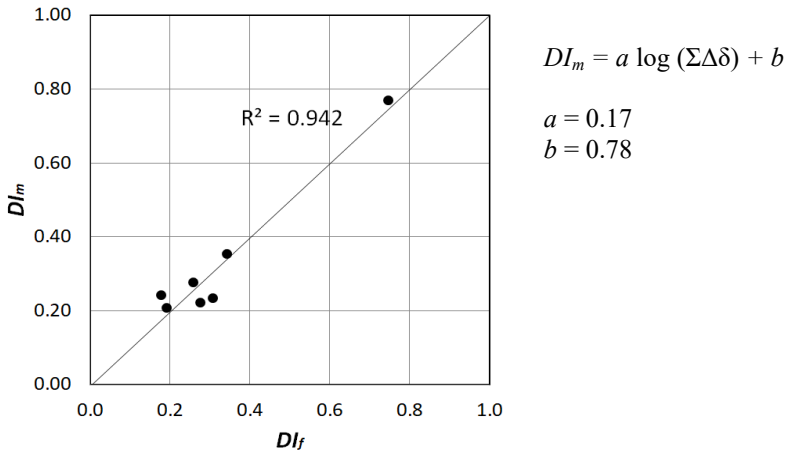


Figure 2: Best empirical correlation between DI_f (formulated according to eq. 2) and DI_m.

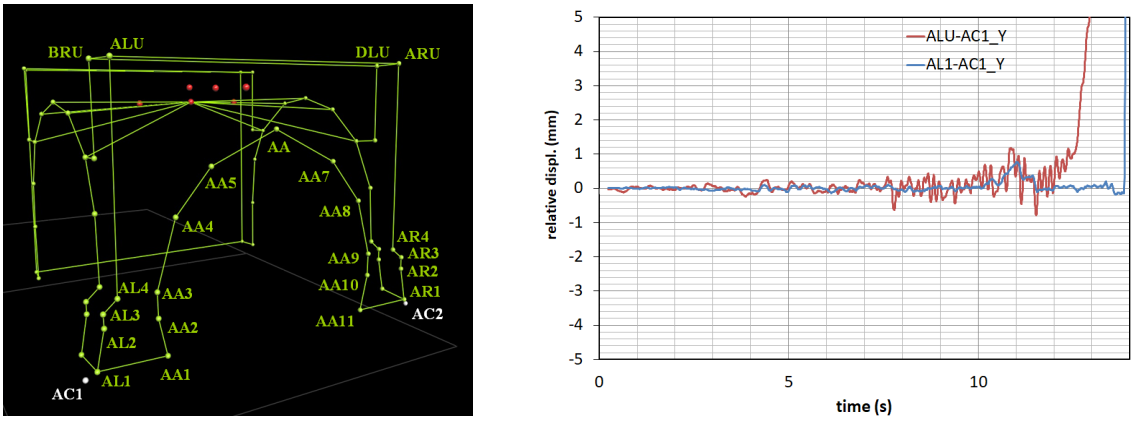

(a) (b)

Figure 4: Markers of mock-up façade (a). In-plane relative displacements between top (ALU) and bottom (AC1) of the façade left corner during seismic test at 0.25 g of PGA.

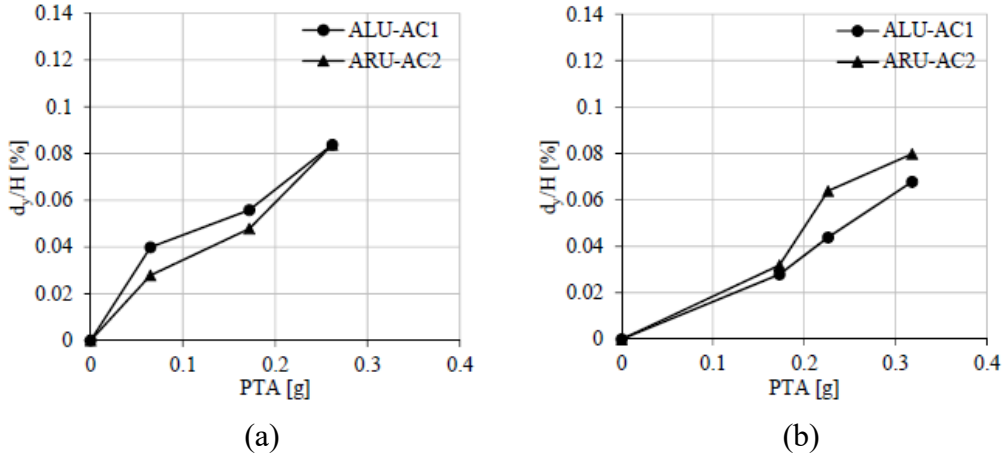

Figure 4: Comparison of in-plane shear deformation (d_y/H) between left (ALU-AC1) and right (ACU-AC2) corners of the façade during seismic sequence with ties (a) and without ties (b).

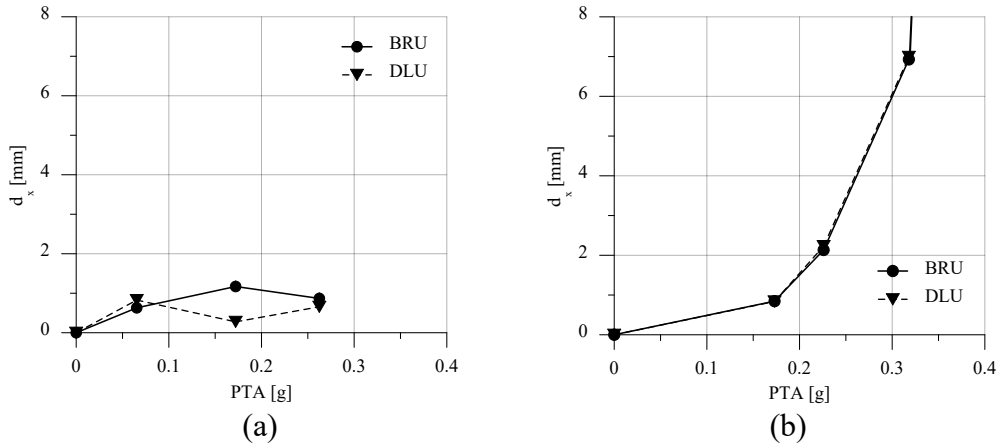

Figure 5: Maximum displacements d_x in direction of tie-rods achieved by the markers on top of mock-up façade on the left and right corners (BRU and DLU respectively) with ties (a) and without ties (b).

Through the monitoring of the markers motion, it was possible to detect even the initial deformations that occurred at the first steps of the seismic sequence, as depicted in the graphs of Figure 4 and 5. In particular, in Figure 4, the torsional effects are evidenced by the comparison between the behavior of the left and the right corners on the façade. While out-of-plane displacements on top of the left and right corners of the mock-up façade are compared in Figure 5.

5 CONCLUSIONS

A methodology was explored for the detection of damage occurrence and its evolution in historic masonry mock-ups tested on shaking table. In particular, the construction of a simplified damage index based on the displacements measured through a 3D motion capture systems to be utilized in shaking table testing was proposed. The attempt is to take advantage of the potentiality of such measurement systems to track the displacements of a large number of markers that can be easily and cheaply located on the tested mock-ups. The displacement-based index was determined among a series of regression models through the best-correlation criterion with a consolidated global damage index, based on the change in modal frequencies.

The application to the case study showed the potentialities of the methodology. The best regression model showed very high correlation. In fact, even the other models gave quite

good correlations (R^2 higher than 0.75), despite the contribution of energy absorption was neglected. It must be also noted that further experiments are needed to consolidate the model, as the case study provided results concentrated at low levels of damage (DI < 0.3), making the found regression equation not highly representative of all possible damage states. This because the studied masonry mock-up collapsed with quite fragile behavior, rapidly passing from low-damage to final failure.

Moreover, comparing the displacements of different markers in the same direction, in-plane and out-of-plane deformations of walls were monitored to assess the torsional and bending effects. This allowed to follow the evolution of the failure mechanism, which provided valuable information to assess the dynamic behavior of the structure.

Abstract

In recent years, the need of retrofit interventions on existing buildings is increasing, also due to the high economic losses recorded after the recent seismic events. The intervention techniques based on stiffening and energy dissipation are one of the most widespread among the several available. Despite the great diffusion of this kind of interventions, there are still no clear and shared rules about design principles and, above all, about the performance objectives to be followed within the design. In particular, there is a lack of design approaches based on optimization of intervention costs and cost-benefit assessment. This paper concerns the optimal design of dissipative braces for seismic retrofitting of existing reinforced concrete buildings in the context of a multi performance design problem. Topological and dimensional optimization of the braces is achieved by minimizing the real intervention cost through an innovative formulation of the objective function. The procedure is based on elastic linear analyses, keeping in count the inelastic behavior of dissipative devices and concrete frame through linear equivalent schemes. The reliability of such linearized schemes is discussed by a comparison with structural response obtained with Non-Linear dynamic analyses on a case study structure. Further, it will be shown how the procedure allows, besides the design of the braces characteristics, a critical assessment and choice of the performance levels in order to optimize the cost benefit ratio of the intervention, thus showing its effectiveness as decision-making tool for seismic risk mitigation.

Keywords: Bracing; Energy Dissipation; Optimization; Retrofit; Multiperformance.

1 INTRODUCTION

Nowadays, the seismic protection of existing buildings is one of the most relevant topics in earthquake engineering. The recent seismic events that hit many countries all over the world (Umbria-Marche 1997, Italy; L'Aquila 2009, Italy; Christchurch 2011, New Zealand; Tohoku 2011, Japan; Emilia 2012, Italy; Centro Italia 2016, Italy) have highlighted the weaknesses of existing building heritage, causing many casualties and very high economic losses [1]–[3]. For many years politics, economists and the whole scientific community have not appropriately considered the problem of the enormous costs of reconstruction due to seismic events that have been very high [4] [5]. In the recent years, the need of a seismic risk mitigation strategy has emerged. In order to gain this goal, decision making tools are needed to obtain adequate seismic protection with the least financial investments possible.
To this aim, the existing design methodologies are often inappropriate because don't keep in count the financial aspects of a retrofit interventions [6]. Therefore, new methodologies based on seismic risk assessments are substituting traditional performance based approaches [7]–[10].
The risk-based methodologies allow to evaluate the economic losses of an asset throughout its nominal life by correlating seismic hazard, structural response and damages. The aim of retrofit interventions is to mitigate the damages and consequent economic losses by modifying the structural response. The intervention will be profitable if its cost is commensurate with the gain obtained in terms of damage reduction, in other words in the presence of an advantageous cost-benefit ratio. In this moment, there is a lack of methodologies capable of performing a cost-benefit assessment for retrofit interventions.
Among the several intervention techniques available, the most interesting in order to find an optimal cost/benefit ratio are the ones based on stiffening and energy dissipation [11]–[15]. The main advantage of this techniques is their potential low invasiveness and their broad adaptability to different performance requests.
Many design process and methodologies are available in the international literature for dissipative bracing design, some of them pursue an optimality criterion (e.g. minimum interstory drift, minimum base shear, maximum energy dissipation) [16]–[23], while others allow to find the brace characteristic and disposition just by guaranteeing some performance requirements through simplified procedures [24]–[28]. The design procedures based on an optimality criterion are commonly based on complex models that explicitly keep in count the nonlinear effects, while the simplified procedures are commonly based on the use of single degree of freedom (SDOF) equivalent models. Among the procedure previously cited, only few of them foreseen a multiperformance approach and, moreover, none of them foresee a risk-based design for retrofit intervention, even in the case the cost intervention is explicitly kept in count [20]–[22].
In this paper is adopted the optimization procedure proposed in [29], that allow a multiperformance design of braces by minimizing the intervention cost and by constraining the interstory drift ratio (IDR). The structural performance is assessed through linear analyses by adopting a model with a linearized behaviour of both existing frame and dissipative elastoplastic device. On the case study presented herein, will be shown how this procedure allows a dimensional and topological optimization of the braces by minimizing the intervention costs. Furthermore, a comparison between the intervention costs obtained for several performance requests is shown, in order to evidence the effectiveness of this procedure as a decision-making tool.

2 STRUCTURAL BEHAVIOUR AND MODELLING

The optimization procedure adopted herein is based on elastic linear analyses. The structural model keeps in count the non-linear behaviour of existing frame and dissipative braces through properly developed linearization schemes. The linearized secant stiffness of the frame is calculated on the basis of the maximum ductility demand expected on structural elements, while the braces behaviour is linearized within the procedure on the base of calculated local displacement demands. The global stiffness matrix is then assembled by adding to the un-braced frame stiffness matrix, the contribution of each brace assessed within the procedure. Similarly, the energy dissipated by each brace is assessed within the procedure and added to the energy dissipated by the frame in order to compute a global equivalent damping ratio for the braced building and reduce the seismic forces.

2.1 Existing frame

The existing frame behaviour is assumed as bilinear, as it is shown in Figure 1. The secant stiffness K_0 is calculated in correspondence of the final desired displacement of the braced structure, u_d, which can be determined on the base of the drift profile used as a constraint in the optimization procedure. Once known such final displacement, a reasonable estimate of the secant linear stiffness of each structural element can be determined on the base of expected global ductility demand through the following expressions [30]:

$$I_{ieq} = \frac{I_i}{\mu} \tag{1}$$

$$\mu = \frac{u_d}{u_y} \tag{2}$$

where: I_{ieq} is the equivalent inertia of the i-th section, I_i is the inertia of the i-th section, μ is the global ductility demand, u_d is the final displacement and u_y is the yielding displacement of the frame.

In correspondence of the final desired displacement, u_d, the energy dissipated by the frame is assessed through the following expression:

$$E_0 = 0.33 \times 4 \times \left(F_y u_d - F_y u_y \right) \tag{3}$$

where: F_y and u_y are the yielding force and the yielding displacement of the existing frame, respectively.

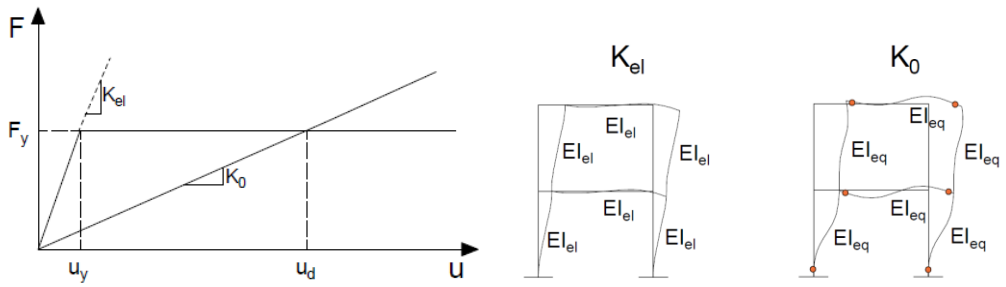

Figure 1: Existing frame behaviour, elastic stiffness K_{el} and equivalent secant stiffness K_0.

2.2 Dissipative brace

The dissipative brace is composed by a series disposition of an elastic steel truss and an elastoplastic dissipative device. The global bilinear behaviour of the brace is linearized in correspondence of its maximum displacement, u_u. Differently than for the existing frame, the linearization process of the brace is performed within the optimization procedure on the base of calculated local displacement of each brace. Given the force-displacement relationship of Figure 2, the linear secant stiffness of each brace and the associated dissipated energy can be calculated as follows:

$$K_i^B = F_{ui}^B / u_{ui}^B \tag{4}$$

$$E_i^B = 4 \times \left(F_{yi}^B u_{ui}^B - F_{ui}^B u_{yi}^B \right) \tag{5}$$

where: K_i^B, E_i^B F_{yi}^B, u_{yi}^B, F_{ui}^B, u_{yi}^B are the equivalent stiffness, the energy dissipated, the yielding force, the yielding displacement, the ultimate force and the ultimate displacement of the i-th brace, respectively.

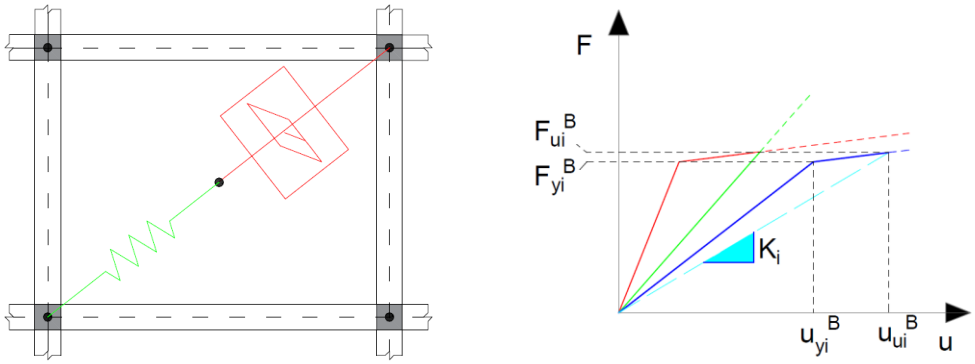

Figure 2: Brace assemblage and force-displacement relationship adopted for the brace (blue line), the steel truss (green line) and the dissipative device (red line).

2.3 Braced structure

In Figure 3 it is shown the sketch of the assembling procedure of stiffness and dissipated energies within the procedure. The global stiffness matrix of the braced structure is assembled by simply adding the contribution of the existing frame, K_0, and the contributions of each brace, represented through an influence matrix ΔK_i, using the following expression:

$$\mathbf{K} = \mathbf{K}_0 + \sum_i \Delta \mathbf{K}_i \tag{6}$$

Similarly, the total energy dissipated by the braced structure, E, is assembled as follows:

$$E_D = E_0 + \sum_i E_i^B \tag{7}$$

By using the total energy dissipated obtained through Eq.7, the equivalent damping ratio of the system can be assessed as follows:

$$\zeta_{eq} = \frac{1}{4\pi} \frac{E_D}{E_p} + \zeta_v \tag{8}$$

where E_p is the elastic energy of the braced structure and ζ_v is the added viscous damping.

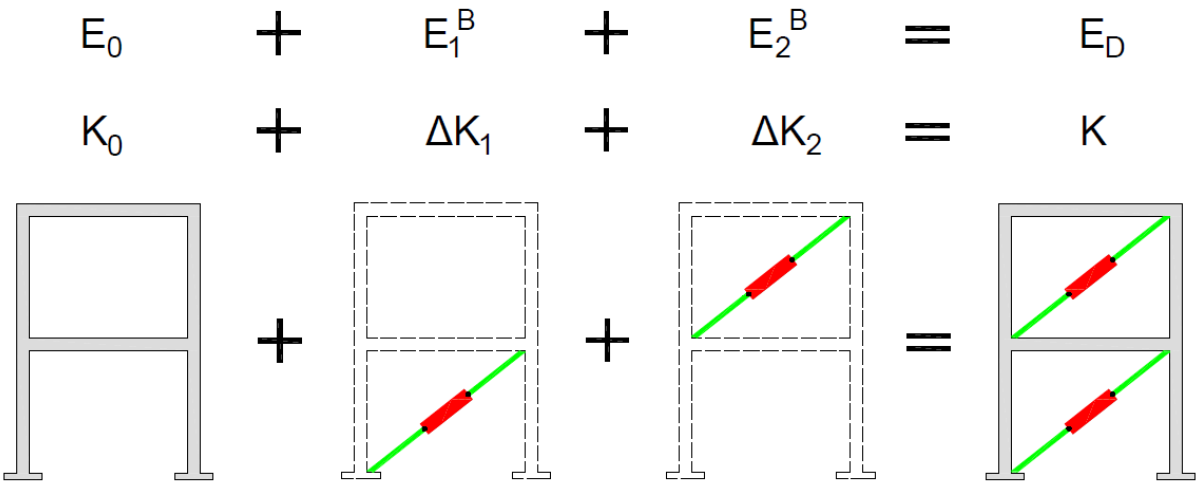

Figure 3: Assembling of stiffness and dissipated energies within the procedure.

3 OPTIMIZATION PROCEDURE

The optimization procedure is asked to provide the dimensional and topological characteristics of the dissipative braces. With this aim and given the brace characteristics exposed in section §2.2, the unknowns of the optimization problem, namely the independent variables, are defined as follows:

$$\mathbf{x} = \left[\mathbf{A^A} \quad \mathbf{F_y^D} \quad \mathbf{u_y^D} \right] \tag{9}$$

where: $\mathbf{A^A}$ is a vector whose generic component A_i^A is the area of the i-th steel truss, $\mathbf{F_y^D}$ is a vector whose generic component F_{yi}^D is the yielding force of the i-th dissipative device and $\mathbf{u_y^D}$ is a vector whose generic component u_{yi}^D is the yielding displacement of the i-th dissipative device.

The objective function of the optimization procedure can be defined, as follows:

$$O.F.(\mathbf{x}) = \sum_{i=1}^{n} (C_i^S(A_i^A) + C_i^D\left(F_{yi}^D\right) + C_i^M(A_i^A) + \sum_{r=1}^{n_p} C_r^F(\mathbf{x}) \tag{10}$$

where: C_i^S is the cost function of the steel elements, C_i^D is the cost function for the dissipative devices, C_i^M is the cost function for the masonry works, C_i^F is the cost function for the foundation system interventions.

A detailed description of Eq. 10 may be found in [29]. The constraints of the procedure are expressed in terms of interstory drift ratio and can be formalized as follows:

$$\mathbf{h_u}(\mathbf{x}) = \mathbf{IDR}(\mathbf{x}) - \mathbf{IDR}^{Lim} \tag{11}$$

where: $\mathbf{h_u}$ is the vector of constraints, **IDR** is the vector containing the interstory drift ratio obtained from structural response and $\mathbf{IDR}^{Lim}$ is the vector of maximum interstory drift ratio desired.

The optimization procedure can consequently be defined as follows:

$$\begin{aligned} &\min \quad O.F.(\mathbf{x}) \\ &\begin{cases} \mathbf{h_u}(\mathbf{x}) = \mathbf{IDR}(\mathbf{x}) - \mathbf{IDR}^{Lim} \le 0 \end{cases} \end{aligned} \tag{12}$$

4 NUMERICAL EXAMPLE

The procedure has been applied to a case study which represent the typical Italian reinforced concrete building realized in the absence of seismic provisions. It has six floors with a height of 3m, three spans with a length of 5m. The considered floor mass is 112.5kNs^2/m. The beams have a 30x50cm section, external columns have a 30x30cm section and central columns are tapered along the building height: a 30x60cm has been considered for the first three floors while a 30x30cm section has been considered for the other three floors. Braces are located in the central span of the building with a diagonal disposition, as shown in Figure 4.

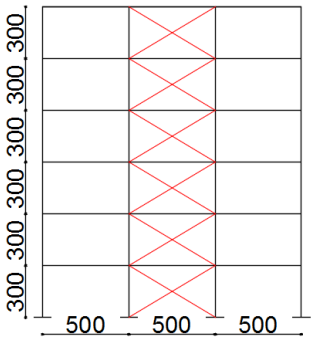

Figure 4: Case study structure and brace initial arrangement.

The optimization problem aims to find the optimal size and disposition of braces in order to obtain the desired interstory drift ratio for different action levels. The considered action levels are related to the Italian site of Reggio Calabria (LAT 38.11, LON 15.66) for the return periods (T_r) of 30, 101, 475 and 975 years, soil C and T1 site conditions as defined in the italian seismic code [31]. For each of these action levels the acceptance criteria for interstory drift ratio are defined as 0.1%, 0.4%, 0.7% and 1%, respectively. By considering these action levels and acceptance criteria, the optimization problem of Eq. (12) is extended to a multi-performance problem that can be posed as follows:

$$\begin{aligned} &\min \quad O.F.(\mathbf{x}) \\ &\begin{cases} \mathbf{h}_{u-30}(\mathbf{x}) = \mathbf{IDR}_{30}(\mathbf{x}) - \mathbf{IDR}_{30}^{Lim} \le 0 \\ \mathbf{h}_{u-101}(\mathbf{x}) = \mathbf{IDR}_{101}(\mathbf{x}) - \mathbf{IDR}_{101}^{Lim} \le 0 \\ \mathbf{h}_{u-475}(\mathbf{x}) = \mathbf{IDR}_{475}(\mathbf{x}) - \mathbf{IDR}_{475}^{Lim} \le 0 \\ \mathbf{h}_{u-975}(\mathbf{x}) = \mathbf{IDR}_{975}(\mathbf{x}) - \mathbf{IDR}_{975}^{Lim} \le 0 \end{cases} \end{aligned} \tag{13}$$

Where $\mathbf{h}_{u\text{-}j}$ is the vector of constraints for the j-th hazard level, $\mathbf{IDR}_j$ is the vector of IDR obtained for the j-th hazard level and $\mathbf{IDR}_j^{Lim}$ is the vector of acceptance criteria adopted for the j-th hazard level.

The results of the optimization problem are shown in Figure 5. Brace stiffness and strength reduces along the height with the exception of the fourth floor where the braces are sensibly stiffer than the floor below in order to balance the stiffness reduction due to the column tapering. In Figure 6a are shown the interstory drift ratio obtained with the elastic linear analyses performed within procedure, as it can be seen the drift are very regular along the height, with the exception of the last floor for events with low rate of occurrence. Furthermore, it should

be observed that the IDR for T_r=101yrs are quite lower than the maximum drift allowed (i.e. IDR_{101}^{Lim}=0.4%). In order to verify the reliability of the linearization procedure, several Non-linear-dynamic analyses are performed in the software Opensees [32] by considering the ductile flexural behaviour and by using the set of natural ground motions described in [33]. Despite of several modeling possibilities of fragile and degradation phenomena [34]–[38], it has been chosen to perform analyses with a model coherent with the one adopted within the procedure that does not take into account such phenomena, further information about modeling assumptions may be found in [29] and [39]. The average interstory drift ratio obtained through NL time history analyses are in good agreement with the one obtained through the procedure, proving the reliability of linearization schemes adopted. Furthermore, a parametric study has been performed solving several single-performance problems accepted through the optimization problem herein proposed by adopting different maximum IDR. In Figure 7 is shown the variation of the intervention cost with the maximum IDR accepted. It can be noticed that maintaining the structure in the elastic field (i.e. IDR <0.4%) considerably increases the costs of intervention, while admitting slight plasticization (i.e. IDR> 0.7%) allows to contain costs considerably, as well as using a multi-performance approach analogous to the one described above (i.e. MP in Figure 7). The intervention cost thus evaluated, if compared with the expected annual losses due to the achievement of the requested performances, can therefore be used to evaluate which performance configuration guarantees the optimal cost-benefit ratio.

5 CONCLUSIONS

In this paper is presented an optimization procedure which allows the design of bracing systems by minimizing the intervention costs through a multi-performance approach. In order to keep in count the nonlinear behaviour of frame and braces, equivalent linearization schemes are adopted. The analyses on the case study have shown how the braces designed through this procedure allow a regularization of the building behaviour along the height and the achievement of the desired performance requirements for all the considered action levels. The results obtained with NL analyses are in good agreement with the one obtained with linear analyses performed within the procedure, showing how the linearization schemes are reliable in order to describe the structural behaviour even when marked non-linear behaviour is expected. This procedure is therefore able to solve a complex multi-performance problem by linear analysis, with the great advantage of limiting the computational times and without the need to adopt complex structural models with explicit modeling of nonlinearities, thus showing itself as a

useful design tool. Furthermore, the comparison of results in terms of intervention costs, once given several performance requirements, show the effectiveness of the procedure as a fast and reliable tool to estimate the intervention cost and choice the performance requirements to optimize cost-benefit ratio too.

Abstract

The main objective of this paper is to assess the effect of different modelling approaches of brace-to-frame gusset plate connections for seismic performance assessment of steel concentrically-braced frames (CBFs). Two scenarios are considered, namely: i) simplified simulation of braces through a centreline-to-centreline pinned-ended idealization; ii) explicit simulation of brace-to-frame gusset connections. A suite of building archetypes, with different bracing configurations and building heights, are used to show the effect of the aforementioned modelling variants on different metrics of seismic performance (e.g. lateral deformations, collapse risk, economic losses). Across the group of metrics considered, it is shown that the non-consideration of brace-to-frame connections may entail biased characterizations of seismic performance.

Keywords: concentrically-braced steel frames, brace gusset connections, OpenSees, seismic performance.

1 INTRODUCTION

Seismic performance assessment of buildings may be conducted through simplified numerical models based on several modelling assumptions. Such assumptions, however, may or not entail less accurate estimates of seismic performance. In the context of steel concentrically-braced frames (CBFs), more simplified strategies, in which diagonals are simulated using their centreline-to-centreline length coupled with fully-pinned boundary conditions, have been adopted in the literature [2]. On the other hand, more refined numerical models may be associated with explicit simulation of the brace-to-frame gusset plate connections [1], in which the gusset geometry plays a primordial role on the rigidification of portions of the beams and columns intersected by the gusset plate connection, as well as the physical length and boundary conditions of the bracing diagonals. As one may infer, this modelling approach requires the complete definition of the plate characteristics through a seismic design process, which may not be easily achievable for large building populations. Furthermore, it is unclear in the literature whether or not the two modelling approaches entail relevant differences in seismic performance characterizations across different bracing configurations and metrics of seismic performance (e.g. collapse risk, earthquake-induced economic losses). Based on the aforementioned aspects, this research study evaluates the implications of non-explicit simulation of brace-to-frame connections across different metrics of performance. This is achieved by resorting to a suite of archetype buildings seismically designed to Part 1 of Eurocode 8 (EC8-1) [3], using different bracing configurations and building heights.

2 ARCHETYPE BUILDING POPULATION

In order to assess the implications of numerical modelling refinement of brace-to-frame gusset connections, a comprehensive group of CBF archetypes was defined and seismically designed to EC8-1. According to EC8-1, several bracing configurations can be adopted for steel CBF buildings (see Figure 1). Depending on the bracing type, different design approaches are prescribed by the code. The code also differentiates the upper-bound reference value of the behaviour factor, q, which, for the medium ductility class (DCM), is set equal to 4 and 2 for non-chevron and chevron CBFs, respectively.

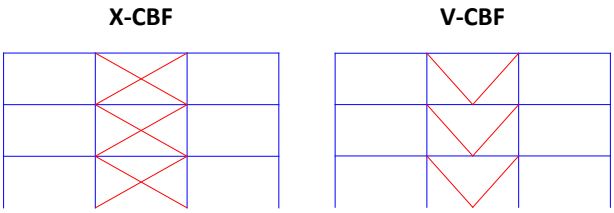

Figure 1: Considered concentric bracing configurations.

For this research study, the CBF typologies shown in Figure 1 were considered and Lagos, a moderate-seismicity location in Portugal was adopted to design a set of archetype buildings to EC8-1. The elastic response spectrum specified by the code for this location is shown in Figure 3. A single plan layout was adopted (see Figure 2), with a regular grid of 6m spans across both the longitudinal and transversal directions. The lateral load-resisting system (LLRS) in the longitudinal direction is composed by the two external frames, as highlighted in red in Figure 2. The internal longitudinal frame was assumed to provide no lateral resistance, serving only as a gravity-carrying system. Furthermore, the transversal and longitudinal LLRSs were assumed to be independent from each other, and only the latter was focus of attention herein. For all designs, the relevant tributary areas for gravity loads and seismic

masses were computed. The same level of distributed gravity loads was adopted for all designs, as summarized in Table 1.

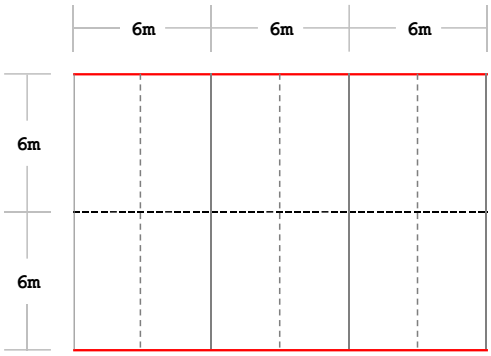

Figure 2. Plan view of the building configuration adopted.

Floor	Load type	Load [kN/m^2]
Top	Dead	4.75
	Live	1.00
Other	Dead	5.75
	Live	2.00

Table 1. Distributed gravity loads.

In elevation, archetypes of 3, 5 and 8 storeys were considered, with a bottom-storey height of 4.5m, and the remaining storey heights of 3.5m. In total, fifteen archetype steel CBF buildings were adopted in this study.

3 NUMERICAL MODELS AND GROUND MOTION RECORDS

To what regards the simulation of steel CBFs subjected to earthquakes, Karamanci and Lignos [4] have recently proposed a numerical modelling approach for the seismic performance assessment of steel CBFs using OpenSees [5]. With this approach, concentrated plasticity rotational springs simulating the inelastic response of both beams and columns are adopted [6]. For the braces, the model employs displacement-based distributed plasticity elements with an initial global imperfection, with material-level considerations regarding the effects of low-cycle fatigue. Brace-to-frame connections are also explicitly simulated, by resorting to the recommendations of Hsiao et al. [1]. According to the authors, the numerical length of the diagonals should reflect the physical dimensions of the members, and the out-of-plane response of the gusset plate is accounted for through inelastic rotational springs. The connection of these springs to the beams and/or columns is attained through rigid elements whose dimensions should consistent with the geometry of the gusset plate. In the absence of any gusset plate, the response of the beam-column shear tab connection should be considered at its physical location. Mohsenzadeh and Wiebe [7] have recently demonstrated that simulating these shear tabs by resorting to fully-pinned connections leads to identical seismic responses to those obtained with explicit connection simulation. All numerical modelling aspects detailed before were adopted for the research study detailed in this paper, under the reference (REF) modelling variant. In the case of the simulation of beam-to-column shear tab connections, a fully-pinned connection was considered [7]. All CBFs were modelled as fixed at the base, and global second-order (P-Δ) effects were explicitly considered. A 2-% Rayleigh damping was adopted by assigning a damping coefficient of 2% [8] to the first and one of the last significant modes of the structure, the latter taken as the number of storeys[9]. The stiffness component of the damping model was computed only for the elastic elements of the model, thus avoiding large artificial damping forces [4][7]. The gravity framing system was explicitly simulated following the recommendations available in the literature [4][7].

As one may infer from the description discussed before, the complexity of the REF models can be considered high. Brace-to-frame connections are explicitly simulated, which requires

complete definition of its geometry via a strenuous seismic design process. It should be noted, however, that whether or not more simplified approaches (e.g. fully-pinned boundary conditions for the diagonals) entail unrealistic estimates of seismic performance has not yet been thoroughly investigated. Even though Hsiao et al. [1] have demonstrated the importance of explicit simulation of gusset connections through cyclic force-deformation responses of single-span, single bay SD CBFs, a similar sensitivity study focusing on more macro-level metrics of performance (e.g. collapse risk, earthquake-induced economic losses) is mostly absent in the literature. With the aforementioned limitations in mind, a modification to the REF approach was evaluated. This modelling variant, hereafter referred as VAR, reflects a more simplified approach in which diagonal centreline-to-centreline lengths coupled with fully-pinned boundary conditions are adopted [2]. By modifying the reference model, the locations of the rotational springs of beams and columns were shifted to the physical location of beam-column connections (i.e. panel-zone boundaries).

As previously reported, all archetypes were assumed to be located in the city of Lagos, a moderate-seismicity region located in mainland Portugal. Probabilistic Seismic Hazard Analysis (PSHA) was performed for the site in question, using the open source software OpenQuake [10] and the seismic hazard model of SHARE [11]. Additional hazard sources and ground motion prediction equations were also adopted, as proposed by Silva et al. [12]. The hazard curves obtained in this process, in terms of the relationship between the first-period spectral accelerations, Sa(T1) and the annual rate of exceedance, λ, are summarized in Figure 3 for a select number of periods. Disaggregation of the seismic hazard [13] on magnitude, distance and ε was performed, which served as the basis for the ground motion record selection scheme and was used in conjunction with the average shear wave velocity for the first 30 meters of soil, vs,30. For this location, a suite of 30 ground motion records was selected and scaled so that the 2%-damped median spectrum of the suite matched the prescribed response spectrum of EC8-1 for a 10% in 50 years hazard level, considering a wide range of periods of interest. This approach, which is similar to the one adopted in FEMA P695 [14], was attained with the SelEQ [15]. As shown in Figure 3, a fairly accurate correlation between the mean/median spectrum of the selected ground motions and the code-specified response spectrum was achieved.

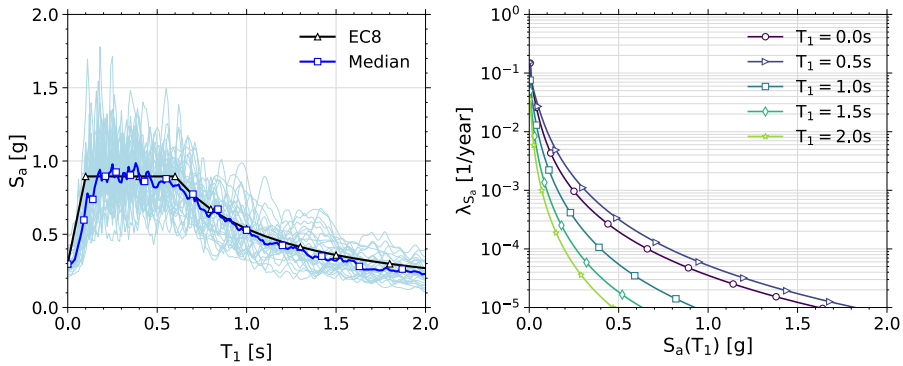

Figure 3: Code-specified and median ground motion response spectrum (left) and seismic hazard curves (right) for Lagos.

4 COMPARISON OF FUNDAMENTAL PERIODS AND SEISMIC DEMANDS

As a result of the application of the modelling procedures detailed before, one major implication of interest relates to the fundamental period, T_1, associated with the archetypes considered in this study, as per Figure 4. Furthermore, the different modelling approaches should

also influence the seismic demand imposed to the building, as summarized in Figure 4 via the spectral acceleration demands associated with the T_1, $S_a(T_1)$, of each model.

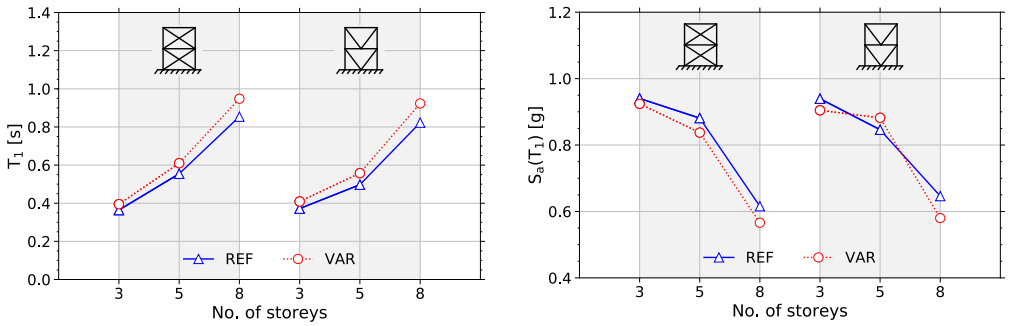

Figure 4: Comparison of fundamental periods (left) and first-period spectral demands (right).

Analysis of the results summarized in Figure 4 allows concluding about the relevant effect of non-explicit modelling of brace-to-frame gusset plates (VAR), namely by comparison to the reference models (REF). This is due to the fact that diagonal members are simulated through centreline-to-centreline lengths, which entails higher brace slenderness levels throughout the suite of diagonals. In turn, the lateral stiffness of the CBF reduces, and the period of vibration increases. These differences are carried to the seismic demands imposed to the archetypes, as denoted by the results of Figure 4. According to the comparison of first-period spectral demands, an important effect of a more simplified consideration of the brace-to-frame connections (VAR) can be observed. With a more simplified modelling approach, differences of $S_a(T_1)$ against the reference model remained roughly between -10% and +5%, being typically larger in amplitude for the taller archetypes.

5 LATERAL DEFORMATIONS AT THE EC8 LIMIT STATE INTENSITIES

The first performance metric evaluated in this study pertains the levels of lateral deformations observed across several seismic intensities of interest within the framework of Eurocode 8. These correspond to design and/or assessment limit states established in Part 1 [3] and Part 3 [16] of EC8. For each of these limit state intensities, every archetype was subjected to the same ground motion suite scaled to the respective intensity of interest. For each archetype, the results were then assessed via the mean response across all 30 records. Figure 5 shows the observed inter-storey drift ratios (i.e. ratio of inter-storey displacements and storey height), ISDRs, for the 5-storey archetypes at the ULS limit state intensity (return period of 475 years). In the figure, the two modelling considered in this study (REF and VAR) are represented.

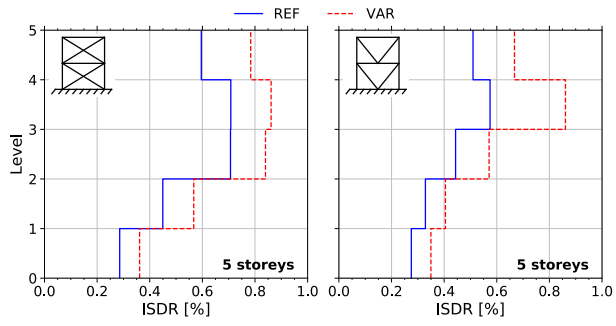

Figure 5: Comparison of ISDRs at the ULS limit state intensity for a 5-storey X-CBF and V-CBF.

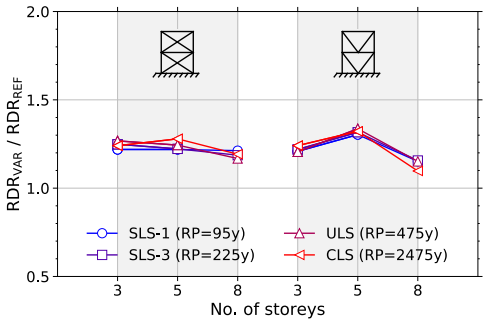

Figure 6: Comparison of roof drift ratios (RDRs) at the EC8 limit state intensities.

As shown in Figure 5, the ISDRs associated with VAR models were larger than those obtained with the REF models at all storeys. This observation was found across all archetypes and limit state intensities, as summarized in Figure 6. In the figure, the roof drift ratio, RDR, taken as the ratio between the lateral displacement of the uppermost floor level and the building height is shown. The results are presented as a direct comparison of the RDRs between those associated with the REF and VAR modelling variants. From the figure, it can be clearly observed that brace simulation through a pinned-ended centreline-to-centreline approach (VAR) may entail significantly higher lateral deformations levels in comparison to a more refined approach (REF). This occurred despite VAR models having lower first-period acceleration demands (see Figure 4). This observation clearly reveals the importance of explicit consideration of brace-to-frame gusset plates to evaluate the seismic response and performance of CBF buildings. The use of more simplified models that do not consider the influence of the dimensions and flexibility of the brace-to-frame gusset plates should be avoided, particularly if deformation-based seismic performance characterizations are adopted.

6 EARTHQUAKE-INDUCED RISK

The second performance metric evaluated in this study pertains the seismic collapse risk associated with the suite of archetypes. This was attained by subjecting building archetypes to Incremental Dynamic Analysis (IDA) [17]. The mean annual frequency of collapse, λ_c, was employed to interpret the collapse risk by integration of the collapse fragility curve and the seismic hazard at the site [18]. The ground motion record suite detailed in Section 3 of this paper was employed for the IDA process. Every time-history analysis was extended by 5 seconds of free vibration time, and the residual deformations of each storey were computed by averaging the lateral deformations of the CBF within this free vibration time. To what concerns the intensity measure (IM) adopted in this assessment, the 2%-damped spectral acceleration at the fundamental period, $S_a(T_1,2\%)$, was adopted. The resulting IDA curve was interpreted to pinpoint the exceedance of the collapse limit state, assumed as the instance associated with either a reduction to less than 20% of the initial slope of the IDA curve or an ISDR above 10% [19]. A collapse fragility curve was then constructed by fitting a lognormal cumulative distribution function, defined by a median value, θ, and a lognormal standard deviation, β. The results obtained in this assessment are summarized in Figure 7, in terms of the probability of collapse within a 50-year timeframe, $P_{c,50}$, across all archetypes and numerical modelling variants.

As shown in Figure 7, VAR models generally produced relevant disparities in relation to the reference modelling approach. This important observation highlights the fact that simulating the braces through a more simplified centreline-to-centreline pinned-ended approach may entail erroneous estimates of collapse performance when compared with results obtained with more refined modelling approaches (REF). It is thus recommended that explicit modelling considerations regarding the brace-to-frame gusset plates should be adopted, regardless of bracing configuration or number of storeys.

The last seismic performance metric employed in this research study concerns the expected annual losses (EALs) associated with the archetype population under assessment. These were computed following the building-specific storey-based loss estimation methodology proposed by Ramirez et al [21], considering the effect of demolition-related losses [22]. In order to compute the demolition-related losses, the probability of demolition given a residual ISDR, P(D|RISDR), was assumed to follow a lognormal distribution with a median of 1.85% and a logarithmic standard deviation of 0.3 [23]. To what pertains the repair losses, the structural damage fragility curves proposed in HAZUS [24] for high-code steel braced frames were used, in conjunction with the repair cost ratios proposed in HAZUS for multifamily dwellings. Fi-

nally, the component category weights were re-scaled to better reflect structural-to-non-structural content distributions in Portugal, namely: i) drift-sensitive structural components, 25%; ii) drift-sensitive non-structural contents, 55%; and iii) acceleration-sensitive non-structural components, 20%. The results obtained in this process are summarized in Figure 8, in terms of the total EALs across all archetypes and modelling variants.

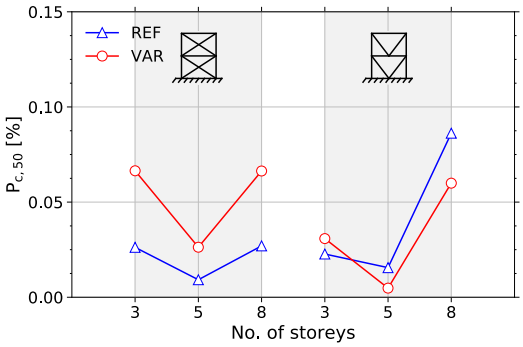

Figure 7: Comparison of collapse risk.

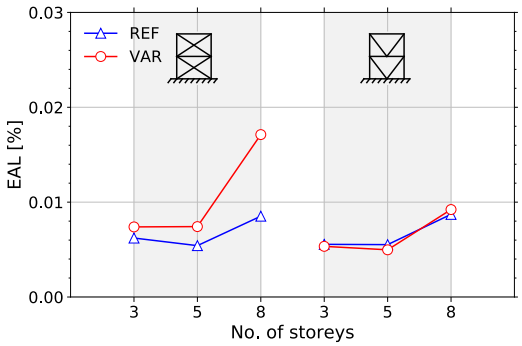

Figure 8: Comparison of expected annual losses.

A number of important conclusions can be inferred from Figure 8. Firstly, the EAL levels associated with the considered CBF archetypes, regardless of the modelling variant employed, were relatively low. In similar fashion to the collapse risk results discussed previously, the low seismic losses shown herein are directly correlated to the seismic hazard associated with Lagos. To what regards the results associated with VAR models, once again clear differences against the results obtained with the REF models were obtained. These finding once again demonstrate the importance of explicit modelling of brace-to-frame gusset plates for seismic performance assessment of steel CBFs.

7 CONCLUSIONS AND FUTURE WORK

In this paper, the sensitivity of seismic performance assessment results to the modelling refinement of brace-to-frame connections on steel CBFs was evaluated. In this context, two modelling variants were applied to a population of EC8-compliant archetypes, of various bracing configurations and building heights, namely: i) REF, in which the gusset plates are explicitly seismically designed and simulated [4]; ii) VAR, in which diagonals are simulated through a centreline-to-centreline length with fully-pinned boundary conditions, therefore neglecting the physical presence of the connection of the brace to the beams and columns [2]. A number of seismic performance metrics were considered as a comparison measure between the results obtained with each modelling variant. From the limited scope of the results obtained, a number of aspects merit discussion.

Firstly, VAR models produced more flexible CBFs in relation to equivalent REF models. This relates to a lower physical brace length compared to a centreline-to-centreline member length, in conjunction with the actual rotational flexibility of the connection. Consequentially, a non-negligible effect on the seismic demand imposed to the structure was also observed. Secondly, through an assessment of lateral deformations at the EC8 limit state intensities (i.e. return periods between 95 to 2475 years), VAR models generally produced unrealistic deformations in relation to the reference results. This observation tended to apply also to earthquake-induced collapse risk and expected annual losses. It is thus recommended that the use of more simplified models that do not consider the influence of the dimensions and flexibility of the brace-to-frame gusset plates should be avoided.

In the authors' opinion, the results shown in this paper demonstrate the relevant implications of non-explicit simulation of brace-to-frame gusset connections in the context of seismic performance assessment of steel CBF buildings. It is important to assess a wider building population to confirm the main findings detailed herein. Furthermore, the possibility of more simplified and expedited processes for the sizing of brace-to-frame gusset plates should be focus of research in the near future. This need is mainly due to the impracticality of explicit seismic design of brace-to-frame connections for large building populations. These aspects are presently being addressed in ongoing research work by the authors of this paper.

RELATIONSHIP BETWEEN RESPONSE MODIFICATION COEFFICIENT AND DISPLACEMENT AMPLIFICATION FACTOR FOR DIFFERENT SEISMIC LEVELS AND SITE CLASSES

Bulent Erkmen[1]

Abstract

Modern seismic design provisions allow structural systems to be designed for reduced forces, which are typically much smaller than the corresponding elastic design loads. This reduction in seismic loads is done by using response modification coefficient. The maximum deflection or drift of structural systems is typically predicted by scaling deflections corresponding to this reduced force on elastic line by displacement amplification factor. The values of these two seismic design factors, which are independent of seismic level and site (soil) class for a given type of structure, are mostly based on accumulated experience from past earthquakes and engineering judgment.

In this study, a large number of five story parking garage structures were designed with a range of response modification factors for two seismic levels and for different site classes. The seismic performance of the structures was determined by performing nonlinear time history analysis with several recorded earthquake records on corresponding site classes. The computed maximum drift values were used to develop relationship between response modification coefficient and corresponding deflection amplification factor for each site class and seismic level. The results show that these two seismic design parameters are related but seismic level and site classes does not have significant effects on the relationship.

Keywords: Response Modification Coefficient, Displacement Amplification Factor, Ductility, Seismic Design.

1 INTRODUCTION

Seismic design of a structural system to remain elastic or free of damage during a severe earthquake loading requires the structure to be designed to resists very large dynamic loads. Such a design approach results in significantly expensive and massive structures. Therefore, moderns seismic design provisions allow structures to be designed for much smaller loads then those required to maintain the structure elastic. This reduction is done by using reduction factor known as response modification coefficient (R), which solely depends on building seismic force-resisting system. The R coefficient was first introduced in 1978 by Applied Technology Council [1]. In the mid-1980s, researcher at the University of California at Berkeley performed a number of experiments to construct draft formulas for R as a function of reserve strength, ductility, and damping [2]. Relationships for R coefficient as a function of different parameters such as ductility, structure fundamental period, post-yielding stiffness, and soil characteristic were proposed by Newmark and Hall [3], Riddell et al. [4], Miranda [5], Nasar and Krawinkler [6], Vidic et al. [7], and Uang [8]. However, although value of R accounts for structural damping, ductility, over-strength, and redundancy, the code assigned values are mainly based on engineering judgment and seismic performance of structural systems in previous earthquakes [1, 8].

Because the reduced seismic forces are used in design, the computed lateral displacements from elastic analysis corresponding to design loads are amplified in order to estimate the actual nonlinear and inelastic lateral displacements that develop during design earthquake. This is done usually by using displacement amplification factor C_d. *Figure 1* show effects of these two seismic design factors on seismic design. The value of R as given in ASCE/SEI 7-16 [9] is between 1.5 an 8, where a value of 1.0 correspond to elastic structure, and those for C_d are between 1.0 and 6.5.

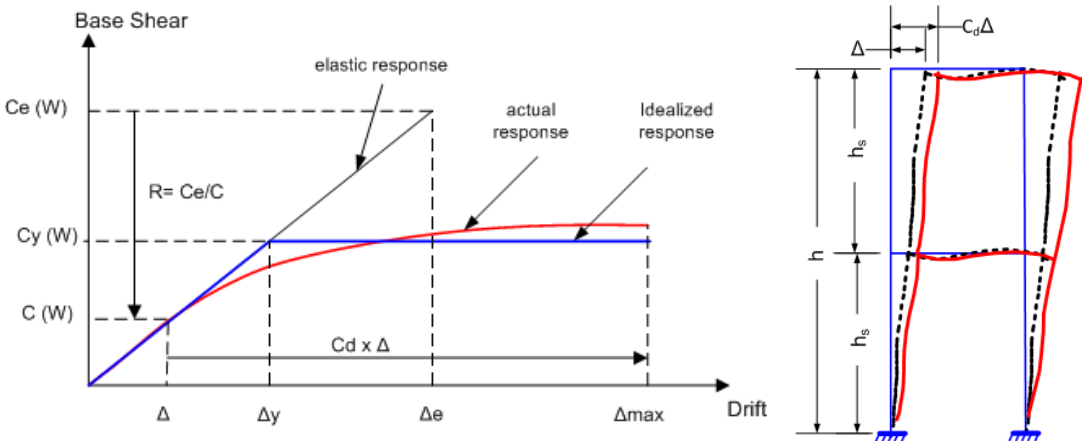

Figure 1: Design spectra and seismic design parameters.

Although it is well known that both R and C_d are interrelated, there is a limited number of studies investigating this relationship. The Uniform Building Code, which uses R_w as force reduction coefficient, assigns $3R_w/8$ for C_d factor [8]. The Commentary of the SEAOC Recommended Lateral Force Requirements, which is the basis for UBC seismic design provisions, states that C_d can be as high as R_w [8].

A review of national building codes indicates that the ratios of R and C_d vary considerably from one code to another. The objective of this study is to determine the relationship between

these two seismic design parameters including effects of site classes and seismic levels. For this purpose, a large number of prototype parking garage structures were designed using *R* values from 4.0 to 8.0 with 0.5 increments. In total, two seismic levels (high and low) and four site classes were considered. For each site class, six actual earthquake time-acceleration data recorded on the same site class were used to preform nonlinear time history analysis of the prototype buildings. The computed deflections were used to establish relationship between seismic design parameters for each seismic level and site class.

2 PROTOTYPE STRUCTURE

A precast parking garage structure was selected as the prototype structure. The structure was designed as five story to include higher modes effects on results. The structure was designed for two seismic levels mainly 0.4*g* (low) and 0.8*g* (high) for spectral response acceleration per ASCE/SEI 7-16. For building location, five site classes (i.e., A, B, C, D, and E) defined in ASCE/SEI 7-16 were considered. However, site classes A and B were considered as a single site class (AB) since the corresponding design spectra and design requirements were not much different. The plan and elevation views of the building are given in *Figure 2*. Each story was 3.2 m high with a roof of 1-m high from top of the spandrels. The floor plan is typical for parking garage structures, and it features four unbonded post tensioned precast (PTT) shear walls as the only seismic force-resisting system in the N-S direction. Two lines of "light bearing walls" were used as seismic force resisting system in E-W direction. In this study, building seismic performance only in N-S direction was considered.

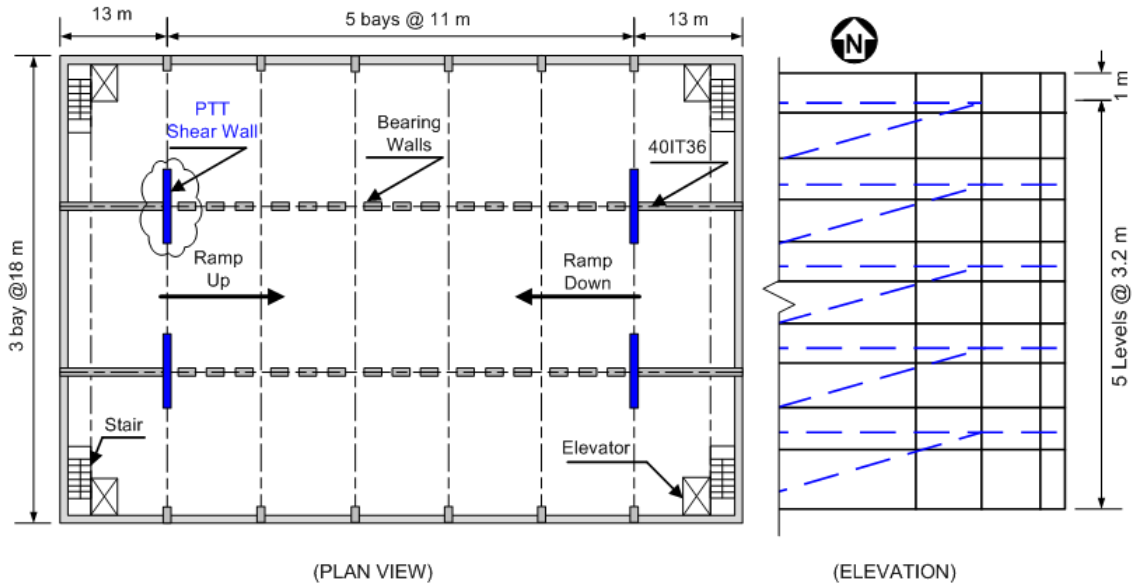

Figure 2: Plan and elevation views of prototype parking structure.

The unbonded post-tensioned precast shear walls are jointed construction, and they do not possess disadvantages of monolithic shear walls as shown by the PRESSS (PREcast Seismic Structural Systems) Research Program [10]. In such seismic force-resisting systems, concrete wall units remain almost undamaged due to lack of bond between post-tensioned tendons and concrete. The walls designed based on this design philosophy also known as jointed construction resist lateral loads by opening and closing of joints between precast members without causing significant damage to structural members. Unbonded precast concrete shear walls have been studied both experimentally and analytical by a number of researchers including Kurama et al. [11]., Shultz et al. [12], and Erkmen et al. [13].

The cross-section and elevation of prototype walls are given in *Figure 3*. Each wall has five precast wall panels with a horizontal joint at each floor level. The selected wall dimensions were based on site class and seismic level. The number and location of unbonded tendons were selected to ensure that each wall has the desired lateral strength level. Building overstrength was assumed to be unity. The amount and location of interlocking spirals (confining reinforcement) was determined based on design recommendations per ACI ITG-5.1-07 [14] and ACI ITG-5.2-09 [15].

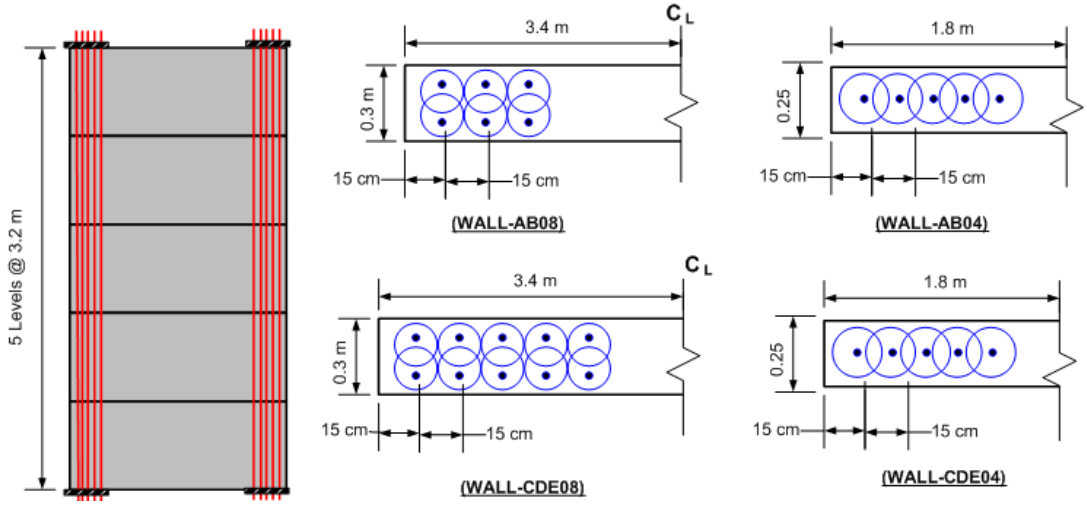

Figure 3: Plan and elevation views of prototype PTT walls.

2.1 Analytical Model and Verification

Nonlinear response-history analysis results of the porotype building were used to determine maximum lateral deflection of the building. Such nonlinear dynamic analyses shall utilize a structural mathematical model, which is capable of capturing nonlinear hysteretic behavior of structure [9]. The computational model was developed and verified using DRAIN-2DX program, which is a general-purpose computer program for both linear and nonlinear static and dynamic analysis of plane structures [16].

The computational model was verified using experimental test results given by Schultz et al [12]. The test PTT wall, which is given in *Figure 4*, was a 2/3-scale representation of the lowest two stories of a prototype precast concrete shear wall in a six-story office building. The wall featured six unbonded post-tensioned tendons and typical construction materials. The wall was tested under quasi-static cyclic loading and subjected to a combination of vertical and in-plane lateral loads history.

The main features of the developed analytical model are given in *Figure 4*, and a detailed description of the model and its verification are given by Erkmen et al [13]. The experimental and computed analytical responses given in *Figure 5* show no significant differences between the measured and computed stiffness, load capacity, and absorbed energy capacities of the wall.

2.2 Selection and Scaling of Ground Motions

Six strong ground motion records were selected for each ASCE/SEI 7-16 Site Class A and B, C, D, and E. The ground motions records were obtained from the Pacific Earthquake Engineering Research (PEER) Center NGA-West2 database. A summary of all selected ground motions is given in *Table 1*. The ground motions records were selected giving preference to station site class, spectral shape over the period range of interest, free-field records, magnitude, and closest distance to the rupture plane.

Table 1: Summary of ground motion records used for dynamic analysis

The ground motions were scaled to match design spectrum based on ASCE/SEI 7-16 recommendations [9]. The ground motions were scaled using a constant scale factor to all acceleration ordinates of the motions such that the average value of the response spectra for the suite of all motions considered is not less than the design response spectrum for the site over the period range $0.2T$ to $1.5T$, where T is the natural period of the structure in its fundamental mode. The upper limit on the period is intended to account for period elongation due to inelastic actions and gap opening of the wall at its horizontal joints, and lower limit is intended to capture higher modes of response. The ASCE/SEI 7-16 design response spectrum for each site class at high seismic level (spectral response acceleration of $0.8g$) and scaled earthquake response acceleration spectra are given in *Figure 6*. The same approach was employed to scale the selected ground motions to low seismic level, which is $0.4g$.

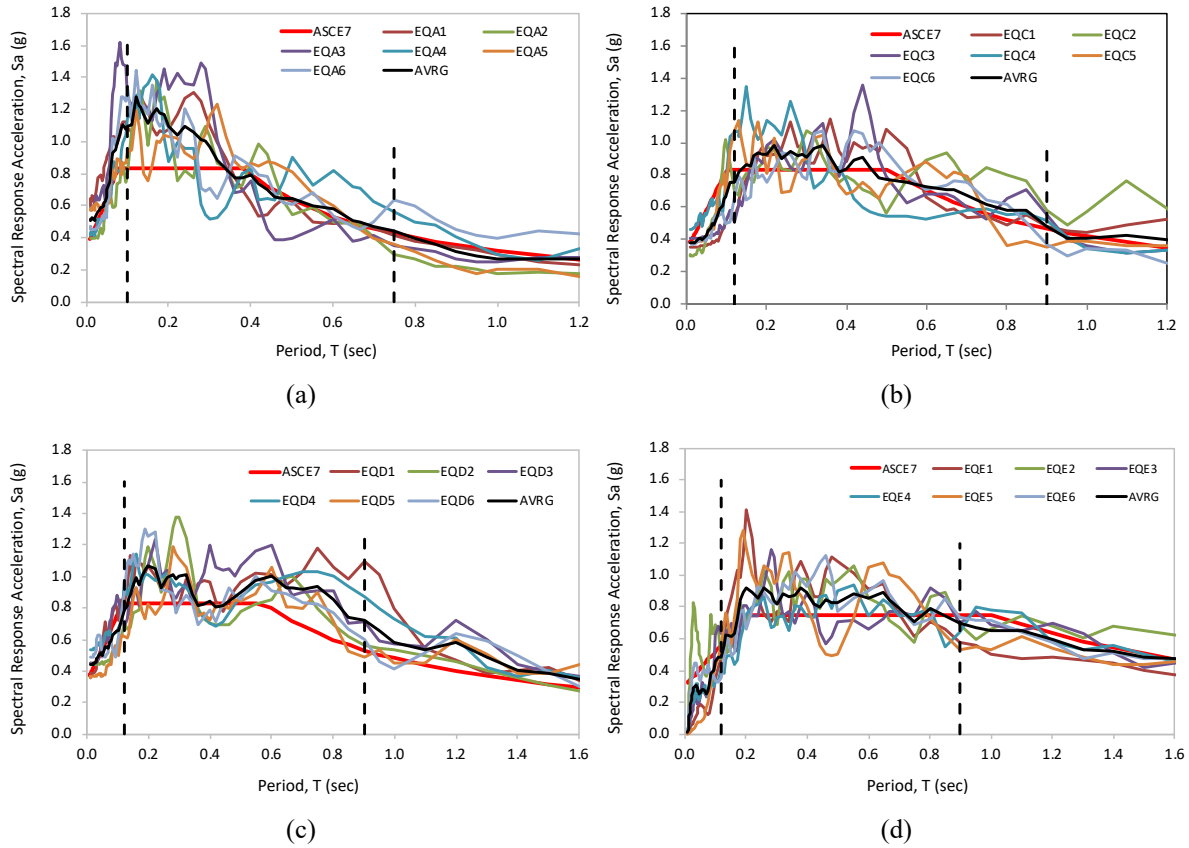

Figure 6: ASCE7 Design and spectral acceleration spectrum of selected ground motions at 0.8*g*

3 RESULTS AND DISCUSSIONS

The displacement amplification factor C_d was computed for the prototype buildings on the basis of computed building peak drift values using nonlinear time history analysis with the scaled ground motions. The C_d value was computed as the ratio of maximum drift to building drift corresponding to its design level lateral force. However, because the overstrength is neglected in the developed analytical models, the design level approximately corresponds to structure yielding. The computed C_d values for each site class and R value are given in *Figure 7* and *Figure 8* for seismic levels 0.4*g* and 0.8*g*, respectively. The results show that C_d value for prototype building increases with the increasing R value of the building. Large R values requires structural systems to be more ductile. Therefore, this observation is consistent with typical code values such as ASCE/SEI 7-16, where C_d value increases with increasing R value.

Figure 9 shows the computed average C_d value for each site class for both seismic levels. The average results show that structures located on sites with high seismic levels typically need to be designed with higher ductility capacities (larger C_d). However, the effects of seismic level and site class on C_d are not significant and probably can be ignored for design purposes. The only exception is Site Class E, which indicates that relatively larger C_d values are required as the site seismic level increases. However, because the structures designed with R values larger than 4.5 with high seismic level and 6.0 for low seismic levels failed (defined as maximum drift more than 2.5%), this observation is based on a limited number of structures. Finally, the average C_d values show that a C_d value that is equal to R value is conservative and reasonable for design purposes.

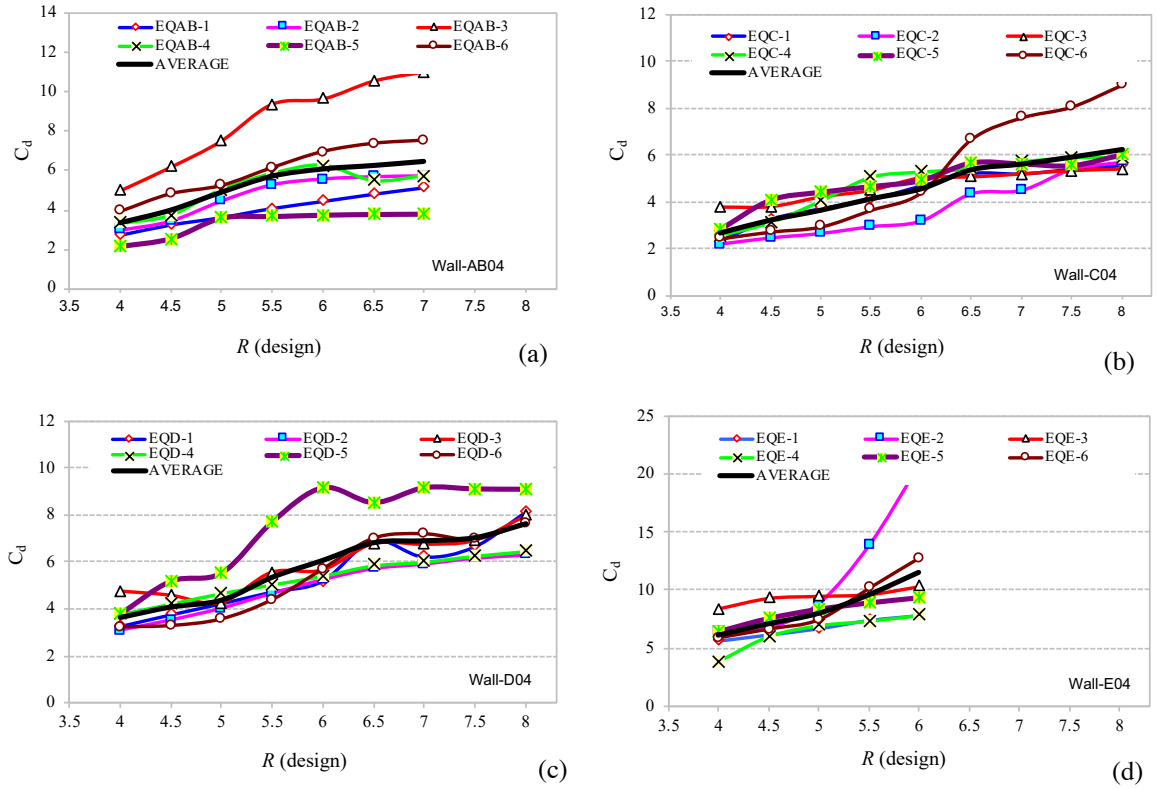

Figure 7: Computed C_d and R relationship at 0.4g for site class (a) AB, (b) C, (c) D, and (d) E

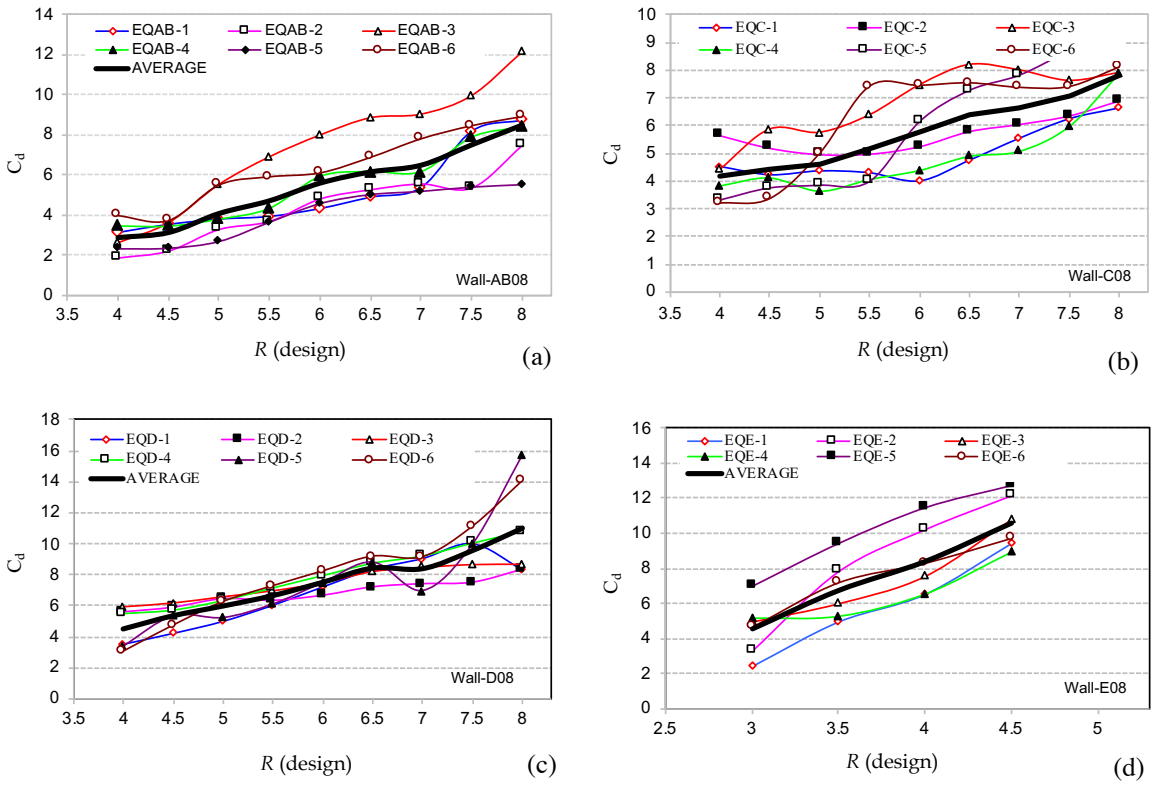

Figure 8: Computed C_d and R relationship at 0.8g for site class (a) AB, (b) C, (c) D, and (d) E

4 CONCLUSIONS

A large number of prototype parking garage structures were designed for two seismic levels and several site classes. The structures were designed for values of response modification coefficient R ranging from 4.0 to 8.0. In total 24 recorded ground motions were used to perform nonlinear time history analysis of the designed structures. The computed maximum drifts were used to compute the required minimum displacement amplification factor C_d to ensure that structure does not collapse. Based on results presented the following main conclusions are made:

1. The seismic design parameters R and C_d are interrelated. For structures with larger R values the demand for C_d or ductility is also high.
2. Although demand for C_d increases as the site class become softer, the effects of site class are negligible for Site Class A, B, C, and D. However, structures located on Site Class E seems to have a requirement for larger values of C_d than those located on other site classes.
3. Increasing site seismic level increases the requirement for minimum value of C_d or building ductility, but the increase is typically not significant and can be ignored.
4. A value of C_d that is equal to building R value seems to be a reasonable design approach that envelope C_d requirements for structures presented in this study.

Abstract

The development of simplified probabilistic performance assessment methods has opened up the possibility for risk targeted seismic design guidelines. As an example, international codes such as Eurocode 8 and ASCE7-10 have proposed simplified risk targeted seismic design objectives. The SAC/FEMA approach might be considered as one of the basic means of achieving such probabilistic performance objectives. However, this methodology is typically applied assuming that the equal displacement rule is a valid means of relating changes in intensity to changes in deformation demands, which can limit its accuracy. To address this, the results of a robust campaign of nonlinear time history analyses of a wide range of single degree of freedom systems are used to establish new intensity-displacement relationships and thereby improve the accuracy of the SAC/FEMA approach. In order to illustrate how the proposed relationships can be used in practice, the paper finishes by assessing the annual probability of exceeding the ultimate limit state for a 1-storey steel eccentrically braced system and a 1-storey rocking frame system. The results demonstrate that the refined approach is a practical and reasonably accurate means of obtaining probabilistic measures of seismic performance.

Keywords: Structural Performance, Probabilistic, Limit State, Exceedance, Assessment.

1 INTRODUCTION

The dynamic interaction between community expectations and earthquake engineering developments has seen the emergence of performance based earthquake engineering (PBEE). The PBEE framework new emerged innovation attempts to increase the level of safety not only by quantifying risk to people lives against the seismic events, but also by communicating the likely damage and business interruption. The required increase in structural performance confidence has been found to be provided by accounting for uncertainties in demand and capacity which has brought to light the necessity of simplified probabilistic design and assessment methods. In response to this, different methodologies have appeared to simplify both earthquake engineering aspects, structural demand/capacity assessment [1-4], and hazard function estimation [1, 5, 6].

The SAC/FEMA framework [1] is considered to be one of the pioneering approaches in the evolution of PBEE methodologies. This approach measures the structural performance by combining the probability of exceeding a target limit state with the associated hazard function, as shown by Eq. (1).

$$P_{LS} = \int P[C < D]|dH_D(d)| \tag{1}$$

Where P_{LS} is the annual probability of exceeding limit state, $P[C<D]$ is the cumulative distribution function (*CDF*) expressing the probability of exceedance of limit state at each shaking level, and $H_D(d)$ is the hazard function which defines the relation between shaking intensity and annual rate of exceedance.

There are several methods available in the literature to generate the fragility function, $P[C<D]$. Incremental dynamic analysis (IDA) [7] or multi stripe analyses (MSA) [8] are common procedures by which engineers compute the probability of exceeding a limit state. However, the annual probability of exceedance has not become a convenient tool to measure the structural performance comparing different alternatives in the phase of design or assessment due to complexity and required time. This is considered to be one of the benefits of the SAC/FEMA framework.

The SAC/FEMA framework establishes a solution in closed form to evaluate integral illustrated by Eq. (1), shown by Eq. (2) to Eq. (5). As is indicated by Eq. (2), annual probability of exceeding a limit state, here is called annual probability of failure (APOE), is computed by multiplication of annual rate of exceedance associated failure mechanism spectral acceleration (Sa) and three coefficients, C_H, C_f, and C_x. It has been assumed that the epistemic uncertainties hidden in ground motion prediction equations is accounted for adopting the mean of the hazard function values instead of median, and hence, C_H is a factor to convert the median to a mean value accounting for the epistemic uncertainty involved in ground motion prediction equations; C_f is the factor to account for the aleatory uncertainties in demand and capacity; and C_X is takes into account the confidence level. In this paper C_x and C_H are taken equal to one by targeting 50% confidence level and using median hazard value.

$$P_{LS} = H(S_a)C_H C_f C_x \tag{2}$$

$$C_f = \exp\left(\frac{k^2}{2b^2}(\beta_{DR}^2 + \beta_{CR}^2)\right) \tag{3}$$

$$\theta = aS_a(T_1)^b \tag{4}$$

$$H(S_a) = k_0(S_a)^{-k} \tag{5}$$

Where, *Sa,c* is the spectral acceleration associated with the failure mechanism displacement capacity; *H(Sa,c)* is the hazard function; β_{DR} and β_{CR} are the dispersion associated with demand and capacity distribution; Θ is the drift ratio; *a* and *b* are the coefficients corresponding to the IM-EDP relation; and k_0 and *k* are the first order fit hazard function coefficients.

This approach is based on few a assumptions which make the whole framework run in a simplistic way. However, they introduce some level of errors and cause some limitations as well, as has been identified by others [5, 9]. First, it presumes that the variation in the structural demands due to variability in shaking intensities could be approximately represented by Eq. (4), which is in line with the so-called empirical 'equal displacement rule' (EDR) [10]. Hence, one may employ Eq. (6) to estimate the spectral acceleration which causes target displacement demand associated with a specific limit state failure mechanism.

$$S_a = (\frac{\theta}{a})^{\frac{1}{b}} \tag{6}$$

Where the parameters have been defined before.

In this paper, new 'b' values are proposed, and the accuracy of the IM-EDP relation, Eq. (4) and Eq. (6), is investigated using the newly proposed 'b' values and 'b=1'. For that purpose, first, the IM-EDP relation is investigated for a wide range of SDOF systems; and updated 'a' and 'b' values are established. Consequently, to examine the accuracy of predicting the causal IM associated with the limit state failure, MSA are conducted for two case study buildings located in Christchurch and Wellington New Zealand, and the median of spectral accelerations distribution obtained for different limit states failure are compared with those obtained by applying Eq. (6) adopting the updated 'b' values. Furthermore, the precision of the APOE predicted by the SAC/FEMA framework is evaluated comparing that achieved with those from MSA results.

2 METHODOLOGY

In order to examine the relationship between intensity and demand, results of nonlinear time history analyses (NTHA) reported in [11] are assessed. The results include a wide range of single degree of freedom (SDOF) systems with periods of 0.1s, 0.2s, 0.3s, 0.4s, 0.5s, 0.6s, 0.8, 1.0s, 1.5s, 2.0s, 2.5s, 3.0s, 3.5s, 4.0s; and yield coefficients (defined as base shear at yield divided by system weight) of 0.025, 0.05, 0.075, 0.10, 0.125, 0.15, 0.20, 0.30, 0.40, 0.50 using 4284 ground motions available in the PEER database. Further, the hysteretic models adopted shown in Figure 1 include the Bilinear hysteretic model, which represents steel structures and base isolated systems, and the Flag-shaped model representing rocking frames fitted with energy dissipating devices. Moreover, for both hysteretic models the strain hardening ratio is assumed 0.05 compatible with general practice, and 5% tangent stiffness damping is adopted for each analysis.

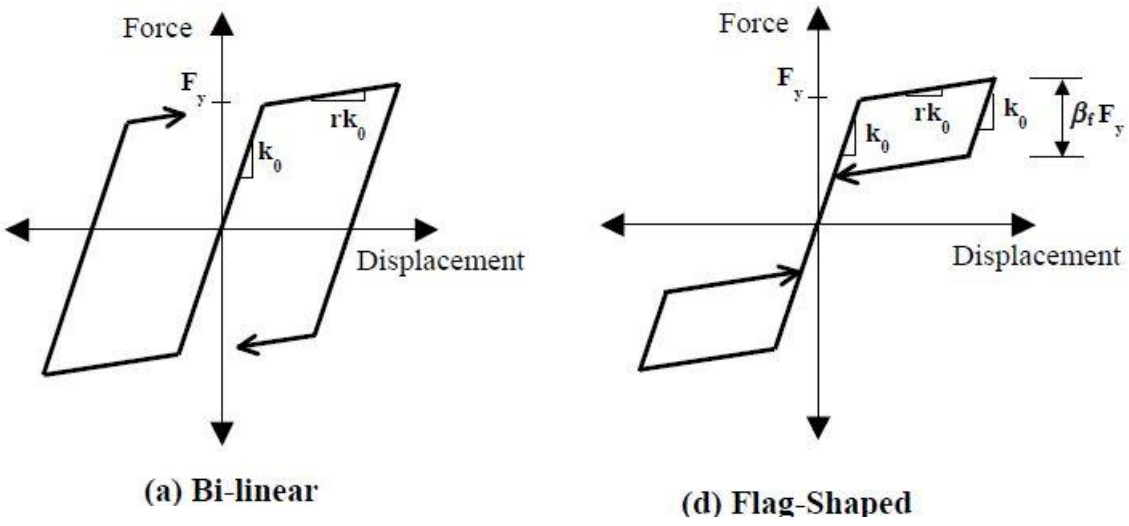

Figure 1. The adopted hysteretic models for single degree of freedom systems (a) Bilinear, (b) Flag-shaped [11]

2.1 Regression fit parameters of the IM-EDP relationship

To estimate the 'a' and 'b' coefficients corresponding to Eq. (6), a nonlinear regression analysis is carried out in MATLAB [12] using the obtained results from the cloud analyses [11] associated with each SDOF system. Figure 2 illustrates typical cloud analysis results corresponding to a SODF system with 0.5s period and the Flag-Shape hysteretic model.

On may expect to achieve similar results regardless of the binning approach associated with nonlinear regression analysis. This implies that the final coefficients derived by regression analysis will be identical no matter if Eq. (4) or Eq. (6) has been adopted as the model function. However, in this work it turned out that this statement will remain valid if a sufficient number of analyses have been conducted. The errors corresponding to each function model adopted in the nonlinear regression analysis are illustrated in Figure 3 and Figure 4.

The error distribution clarifies if the used model function can represent the data distribution without introducing any bias, and the validity of this assumption is assessed if the regression associated errors follows a normal distribution. As such for the conducted regression analyses, the distribution of the errors has been found. Figure 3 presents the error distribution associated with the results displayed in Figure 2. According to Figure 3, it is perceived that Eq. (6) efficiently represents the model function adopted in nonlinear regression analysis without generating any bias, hence, the found 'b' values are considered reliable. Figure 4, on the other hand, illustrates that Eq. (4) may not be used as the model function as the error is not distributed uniformly with *Sa* values increasing along the horizontal axis.

2.2 Proposed relationship between IM-EDP

Table 1 lists the median of the obtained 'b' values obtained for a range of different yield strength coefficients associated with each SDOF period. Examination of the new 'b' values reported by Table 1 illustrates three points. First, the listed dispersion by Table 1 is relatively small which implies that the proposed 'b' values change little with change of yield coefficient. Second, flag-shape systems have larger 'b' values in comparison with the Bi-linear systems for all periods as one may expect beforehand. This is in line with the amount of energy that is

dissipated by each hysteresis rule as elaborated by Figure 1 indicating that the nonlinear displacement demand will be less if more energy is dissipated by hysteresis loops. Third, the suggested 'b' values reduce with increasing period for both hysteresis rules.

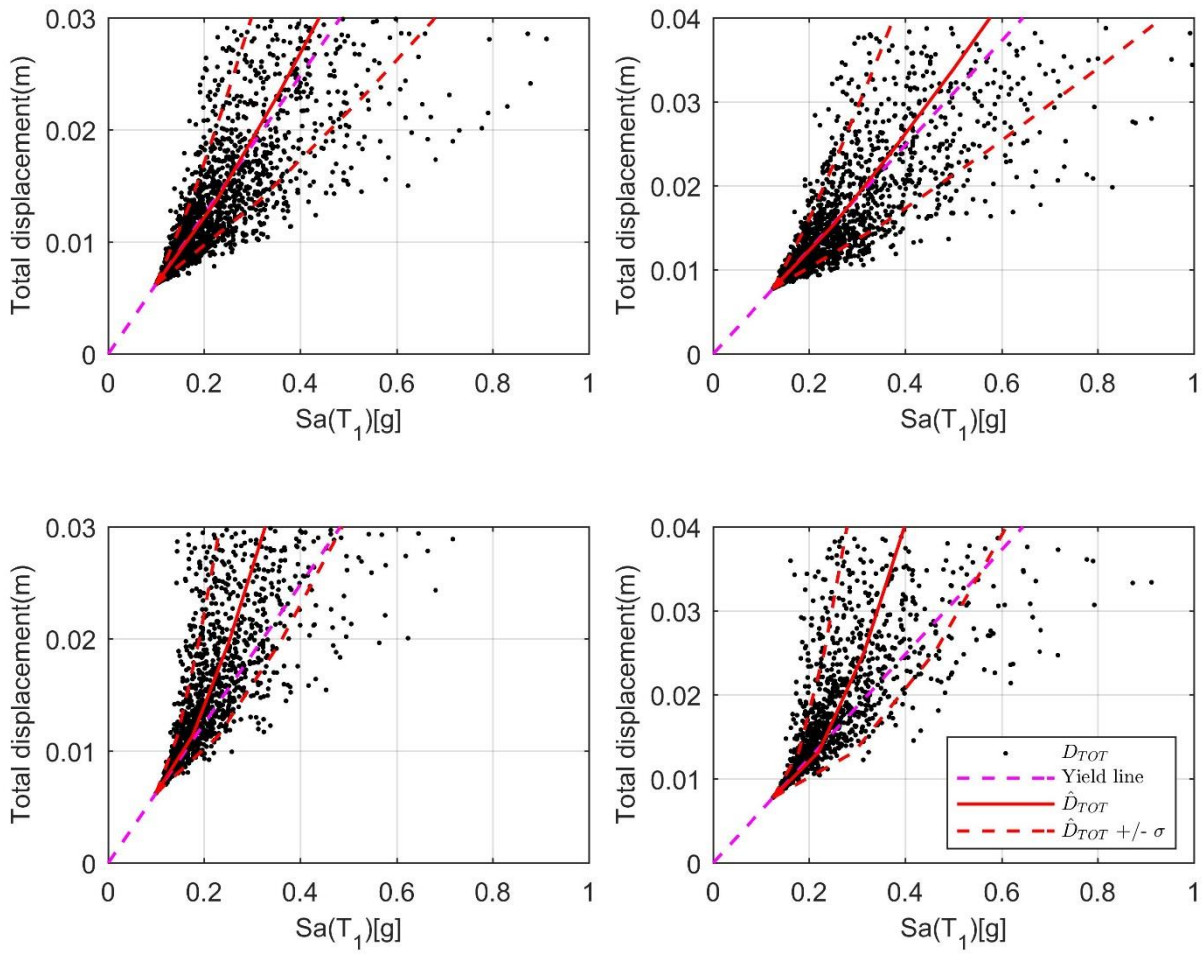

Figure 2. The NTHA results associated with 0.5s SDOF system Bi-linear Cy =0.10 (top-left) and Cy =0.125 (top-right); Flag-shape Cy=0.1 (bottom-left) Cy=0.125 (bottom right) (from [16])

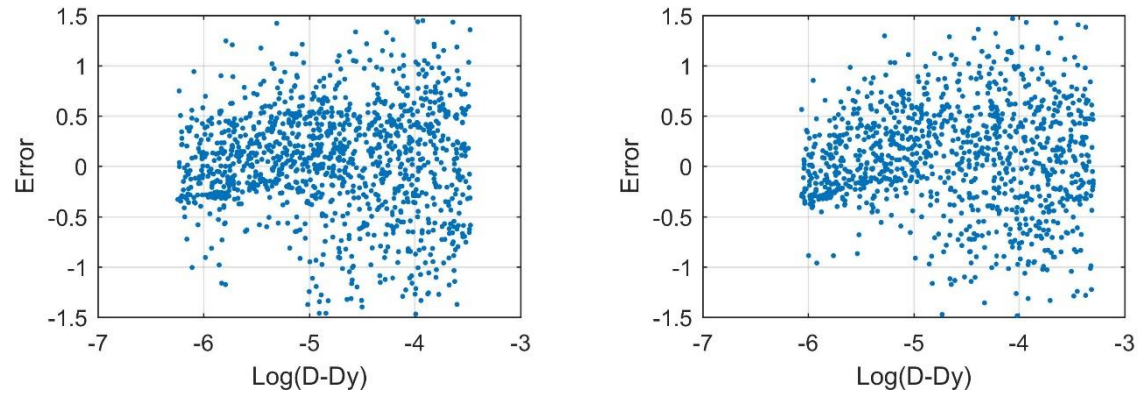

Figure 3. The error distribution associated with horizontal binning approach for SDOF with period of 0.5s and Flag-shape hysteretic model (left: Cy=0.10; right: Cy=0.125) (from [16])

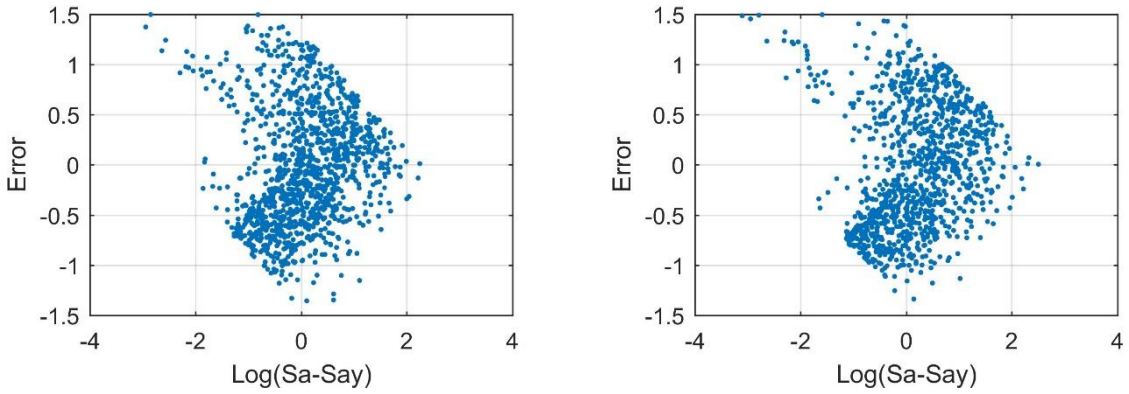

Figure 4. The error distribution associated with vertical binning approach for SDOF with period of 0.5s and Flag-shape hysteretic model (left: Cy=0.10; right: Cy=0.125) (from [16])

Table 1. The proposed 'b' values associated with different periods and hysteretic models from [16]

Period	Bilinear		Flag-shape	
T(s)	$\hat{b}$	β_b	$\hat{b}$	β_b
0.1	1.25	0.05	1.43	0.06
0.2	1.14	0.02	1.21	0.02
0.3	1.11	0.02	1.17	0.02
0.4	1.10	0.03	1.16	0.03
0.5	1.08	0.01	1.14	0.01
0.6	1.06	0.01	1.11	0.02

4.0	1.03	0.02	1.09	0.03

$\hat{b}$ Indicates the median associated with lognormal distribution;
β_b represents the associated dispersion

3 HIGHLIGHTING IMPACT OF USING THE NEWLY PROPOSED IM-EDP RELATIONSHIP

The proposed 'b' values reported in Table 1 should be applicable regardless of ductility range, as one may deduce from Figure 2 and Figure 3. Further, comparing the accuracy of the predicted *Sa* values for the same limit state for different site locations reveals how independent the results are due to site variation. Thus, to illustrate the benefits of the proposed 'b' values for different ductility ranges and site locations, two different case study buildings are modeled and analyzed in Ruaumoko [13]. Multi stripe analyses are carried out using the selected ground

motions for Christchurch and Wellington from [14]. Consequently, Eq. (6) employs the updated 'b' values, and the accuracy of predicted Sa causing limit state failure is gauged. Furthermore, APOE is computed and compared for each case study building according to the MSA results and SAC/FEMA approach.

3.1 Case study buildings

A 1-storey warehouse building and parking lot building are considered to be assessed as the case study buildings with two site locations being Christchurch and Wellington in New Zealand. The height and span used to represent these buildings are 3.5m and 6m respectively. The lateral resisting systems of the buildings are an eccentric braced frame (EBF) and a rocking reinforced concrete frame (RF), respectively. Figure 5 illustrates the schematic shape and dimensions of each case study building.

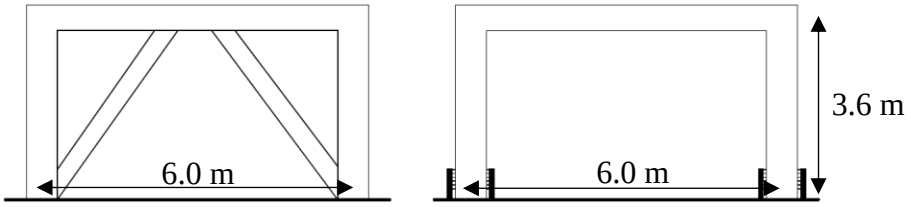

Figure 5. The case study building (left) EBF system (right) rocking RC frame;

3.2 MULTI STRIPE ANALYSES

In order to evaluate the structural performance, MSA is conducted, and hence NTHA are carried out using different sets of selected ground motions compatible with conditional spectra at different rates of exceedance [8]. Hence, the selected ground motions conditioned on a period of 0.5s for Christchurch and Wellington [14] are used. Figure 6, as an example, shows the spectral acceleration response for the selected 40 ground motions associated with the 475y return period and corresponding hazard curve. Moreover, Figure 7 presents the structural response at different hazard levels using the hazard consistent set of selected ground motions for the Christchurch case study buildings as an example.

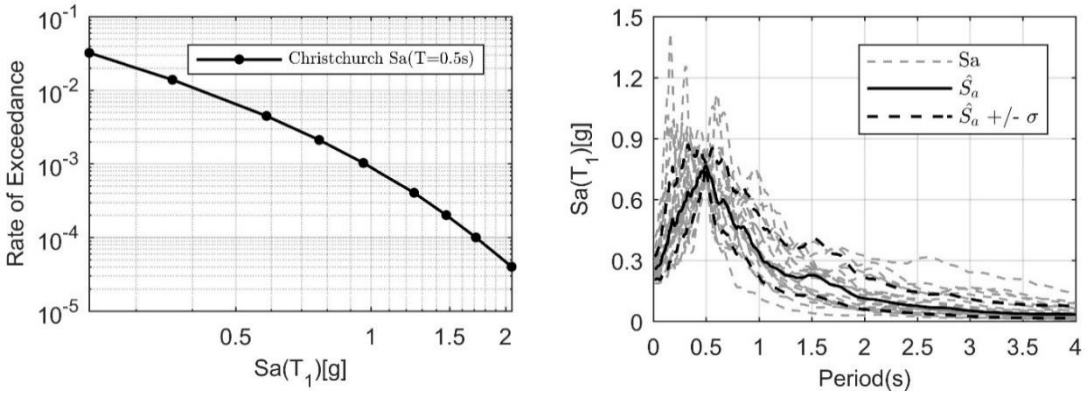

Figure 6. (left) The 0.5s spectral acceleration hazard curve associated with the Christchurch 500y return period (right) the selected ground motions corresponding to design base hazard level

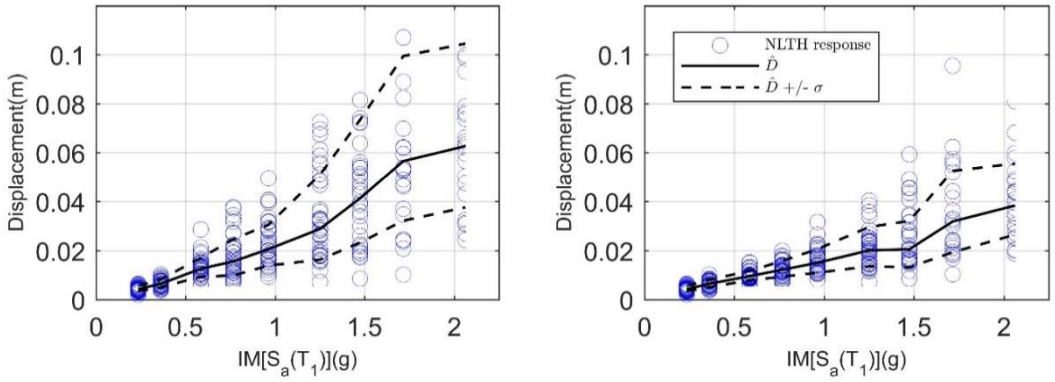

Figure 7. The multi strip analyses results (left) rocking frame (right) eccentric braced frame located in Christchurch

Table 2 compares the median intensity for different limit states obtained applying Eq. (6), adopting 'b=1', and also 'b' values reported in Table 1. It is observed that the proposed values of 'b' provide more accurate predictions of the spectral acceleration for both case study buildings with low sensitivity regarding site location. It is also noticed that the Christchurch EBF case study building second limit state Sa prediction accuracy is slightly low although the Sa associated with first and third limit state has been successfully predicted. Figure 7 examination clarifies that the median IM-EDP variation would slightly change if a larger number of ground motions could be adopted for MSA, and consequently a better estimation of IM-EDP relation would be achieved.

Table 2. The predicted spectral acceleration associated with different limit states and case study buildings

Location	Approach	EBF			RF		
		1%	2%	3.5%	1%	2%	3.5%
CHCH	Eq. (2)	0.58	1.10	1.82	0.53	0.9	1.37
	MSA	0.63	1.30	1.90	0.54	0.98	1.40
	'b'=1	0.57	1.15	2.01	0.56	1.13	1.97
WELL	Eq. (2)	0.58	1.10	1.82	0.53	0.9	1.37
	MSA	0.58	1.12	1.74	0.54	0.92	1.31
	'b'=1	0.57	1.15	2.01	0.56	1.13	1.97

The probability of exceeding limit state is required to compute the system APOE, as illustrated by Eq. (1). Using the obtained MSA results for each building and corresponding limit state a fragility curve is fitted using an optimization algorithm proposed by Baker [15]. Figure 8, and Figure 9, depict the fragility curves associated with different limit states for the EBF and RF systems located in Christchurch and Wellington, respectively.

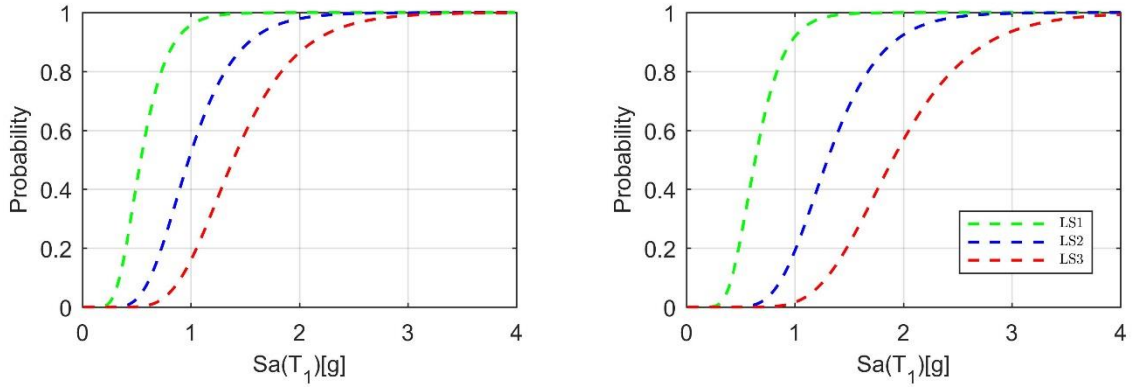

Figure 8.The achieved fragility curves corresponding to (left) rocking frame and (right) eccentric braced frame located in Christchurch

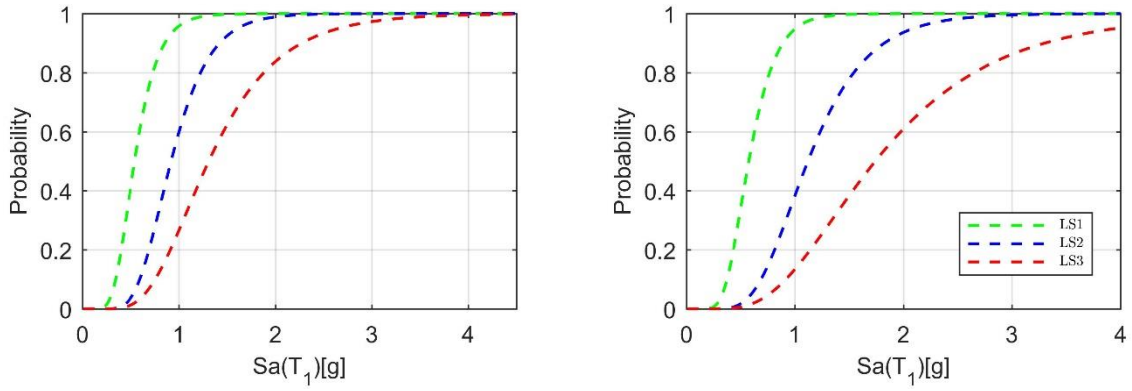

Figure 9. The achieved fragility curves corresponding to (left) rocking frame and (right) eccentric braced frame located in Wellington

4 COMPUTATION OF THE ANNUAL PROBABILITY OF EXCEEDANCE LIMIT STATE (APOE)

The APOE is computed combining each fragility curve with the corresponding hazard curve. The computed APOE following the aforementioned procedure is compared later with that found applying the simplified SAC/FEMA approach. The APOE is computed based on the achieved results in the previous section. This will provide a benchmark to assess the accuracy of the SAC/FEMA approach in two different cases: (a) assuming 'b=1' and (b) proposed 'b' values within Eq. (6).

The APOE computation approach via the MSA results is referred to here as the rigorous method. Following the rigorous approach, the generated fragility curves for each case study building are combined with the associated hazard curve adopting a numerical solution to evaluate Eq. (1), and the obtained APOE is reported in Table 3. It is detected that the APOE associated with Wellington case study building is larger than Christchurch, which is in line with difference between the two site locations' associated hazard. Further, the achieved APOE is larger for the RF case study building as the Flag-shape system dissipates less energy than the Bilinear system.

Table 3. The achieved APOE based on MSA results associated with different limit states and site locations

LS	Ductility	CHCH-EBF	CHCH-RF	WELL-EBF	WELL-RF
Drift	μ	$APOE_{LS}$	$APOE_{LS}$	$APOE_{LS}$	$APOE_{LS}$
3.50%	5.1	1.00E-04	4.50E-04	1.00E-03	1.50E-03
2.00%	2.9	5.30E-04	1.50E-03	1.90E-03	2.50E-03
1.00%	1.5	4.80E-03	7.20E-03	4.90E-03	5.40E-03

4.1 SAC/FEMA Approach

The SAC/FEMA methodology [1] is applied here to assess the performance of each case study building. The framework approximates the hazard curve using first order power law fit, adopting Eq. (5), as is illustrated by Figure 10. Further, the proposed closed form solution is applied to compute the system APOE regarding each limit state. This framework aggregates the probability of exceeding limit state with hazard function as presented by Eq. (2).

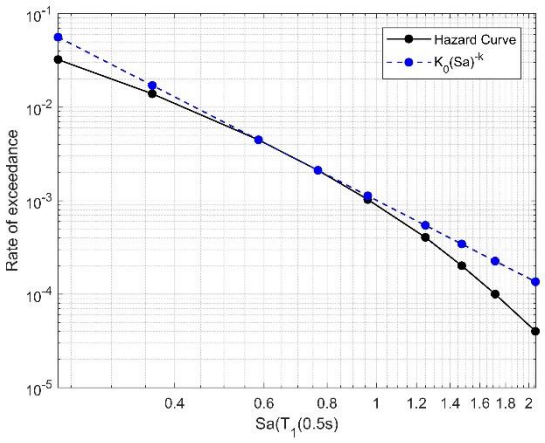

Figure 10. The hazard curve associated with Christchurch 0.5s, and the best fit curve using power law function

The proposed ‘b’ value affects the SAC/FEAM results in two different ways. First, more accurate prediction of the displacement demand is achieved through new IM-EDP relation, as was presented by Table 2. Second, a better estimation of C_f coefficient is yielded as elaborated by Eq. (3). Thus, the role of ‘b’ value on the uncertainty effect estimation in SAC/FEMA approach is investigated. To this end, the APOE is calculated for the buildings adopting simplified SAC/FEMA approach in two different cases. First, adopting Eq. (6) assuming ‘b’ equal 1; and second using the proposed ‘b’ values. Furthermore, to have a fair comparison, the MSA suggested dispersion and associated spectral acceleration values are adopted for the simplified method. Table 4 lists the parameters values used in the simplified method to quantify the APOE for each case study building and the target limit state. Table 5 presents the APOE found from the simplified methods adopting the aforementioned two cases assumptions.

Table 4. The adopted parameters to assess SDOF (T=0.5s) performance at different limit states

	1.0%	1.11	4.9e-3	1.09	4.8e-3	1.13	5.3e-3	1.10	5.2e-3

Table 6 compares the results achieved from MSA, and SAC/FEMA framework based on two different proposed 'b' values as elaborated in previous section for each site location. It is detected that the accuracy of the SAC/FEMA approach has improved for all limit states and both structural systems. Furthermore, the accuracy improvement seems stable although the site location varies. The accuracy improvement of SAC/FEMA in both levels, IM-EDP and APOE estimation, have been achieved remembering the estimated intensity measure associated with exceeding different limit states displayed in Table 2.

5 CONLUSION

This paper improves the accuracy of the SAC/FEAM approach by refining the IM-EDP relationship and uncertainty estimation through updated 'b' values. The accuracy of Eq. (6) assuming *'b'* equal to one has been trialed for an extended range of SDOF systems with a range of versatile fundamental periods and hysteretic rules. Through this study, it becomes evident that assuming *'b'* equal to one might be deemed reasonable for displacement demand estimate of SDOF systems with period ranging between 1.5s and 3.0s and the Bilinear hysteretic model. However, it is not expected to generate an accurate performance prediction for the other period ranges and hysteretic rules. Consequently, it is concluded that the updated IM-EDP relationship is able to differentiate the expected performance for different structural systems, and also is applicable for different site locations. Further, the study shows that for simple case study buildings the estimated APOE is of comparable accuracy with that achieved from a more rigorous MSA approach. This implies that the improved SAC/FEMA framework could provide a reliable tool to quantify the structural performance. Further study is recommended to examine the uncertainty in capacity, and its effect on structural performance assessment.

Abstract

A performance-based hybrid force-displacement (HFD) seismic design method is proposed for three types of reinforced concrete structures, i.e., moment resisting frames, frame with infills and wall-frame dual systems. HFD is a force-based method which controls with high accuracy both structural and non-structural deformation limits, since, both limits are input variables for the initiation of the design. This is accomplished by constructing explicit empirical expressions for a behavior (strength reduction) factor, which incorporates target non-structural and structural deformation metrics such as inter-storey drift ratio and member plastic rotation. Use of this factor in conjunction with an elastic acceleration spectrum can produce designs in one-step, by just conducting a strength checking, since the deformation restrictions are automatically satisfied. Those expressions for the behavior factor in terms of target deformation metrics, number of storeys, column to beam strength ratios, beam to column and column-to-wall stiffness ratios, respectively, are derived through extensive parametrical studies involving non-linear dynamic analysis of the above appropriately modeled structures under 100 ground motions scaled for different deformation targets. The proposed HFD method is demonstrated and validated with realistic design examples, which show its advantages over the force-based design method of the European seismic design code, Eurocode 8.

1 INTRODUCTION

The force-based seismic design (FBD) method has been adopted by almost all current codes or standards, e.g., EC8 [1] or FEMA-450 [2]. The FBD accomplishes the design in two steps, firstly by strength checking under the design forces and secondly by deformation checking at the end of the design process. Displacements are determined by the equal displacement rule which usually underestimates them [3-5]. Moreover, the assumption of a reduced by 50% member gross stiffness to account for cracking, which is usually made in all codes, e.g., EC8[1], results to smaller and hence unconservative displacements compared to the more accurate one coming from the secant stiffness to yield assumption [6, 7].

During the last 25 years or so, a new seismic design philosophy called performance-based design (PBD) has emerged, with the goal of achieving a desired structural performance at various seismic action levels [7-9]. Displacements are intimately related to damage, and hence, displacements rather than forces control the damage or performance of a structure during the earthquake, which indicates that displacements are better design parameters than forces.

Contrary to the FBD, displacement-based design (DBD) methods and in particular the direct DBD [7] which employs displacements as the basic design parameters, can effectively control the damage by determining the required strength and stiffness so that displacement restrictions are satisfied [6]. This is done by using a target value of deformation as an input variable in the design procedure to effectively control damage and determine the necessary stiffness with the aid of a displacement design spectrum with high values of damping. Furthermore, the direct DBD does not require an assumption about the member stiffness, since it uses the well-defined and more appropriate secant stiffness to yield. However, the direct DBD method presents some shortcomings: a) it is based on a substitute single degree of freedom (SDOF) representation of the building which lowers the modeling accuracy, b) it imposes limits only on drift demands which are mainly capable to measure non-structural damage and not appropriate for structural damage, c) engineers are not familiar with the displacement design spectrum used by this method and d) almost all the current commercial structural design software packages have implemented the FBD method rather than the DBD method. Other types of DBD methods can be found in the works of Chopra and Goel [10] and Panagiotakos and Fardis [11]. Moreover, one can refer to [12] where eight DBD methods are studied and their limitations are identified through their application to realistic design examples.

Recently, the hybrid force/displacement (HFD) seismic design method, which follows the PBD philosophy, has been developed for steel plane and space frames by Karavasilis at al [13] and Tzimas et al. [14,15]. This method appropriately combines advantages and eliminates or reduces disadvantages of both FBD and DBD seismic design methods. Thus, the HFD 1) is essentially a force-based seismic design method working with acceleration response/design spectra, thereby retaining familiar concepts to engineers and compatibility with all commercial structural design software packages and 2) utilizes a behavior (strength reduction) factor, which is deformation-dependent and takes into account structural and non-structural deformation limits. Thus, the design process is accomplished in only one step (strength check), since the second step (deformation check), in contrast to the FBD method, is automatically satisfied. Besides, the HFD method does not employ a substitute SDOF structure and does not require the use of displacement response/design spectra as is the case with the direct DBD method.

In this work, the HFD method is extended to the seismic design of reinforced concrete (RC) plane structural systems, i.e., moment resisting frames (MRFs), infilled MRFs (I-MRFs) and wall-frame dual systems (WFDS), in an effort to provide an alternative seismic design method for these

three types of RC structures under the framework of performance-based design. The main tool in this method is a behavior (strength reduction) factor q, which depends on the geometrical and material characteristics of the structure as well as on the structural (member plastic rotation θ_{pl}) and non-structural (interstorey drift ratio IDR) deformation, the soil class and the performance level.

For the purpose of this work, 19 RC-MRFs, 19 WFDS and 19 I-MRF with a wide range of dynamic and mechanical characteristics are studied. The frames are designed on the basis of EC8 [1] and EC2 [16] and analysed through Non-Linear-Time-History/Incremental Dynamic Analysis (NLTH/IDA). A total number of 100 ordinary (far-fault) ground motions (25 for each soil type A, B, C, D as categorized by EC8[1]), appropriately scaled to capture different deformation targets, are used to study the response of the above RC structures. In the proposed HFD method, displacements are not affected by the code-based assumption of the reduced by 50% stiffness as they are in the case of the FBD. This is because the HFD method is constructed based on member stiffness equal to secant stiffness to yield.

In conclusion, a response databank is obtained with the execution of more than 65000 NLTH/IDA analyses and four empirical relations, linking the behavior factor to structural and non-structural deformation limits, are constructed through nonlinear regression analyses. These are the following: a) an expression that estimates the roof displacement at the first yield ($u_{r,y}$), b) a relation that connects the design roof displacement ductility ($\mu_{r,d}$) with the behavior (strength reduction) factor (q), c) a relation that correlates the maximum inter-storey drift ratio (IDR) with the roof displacement (u_r) and d) a relation that connects the maximum plastic rotation (θ_{pl}) with the roof ductility (μ_r). Some parameters regarding structural characteristics, such as the number of storeys and the column-to-beam strength ratios, beam-to-column and wall-to-column stiffness ratios, respectively, and the thickness and elastic modulus of infilled wall panels are also correlated with these relations. By applying the proposed empirical expressions in the framework of the HFD method, one can easily conduct performance-based seismic design for RC-MRFs, I-MRFs and WFDSs in one step involving only strength checking since deformation requirements are automatically satisfied by using a deformation dependent behavior factor.

A comparison of the proposed HFD method with the FBD method adopted in EC8 [1] is made on the basis of realistic design examples. The results of non-linear dynamic analyses demonstrate the advantages of the HFD seismic design method over the FBD method of EC8 [1].

2 THE HFD SEISMIC DESIGN METHOD

Having in mind the stepwise design framework of the HFD method for plane steel MRFs in [14], one can extend it here to RC-MRFs, I-MRFs and WFDSs as follows:

Step 1: Selection of performance objectives. The target performance metrics, i.e., IDR and θ_{pl} for the in-plane non-structural and structural damage, respectively, are selected according to the desired performance objectives and structural system. The performance levels are assumed here to be the immediate occupancy (IO) under the frequently occurred earthquake (FOE), the life safety (LS) under the design basis earthquake (DBE) and the collapse prevention (CP) under the maximum considered earthquake (MCE). The target values used to describe these performance levels for RC-MRFs, I-MRFs and WFDSs are shown in Table 1 [17-19]. For I-MRFs, the in-plane damage of infilled walls mainly controls their design, thus, only the maximum inter-storey drift ratio (IDR) is used here as the target performance metric.

RC-MRF and WFDS						IMRF		
IO		LS		CP		IO	LS	CP
IDR	θ_{pl}	IDR	θ_{pl}	IDR	θ_{pl}	IDR	IDR	IDR
1%	0.01	2%	0.02	4%	0.025	0.4%	0.8%	1.5%

Table 1: Representative performance-based target deformation values for RC-MRF, I-MRF and WFDS.

Step 2: Initial design of structures and estimation of input variables. RC structures are initially designed according to the EC8[1] and EC2[16] under the FOE with a behavior factor q =1. An initial estimation of some characteristic variables is done during this step. These variables are the column-to-beam strength ratio α, the beam-to-column and column-to-wall stiffness ratio ρ and γ, respectively, defined as

$$a = M_{RC,1,av}/M_{RB,av}$$
$$\rho = \frac{\Sigma(I/L)_b}{\Sigma(I/L)_c} \quad (1)$$
$$\gamma = \frac{\Sigma(I_c)}{\Sigma(I_w)}$$

where $M_{\mathrm{RC,1av}}$ is the average of the plastic moments of resistance for the first storey columns, $M_{\mathrm{RB,av}}$ is the average of the plastic moments of resistance for all beams of all storeys, I is the second moment of inertia at the storey closer to the middle height of the frame and L is the corresponding length (column c, beam b or wall w).

Step 3: Calculation of the behavior factor, q. The behavior factor q is calculated through a two-step process: 1) the target performance metrics (IDR, θ_{pl}) are transformed to the corresponding values of target roof ductility μ_r using a proposed expression and 2) the behavior factor q is determined by a proposed expression in terms of the design roof displacement ductility $\mu_{\mathrm{r,d}}$. The derivation of those expressions will be illustrated in detail in the next section.

Step 4: Iterative design of the structure. The structure is designed using the calculated behavior factor q in conjunction with the elastic design acceleration spectra of EC8 [1]. Thus, the values of α, ρ, γ, $\mu_{r,d}$ and q are updated. The iterative design procedure is continued until the updated behavior factor q do not significantly change from the previous one.

3 DERIVATION OF THE PROPOSED EMPIRICAL EXPRESSIONS

In order to develop the above mentioned empirical expressions of the HFD method, 19 RC-MRF, 19 I-MRFs and 19 WFDSs were designed according to EC8 [1] and EC2 [16] and analyzed through NLTH/IDA analyses under 100 ordinary (far-fault) ground motions selected from PEER [20] and scaled in such a way as to capture the desired deformation or performance levels. Thus, a response databank was obtained from which the proposed empirical expressions were derived through non-linear regression analyses. The details of the derivation procedure are illustrated through the following sections:

3.1 Design and modeling of RC structures

3.1.1 Design of RC structures

19 RC-MRFs, 19 I-MRFs and 19 WFDSs with a number of stories ranging from 2 to 20 were designed according to the EC8 [1] and EC2 [16] with the help of SAP2000 [21] and MATLAB

[22]. All the structures were designed based on a three-dimensional (3-D) model with regular arrangement of structural elements in both plan and elevation, i.e., three (or four for WFDS) bays of 6 m length in both horizontal directions, and a storey height of 3 m. The live load (Q) was assumed to be 2 kN/m^2, while the dead loads (G) were directly calculated by SAP2000 [20] according to the material properties and structural geometry. The additional dead load from the infill wall panels was assumed to be 10.5 kN/m and was distributed on beams. The material properties selected for the design of the RC frames were C25/30 for concrete and S500 for reinforcing steel. The concrete weight density was taken as 23.5 kN/m^3 and Young's modulus of the steel as 200 GPa. Material safety factors of 1.50 and 1.15 were used for the concrete and steel reinforcement, respectively. The seismic loads (E) were produced by the design spectrum of EC8 [1] with a peak ground acceleration a_g = 0.30g (where g denotes the acceleration of gravity, 9.81 m/sec^2), soil type B and behavior factor q = 3.9 for the RC-MRFs and I-MRFs and q = 3.6 for the WFDS, as suggested by EC8 [1] for medium ductility class (DCM). The combinations of loads used for the design were 1.35G+1.5Q and ±E +G+0.3Q for static and dynamic design loads, respectively. The middle two-dimensional (2-D) frames were isolated from the three-dimensional (3-D) frames by appropriately distributing the loads in order both models to have the same fundamental periods and modeled in Ruaumoko 2-D [23] software for conducting NLTH analyses. A typical 3-storey RC-MRF, I-MRF and WFDS are shown in Fig.1.

3.1.2 Modeling of beams, columns, walls and infills

In Ruaumoko 2D [23] software, all structural elements were modeled using a one component (Giberson) beam-element with concentrated hinges described by the modified Takeda hysteresis rule [23] at their both ends. Walls were modeled by a beam-column element with rigid zones at the floor level, plastic hinges at member ends and with uncoupled shear-moment behavior as suggested by [24]. The interaction between axial force and yield moment was taken into account for both columns and walls. The stiffness deterioration was considered for all members incorporating the modified Takeda hysteresis model, as shown in Fig. 2.a.

The ductility-based backbone curve model of Ruaumoko 2D [23], shown in Fig. 2.b, in conjunction with the empirical backbone curve of the moment M versus rotation θ given by [24] are used to model the strength degradation of a member. In Fig. 2.b, DUCT1 refers to the value of ductility where the strength degradation starts to occur and DUCT2 refers to the ductility at the end of the strength degradation [23] assuming here to be at M/M_y= 0.2. In order to consider the development of cracks in flexural structural members, the secant stiffness to yield is used as the effective member stiffness, i.e., $EI_{eff} = M_y/\phi_y$, where M_y is the yield moment and ϕ_y is the corresponding curvature at yielding.

The masonry infill panel of each bay of the I-MRFs is modeled as two equivalent pin-jointed compression diagonal struts that cross each other and placed concentrically across the diagonals of the frame, forming a concentrically braced frame system. The strut thickness t is the same as the infill wall, while its width, w is given as

$$w = dk\frac{c}{z}\frac{1}{(\lambda^*)^\beta} \tag{2}$$

where d is the diagonal length of the infill panel and c, k, z, λ^* and β are parameters referring to the mechanical and geometrical properties of the infill panel and the surrounding RC frame members and can be found in [25,26]. The envelope of the force – deformation relationship for the

equivalent diagonal strut is the one suggested by Panagiotakos and Fardis [27]. The geometrical and material properties of the infill panels used in this study are shown in Table 2, where the subscript 12 denotes the diagonal direction.

More details, regarding the design and modeling of the structures studied herein can be found in the work of Muho et al. [28, 29].

Items of geometrical and material properties	Values
Thickness	9cm/18cm
Compression strength f_c	2.5MPa
Shear strength f_v	0.3MPa
Modulus of elasticity at horizontal direction (E_1)	1375MPa/2000MPa
Modulus of elasticity at vertical direction (E_2)	3000MPa/2000MPa
Poisson ratio (v_{12})	0.15
Shear modulus (G_{12})	1300MPa/870MPa

Table 2: Geometrical and material properties of I-MRFs infill panels.

4 PROPOSED EMPIRICAL EXPRESSIONS

The proposed empirical expressions were derived through nonlinear regression analyses using the Levenberg-Marquardt algorithm of Matlab [22] in conjunction with the response databank. These relations apply only to frames with fundamental period T, column-to-beam strength ratio α, beam-to-column stiffness ratio ρ, column-to-wall stiffness ratio γ, thickness of the infill panel t and the infill modulus of elasticity at horizontal E_1 and vertical E_2 direction inside the range of these parameters defined by the frames used in this study and reading as follows: $0.549 \leqslant T \leqslant 4.414$, $1.142 \leqslant \alpha \leqslant 6.656$ and $0.151 \leqslant \rho \leqslant 0.887$ for RC-MRFs, $0.62 \leqslant T \leqslant 3.73$, $1.531 \leqslant \alpha \leqslant 8.927$ and $0.070 \leqslant \gamma \leqslant 0.451$ for WFDS and $0.23 \leqslant T \leqslant 1.79$, $1.279 \leqslant \alpha \leqslant 6.623$, $1.000 \leqslant E2/E1 \leqslant 2.182$ and $90mm \leqslant t \leqslant 180mm$ for I-MRFs.

4.1 Estimation of yield roof displacement $u_{r,y}$

The yield roof displacement, $u_{r,y}$ corresponds to the formation of the first plastic hinge in the frame. For RC-MRFs, I-MRFs and WFDSs, it can be estimated by the following proposed empirical expressions

$$\text{RC-MRF: } u_{r,y} = 0.04 \cdot n_s^{0.51} \cdot \rho^{0.08} \tag{3}$$

$$\text{I-MRF: } u_{r,y} = 0.018 \cdot n_s^{0.66} \cdot t^{0.28} \cdot \left(\frac{E_2}{E_1}\right)^{-0.61} \tag{4}$$

$$\text{WFDS: } u_{r,y} = 0.042 \cdot n_s^{0.36} \tag{5}$$

, respectively, where n_s is the number of stories, β is the beam-to-column stiffness ration, t is the thickness of the infill panel (in m), and E_1 and E_2 are the modulus of elasticity of infill walls along the horizontal and vertical direction, respectively. The mean, median and standard deviation of the ratio $u_{r,y,exact}/u_{r,y,app}$ are equal to 1.00, 0.98, 0.45, respectively for RC-MRFs, 1.00, 1.02, 0.30, respectively, for WFDSs and 0.98, 0.91, 0.89, respectively, for I-MRFs.

4.2 Estimation of q as a function of $\mu_{r,d}$

By analyzing the response databank of MRF, it was found that the structural characteristics and soil types have no significant effect on the relationship between the design roof ductility $\mu_{r,d}$ and the behavior factor q. The $\mu_{r,d}$ is equal to $\min(\mu_{r,IDR},\ \mu_{r,\Theta})$ with $\mu_{r,IDR}$ and $\mu_{r,\theta}$ computed as shown in the following subsections. Thus, the empirical q - $\mu_{r,d}$ relation for RC-MRFs as derived through regression analysis has the form

$$\begin{aligned} q &= 1 + 1.23\left(\mu_{r,d}^{1.07} - 1\right) \quad \mu_{r,d} \leq 3 \\ q &= 1 + 2.29\left(\mu_{r,d}^{0.75} - 1\right) \quad \mu_{r,d} > 3 \end{aligned} \tag{6}$$

estimates the q factor as a function of the maximum roof ductility μ_r with the mean, median and standard deviation of the ratio q_{exact}/q_{app} equal to 1.00, 0.97 and 0.21, respectively.

The empirical q - $\mu_{r,d}$ relation for WFDSs as derived through regression analysis has the form

$$\begin{aligned} q &= 1 + 0.83 \cdot \left(\mu_{r,d}^{1.32} - 1\right) \quad \mu_{r,d} < 3 \\ q &= 1 + 1.67 \cdot \left(\mu_{r,d}^{0.88} - 1\right) \quad \mu_{r,d} \geq 3 \end{aligned} \tag{7}$$

with the mean, median and standard deviation of the ratio q_{exact}/q_{app} equal to 1.00, 0.99, 0.21, respectively.

By analyzing the response databank of I-MRFs, the number of stories n_s was found to have a significant effect on the $q - \mu_{r,d}$ relation. Thus, the empirical equation obtained through regression analysis has the form

$$q = 1 + 1.21 \cdot \left(\mu_{r,d}^{0.73} - 1\right) \cdot n_s^{0.25} \tag{8}$$

with the correlation coefficient of exact and approximate values, the mean, median and standard deviation of the ratio q_{exact}/q_{app} equal to 0.83, 1.00, 0.97, 0.30, respectively.

4.3 Estimation of $\mu_{r,IDR}$ as a function of IDR

According to Karavasilis et al. [13], the roof displacement u_r for steel MRFs is indirectly connected with the maximum inter-storey drift ratio IDRby the expression $\beta = u_{r,IDR}/(H * IDR)$, where H is the total height of the structure and β is determined by regression analysis. Then the maximum roof displacement ductility is calculated by $\mu_{r,IDR} = u_{r,IDR}/u_{r,y}$ with $u_{r,IDR} = \beta\, H \times IDR$ and $u_{r,y}$ given by Eqs (3) and (5).

A study of the present response databank for RC-MRF and WFDS indicates that β can be expressed in the form

$$\text{RC-MRF: } \beta = 1 - 0.17 \cdot (n_s - 1)^{0.75} \cdot \rho^{0.07} \cdot \alpha^{-0.40} \tag{9}$$

$$\text{WFDS: } \beta = 1 - 0.18 \cdot (n_s - 1)^{0.61} \cdot \gamma^{0.36} \cdot \alpha^{-0.31} \tag{10}$$

, respectively, where the mean, median and standard deviation of the ratio $\beta_{exact}/\beta_{app}$ are equal to 1.00, 1.02, 0.33, respectively, for RC-MRF and 1.00, 1.03, 0.24, respectively, for WFDS.

For I-MRFs, the design roof displacement ductility $\mu_{r,d}$ was chosen to be directly related to the IDR, since it was found to have better correlation and smaller deviation than for the case through β as previously done for RC-MRF and WFDS. Thus, $\mu_{r,d}$ was found to be of the form

$$\mu_{r,d} = 1 + 1.75 \cdot n_s^{0.16} \cdot (1000 \cdot IDR)^{1.55} \cdot \left(\frac{E_2}{E_1}\right)^{0.88} \tag{11}$$

The mean, median and standard deviation of the ratio $\mu_{r,IDR,exact}/\mu_{r,IDR,app}$ resulted to be equal to 1.00, 1.00, 0.21, respectively.

4.4 Estimation of $\mu_{r,\theta}$ as a function of θ_{pl}

By analyzing the databank of RC-MRFs and WFDSs, the relation between the maximum roof displacement ductility $\mu_{r,max}$ and the maximum plastic rotation θ_{pl} was found to depend on the number of stories n_s and the column-to-beam strength ratio α. Thus, the empirical equation which represents the relation $\mu_{r,\theta}$ - θ_{pl} for RC-MRFs and WFDSs resulted to be of the form

$$\text{RC-MRF: } \mu_{r,\theta} = 1 + 0.12 \left(1000 \cdot \theta_{pl}\right)^{0.98} \cdot n_s^{-0.29} \cdot \alpha^{0.45} \tag{12}$$

$$\text{WFDS: } \quad \mu_{r,\theta} = 1 + 0.04 \cdot \left(1000 \cdot \theta_{pl}\right)^{1.19} \cdot n_s^{0.04} \cdot \alpha^{0.32} \tag{13}$$

, respectively, with the mean, median, and standard deviation of ratio $\mu_{r,exact}/\mu_{r,app}$ equal to 1.00, 0.97 and 0.29, respectively, for RC-MRF and 1.00, 1.00, 0.16, respectively, for WFDSs. Both Eqs. (12), (13) satisfy the physical constraint $\mu_r = 1$ for $\theta_{pl} = 0$ and serves to directly determine the roof displacement ductility μ_r given a maximum plastic rotation θ_{pl}, or vice versa.

For the case of I-MRFs the damage is controlled by the IDR and thus there is no need for establishing a corresponding μ_r - θ_{pl} relation.

5 NUMERICAL EXAMPLES

5.1 Design of RC-MRF

5.1.1 A ten-storey designed for LS under DBE and comparison with EC8

Two 10-storey RC-MRFs (Frames A and B) were designed for the LS level according to the proposed HFD method and the EC8 [1] design method, respectively, for α_g= 0.3g and soil class B. Both frames were designed assuming a 50% member gross stiffness reduction. Their sectional dimensions and reinforcement ratios are listed in Tables 3 and 4, where only sectional information for the first two and the last two storeys of the frames are provided due to space limitations.

The proposed HFD method was used to seismically design a ten-storey RC frame (Frame A) for soil class B, PGA_{DBE} = 0.3g and target values of 2% IDR and 0.02 θ_{pl}, which correspond to the LS level. The initial sectional dimensions and reinforcement ratios, shown in Table 3 (iteration 1), were obtained from only strength requirements under the FOE with peak ground acceleration assumed to be equal to 0.5×PGA_{DBE} = 0.15g and behavior factor q = 1.

According to Eq. (1), the values of ρ and α of the frame were equal to 0.41 and 2.45, respectively, while $u_{r,y}$ was found to be 0.121m from Eq. (3). These values serve as the initial estimation of the input variables of HFD in Step (2) of Section 2. Using IDR = 2.0%, n_s = 10, ρ = 0.41, α = 2.45 and u_{ry} = 0.121m, one can determine with the aid of Eq. (9) $\mu_{r,IDR}$=2.10. On the other hand, use of Eq. (12) with θ_{pl} = 0.02, n_s = 10 and α = 2.45 yields $\mu_{r,\theta}$ = 2.74. Thus, the design target roof displacement ductility is equal to min ($\mu_{r,IDR}$, $\mu_{r,\theta}$) = 2.09.

The behavior factor q was found from Eq. (6) to be equal to 2.5 and Frame A was designed again with spectrum analysis, ground acceleration PGA_{DBE}=0.3g and q=2.5. This led to a base shear of 531.7 kN and new sections and reinforcement as shown in Table 3 (iteration 2). The behavior factor did not change a lot until the second iteration. Thus, the design with respect to LS level is finalized.

The initial strength-based design (with q = 3.9) results, shown in the first part (design step 1) of Table 4 for Frame B designed according to EC8 [1], show maximum values for IDR and θ equal to 1.1% and 0.37, which are larger than their limit values of 1% and 0.2, respectively. Thus, an iterative design process led to the second part, not shown in Table 4 (design step 2), where IDR and the stability coefficient θ values resulted to be equal to 0.9% and 0.2, respectively, i.e., within their limit values. However, because the maximum value of θ equals 0.2, the design seismic actions were multiplied by 1/(1−q) = 1.25 to account for second order effects in accordance with EC8 [1]. This led to larger reinforcement ratios in the third part (design step 3) of Table 4. From the above procedure, it can be seen that in order to design a structure to comply both with the strength and deformation limits, many iterations need to be done.

Table 3: Sectional dimensions and reinforcement ratios of each iteration for Frame A.

In order to evaluate the applicability of the proposed HFD method to the design of a ten-storey frame, nonlinear dynamic analyses of the Frames A and B under 25 accelerograms compatible to EC8 [1] elastic spectrum for the FOE (IO) and DBE (LS) were conducted. Table 5 shows NLTH analysis deformation results and the corresponding estimated values by the two design methods as well as the deformation limits values of FEMA [17] for IO and LS levels.

Table 4: Sectional dimensions and reinforcement ratios of Frame B.

HFD (Frame A)				
Response Values	FOE (IO level)		DBE (LS level)	
	NLTH	Estimation HFD	NLTH	Estimation HFD
IDR (%)	1.10	1.18	2.02	2.00
θ_{pl}	0.001	0.002	0.013	0.012
EC8 (Frame B)				
Response Values	FOE (IO level)		DBE (LS level)	
	NLTH	Estimation EC8	NLTH	Estimation EC8
IDR (%)	1.13	0.92	2.19	1.84
θ_{pl}	0.002	-	0.014	-

Table 5: Non-linear dynamic analysis deformation results for Frames A and B and comparison with estimated values by the HFD and EC8 methods; NLTH stands for nonlinear time history analysis.

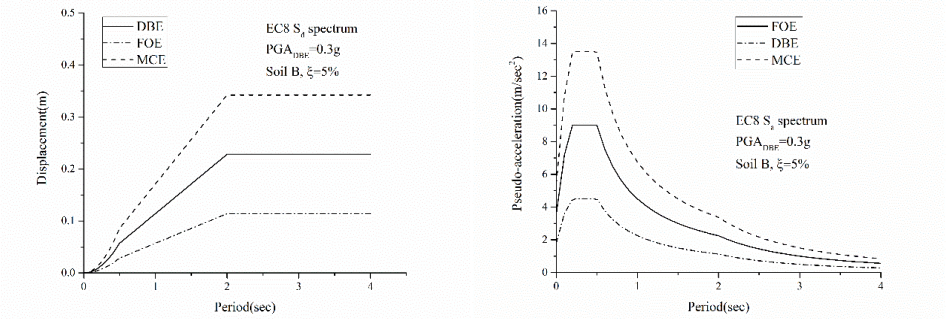
On the basis of the response values of Table 5 the following observations can be made:

1) Even though IDR estimates of Frame B (designed by EC8 [1]) computed by the equal displacement rule do not exceed the limits of 1% and 2% for the IO and LS levels, respectively, the realistic IDR values obtained by NLTH analyses are non-safe sided and exceed the above limit values by 13% and 10%, respectively.
2) IDR estimates of Frame A (designed by HFD) are almost the same with the realistic IDR values obtained by NLTH analyses for both IO and LS levels and the IDR estimate for the LS level does not exceed the limit values of 2%. The IDR value for the IO level though exceeds the limit value of 1% by 10%. However, this result presents no problem since Frame A was designed by HFD method only for LS level and not for both LS and IO level as it is the case of Frame B designed by the EC8 [1] method. In a performance-based design framework, use of the HFD method considers more than one performance level and satisfies all deformation requirements for those levels. In Section 5.1.2 where the HFD method is used in a performance-based design framework with three performance levels to design again the ten-storey frame of this example, one can observe that all deformation requirements are satisfied for all three levels, including the IO level.
3) Estimates of θ_{pl} values for Frame A are almost the same with the realistic θ_{pl} values obtained by NLTH analyses and also do not exceed the limit values of 0.01 and 0.02 for both the IO and LS levels, respectively. Considering Frame B, only one of its beams is exceeding the allowable θ_{pl} value of LS by 4%. Estimates of θ_{pl} values cannot be made by the EC8 [1], and for this reason, there are no corresponding θ_{pl} values in Table 5.

Furthermore, from the procedural viewpoint, one can observe that the number of iterations during the HFD-based design was small, i.e., only two, as shown in Table 5. This fast convergence process is an advantage of the HFD method over the EC8 [1] method, which usually requires many iterations for its deformation check.

5.1.2 A performance-based seismic design

In this section, the ten-storey RC-MRF (Frame A) was re-designed by the HFD method for the three performance levels of Table 1. The peak ground acceleration for the DBE (PGA_{DBE}), was equal to 0.3g. The peak ground acceleration for the FOE and MCE are equal to $0.5\times PGA_{DBE}$ = 0.15g and $1.5\times PGA_{DBE}$ = 0.45g, respectively. The FOE, DBE, and MCE are expressed through the elastic displacement and pseudo-acceleration design spectra of EC8 [1] for soil class B and damping ratio equal to 5% (Fig.3).



(a) (b)

Figure 3: (a) Elastic displacement design spectrum and (b) elastic pseudo-acceleration design spectrum, defined by EC8 [1].

The design for the three performance levels starts with the LS level. The seismic design of the ten-storey frame for the LS level by the HFD method has been presented in detail in section 5.1.1 (Frame A). The q factor of the frame under the FOE is easily obtained as (PGA_{FOE}/ PGA_{DBE})*q_{DBE}=0.5*2.5 ≈ 1.3, where the value of q_{DBE} = 2.5 is from iteration 2 of Table 3. Substituting this value of q=1.3 into Eqs. (6), (9) and (12), the response of the frame under the FOE can be obtained, i.e., $u_{r,d}$ = 0.151m, IDR=1.20% and θ_{pl} = 0.002, indicating that the limit value of IDR=1% for the IO level (Table 1) is exceeded. Correspondingly, $u_{r,d}$, IDR and θ_{pl} of the frame under the MCE are, 0.369m, 2.89%, and 0.022, respectively, which satisfy the CP level limits (Table 1). Therefore, the IO performance level controls the design of the frame. The design procedure for the IO performance level is summarized in Table 6, by taking the final sections of the LS level as the initially assumed sections. The behavior factor would not change a lot until the second iteration. Thus, the design with respect to IO level is finalized.

5.2 A WFDS designed for three performance levels

In this section, a four-storey WFDS named Frame C is designed by the proposed method for the three performance levels of Table 1. The PGA for the FOE (IO level), the DBE (LS level) and the MCE (CP level), over the PGA of DBE are 0.5, 1 and 1.5, respectively [9], where the PGA at DBE was selected to be 0.30g. The design is initiated with the LS level. The sectional dimensions, reinforcement ratios and relative design parameters for Frames C designed for LS level are summarized in Table 8.

The q factor under the MCE is easily obtained as $(PGA_{MCE}/PGA_{DBE}) * q_{DBE} = 1.5 * 3.6 = 5.4$, where $q_{DBE} = 3.6$ is given in Table 8. With $q_{MCE} = 5.4$ known, the roof ductility $\mu_{r,d}$ is found from Eq. (7) to be equal to 4.18. By substituting this value of $\mu_{r,d} = 4.18$ into Eq. (10) and Eq. (13), the maximum values of IDR and θ_{pl} are estimated to be equal to 3.55% and 0.030, respectively. Thus, the CP level limit value of $\theta_{pl} = 0.025$ according to Table 1, is exceeded, which indicates that the CP level controls the design of Frame C. The design procedure for the CP level is summarized in Table 9 by assuming the initial sections to be the same as those of the LS level shown in Table 8. The design with respect to the CP level is finalized within two iterations and it complies with all three performance levels, i.e., IO, LS and CP.

Table 9: Sectional dimensions and reinforcement of each iteration for Frame C designed for three performance levels

The response results for IDR and θ_{pl} and their comparison with the corresponding limit values from Table 1 and the estimated values by the HFD method are shown in Table 10. From this table, one can observe that both IDR and θ_{pl} are below the corresponding limit values of all three

performance levels. Besides, the estimated values are almost the same as the "exact" values obtained from NLTH analyses. Thus, the proposed HFD method can be successfully used for the performance-based seismic design of WFDSs.

	IO				LS				CP			
	NLTH	Limit	Estimation	Check	NLTH	Limit	Estimation	Check	NLTH	Limit	Estimation	Check
IDR(%)	0.86	1	0.92	OK	1.69	2	1.64	OK	2.43	4	2.49	OK
θ_{pl}	0.000	0.01	0.004	OK	0.009	0.02	0.015	OK	0.019	0.025	0.025	OK

Table 10: Nonlinear time history (NLTH) analysis results of Frame C designed by HFD for three performance levels and comparison with limit values.

5.3 An I-MRFs designed for three performance levels

Next, a four-storey I-MRF Frame D is designed for three performance levels as the WFDS of the previous section but with the corresponding target IDR values of Table 1 for I-MRFs.

The design is initiated with the LS level. The sectional dimensions, reinforcement ratios and relative design parameters for Frames D designed for LS level are summarized in Table 11, where only the final sectional information for the first two and the last two storeys are provided due to space limitations.

E_1(MPa)	E_2(MPa)	$\mu_{r,IDR}$	a_g(g)	q	Column	h(cm)	R_c	Beam	h(cm)	R_1^*	R_2	R_3^*	R_4
1375	3000	3.4	0.3	3.5	1	50	1.64%	5	50	1.48%	1.29%	1.49%	1.29%
					2	55	1.63%	6	50	1.46%	1.27%	1.46%	1.27%
					8	50	1.14%	12	50	1.49%	1.29%	1.49%	1.29%
					9	55	1.44%	13	50	1.46%	1.27%	1.46%	1.27%
					15	45	1.23%	19	45	1.34%	1.13%	1.34%	1.15%
					16	50	1.32%	20	45	1.34%	1.13%	1.34%	1.13%
					22	45	1.10%	26	45	0.67%	0.51%	0.77%	0.58%
					23	50	1.09%	27	45	0.72%	0.58%	0.72%	0.58%

Table 11: Sectional dimensions and reinforcement ratios of Frame D.

For the CP level, the q factor under the MCE is easily obtained as $(PGA_{MCE}/PGA_{DBE}) * q_{DBE} = 1.5 * 3.5 = 5.25$, with $q_{DBE} = 3.5$ as shown in Table 11. With $q_{MCE} = 5.25$ known, the roof ductility $\mu_{r,d}$ is found from Eq. (8) equal to 5.53. By substituting this value of $\mu_{r,d} = 5.53$ into Eq. (11), the maximum value of IDR = 1.19 is estimated, which satisfies the CP level limit value of IDR = 1.5% according to Table 1. Thus, here the LS level controls the design of Frame D and the final sectional dimensions and reinforcement ratios which satisfy all three performance levels are the same as the ones of the LS level (Table 11).

Finally, the response results from NLTH analyses under the 25 ground motions compatible to EC8 [1] elastic spectrum for the IO, LS, and CP levels and the response predictions according to the proposed equations are shown in Table 12. From that table, one can observe that the "exact" IDRs obtained from NLTH analyses are below the corresponding limit values of all three performance levels. Besides, the estimated values are almost the same as the realistic ones. Thus, the proposed HFD method can be successfully used for the performance-based seismic design of I-MRFs.

	IO				LS				CP			
	NLTH	Limit	Estimation	Check	NLTH	Limit	Estimation	Check	NLTH	Limit	Estimation	Check
IDR(%)	0.26	0.40	0.34	OK	0.71	0.80	0.80	OK	1.12	1.5	1.19	OK

Table 12: Nonlinear time history (NLTH) analysis results of Frame D for three performance levels and comparison with limit values.

6 CONCLUSIONS

Based on the results of previous sections, the following conclusions can be stated:

1. The hybrid force/displacement (HFD) seismic design method for RC structures has been successfully developed through extensive parametrical studies involving non-linear-time-history/incremental dynamic analyses of 19 RC-MRFs, 19 I-MRFs and 19 WFDSs under 100 seismic motions.
2. The HFD appropriately combines advantages of both force-based and displacement-based seismic design methods. It is a force-based design method working with acceleration response/design spectra and a deformation-dependent behavior (strength reduction) factor and it performs design in one step involving only strength checking.
3. The proposed empirical expressions can estimate the yield roof displacement, the roof displacement ductility as a function of IDR and θ_{pl} and the behavior (strength reduction) factor as a function of the roof displacement ductility.
4. The HFD method was proven, through numerical examples, to accurately estimate and control both structural and non-structural damage and hence to be successfully used as a full performance-based seismic design method, while, at least at the present time, this is not the case with the EC8 method.

Abstract

A project named PERSISTAH is being developed to study the seismic vulnerability of primary schools in Huelva (Spain) and the Algarve (Portugal). This area has a moderate seismicity but this is affected by a nearby area where earthquakes of large magnitude (Mw≥6) and long-return periods happen.
The seismic vulnerability of URM (UnReinforced Masonry) buildings has been observed and analysed in the last decades. The seismic retrofitting of these buildings is required in order to improve their seismic behaviour. Many retrofitting techniques have been developed for that purpose, most of them very complicated and expensive. Therefore, these are not appropriate to retrofit a large number of buildings. This is especially relevant in areas of moderate seismicity where the cost-efficiency ratio must be carefully considered.
The aim of this paper has been to develop a simple, effective and affordable technique to retrofit these buildings. These buildings are characterised by numerous openings which causes a great weakness in the URM walls. Then, a technique that consists in installing a steel encirclement or a grille in the openings of the walls has been proposed. This is a specific retrofitting technique for URM walls since this technique substantially improves the seismic capacity of these structures.
To test the technique a case study is proposed. The building under study is a primary school located in Huelva and built in 1961. Results have shown that the capacity of the building is notably increased. Also, the performance point and the damage level of the structure are decreased.

Keywords: URM buildings, retrofitting technique, Performance-based method, seismic behaviour, nonlinear analysis.

1 INTRODUCTION

The south of the Iberian Peninsula (IP) has a moderate seismicity. This area is close to the borders of the Eurasian and African plates where many active faults exist. Specifically, the southwestern IP is affected by several faults such as the Gibraltar-Azores, the San Vicente Cape and the Horseshoe faults. These faults have originated in the past some important earthquakes like the Lisbon earthquake in 1755 (Mw=8.5) and the 1969 earthquake (Mw=8) [1][2].

The seismic risk in this area is being assessed in a project named PERSISTAH (*Projetos de Escolas Resilientes aos SISmos no Território do Algarve e de Huelva*, in Portuguese). This project is being developed collaboratively by the University of Algarve and the University of Seville due to the similar seismic hazard of both regions. The aim of this project is to minimize the disaster risk of school buildings in the regions of Andalucia (Spain) and Algarve (Portugal). In the PERSISTAH framework, a total amount of 281 schools will be evaluated in both regions. Most of them were built without any consideration of the seismic actions.

Approximately half of the school building stock have URM structures with load-bearing walls. URM buildings are especially prone to damage due to seismic actions. Its vulnerability has been observed and analysed in the last decades by many authors. Some studies have developed different methods to assess the seismic vulnerability of existing buildings. Usually, methods based on the capacity spectrum are used to characterize the vulnerability and fragility of the buildings [3]. The seismic performance analysis results show the damage level that a building would suffer in case of an earthquake. Moreover, it allows to identify the structural characteristics that reduce the vulnerability of the buildings. In some studies, the damage estimated for a specific structure pertaining to a given typology is considered as representative for the whole group of structures belonging to the aforementioned structural typology [4], as is the aim of the PERSISTAH project. These studies have concluded that a seismic retrofitting of the structure would be required in order to improve their seismic behaviour.

The most common retrofitting strategies used for masonry buildings are (a) reinforcement of connections (wall to wall, wall to floor or wall to roof), (b) transforming flexible floors into rigid diaphragms, (c) improving the out-of-plane behaviour through tied rods or ring beams, and (d) reinforcement of masonry panels. These techniques have been applied in numerous studies and they have resulted effective [5] [6] [7] [8]. The case study building has good connections and rigid floors, which makes the reinforcement of panels the most suitable reinforcement technique to improve its behaviour. The reinforcement of panels has been implemented by means of the addition of diverse materials: reinforced concrete, steel, fibre polymer, polypropylene, mortar renders or injections. These techniques are often complex to perform, non-reversible and expensive. Since the aim of the PERSISTAH project is to retrofit a large number of buildings, these techniques are not the best option.

The school buildings are characterised by numerous openings, which cause a substantial weakness in the URM walls in case of an earthquake. In fact, none of these buildings have been designed considering seismic loads, since they were built prior to any seismic code or with emerging and permissive codes. Therefore, they may not be capable of resisting these actions without being damaged. This work aims to study a simple, effective and inexpensive technique to retrofit these buildings, which consists in installing steel encirclements in the openings of the walls.

A recent paper has experimentally studied this technique by means of cyclically testing an specimen to failure [9]. The authors have concluded that the encirclements led to a significant increase in strength and in-plane deformation capacity, as well as in cumulative dissipated energy at collapse. Comparing a retrofitted wall to a solid masonry wall (without openings), they have stablished that the results were very similar, especially in terms of peak strength.

To test this reinforcement technique a case study was conducted. The building is a primary school building located in Huelva (Spain) and built in 1961. It is an E-shaped, two storied building, with clay brick URM load-bearing walls and ribbed floor slabs.

A seismic performance-based assessment based on the N2 method was carried out (section 2.2). Then, a damage assessment was performed (section 2.3). Next, six different variants of the reinforcement technique (encirclements) were studied. Three of them consist solely on adding an L-profile to the window border, and the other three include also different types of grilles covering the window surface (section 2.4). The results of the retrofitted building assessment are shown in section 3 and analysed in section 4. Finally, the conclusions are outlined in section 5.

2 METHOD

2.1 Case study

The building under study is a two-storied school building located in Huelva (Spain) and built in 1961. The plan has an E-shape with 45 m by 21 m as larger dimensions. The building is composed of the intersection of four lineal blocks. One of them is wider, with an entrance gallery, staircases and two classrooms. The other three blocks are narrower, only equipped with classrooms.

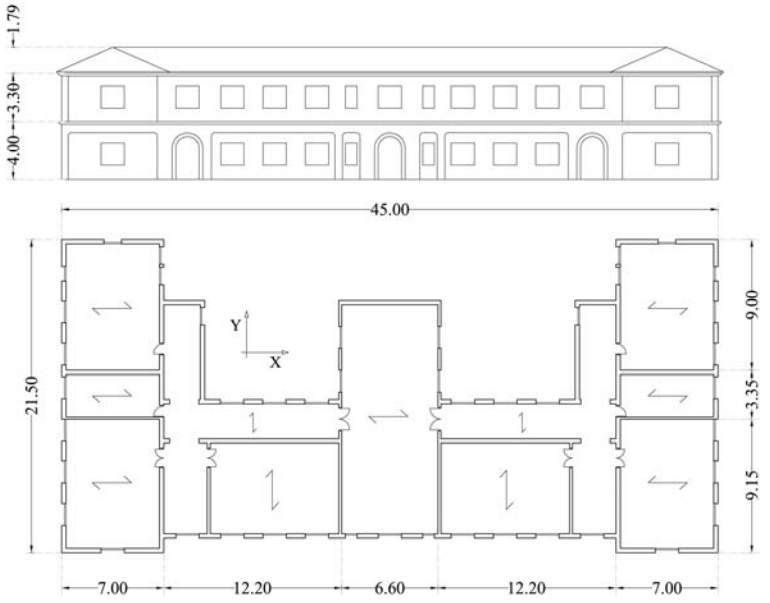

Figure 1: Architectural plans. Base floor (superior). Façade (inferior).

The structural system of the building consists of URM walls of clay brick and cement mortar. The walls have a thickness of 25 cm and a reinforced concrete ring beam on their top level. The floor structure is made up of ribbed floor slabs 25 cm thick. The foundation is a concrete beam on strip footings. The building has a sloping roof with tiles.

The load values used in the analysis were obtained from the Spanish building code [10]. For structural analyses, the dead load assigned to the ground and first floor was 5.3 kN/m^2 (including floor slabs, pavement and partition walls), and 6.3 kN/m^2 to the roof floor (including floor slab, and construction elements of the gable roof). The live load assigned to the school floors was 3 kN/m^2 (public use), and 1 kN/m^2 in case of the roof floor (maintenance).

The mechanical properties of masonry elements are typically available in the literature when these pertain to historical buildings. However, the mechanical properties of modern masonry elements are less likely to be found, as is the case of this building.

On one hand, these properties have been calculated using formulations from current codes as Eurocode 6 [11], and UIC Code 778-3 [12]. On the other hand, the data of the mechanical properties of brick clay and mortar have been obtained from project documents of similar construction dates (Table 1).

Mechanical properties	Value
Compressive strength (f_m) (MPa)	5
Shear strength (t_0) (MPa)	0.24
Young´s modulus (E) (MPa)	3,500
Shear modulus (G) (MPa)	875
Weight density (W) (kN/m^3)	15

Table 1: mechanical properties adopted for the brick masonry walls.

2.2 Seismic performance-based assessment

The URM structures have a non-linear behaviour due to their low tensile strength. Consequently, non-linear analyses must be used to evaluate them. [13]. In order to assess the seismic performance of buildings by means of nonlinear static analyses, the European code EC8-3 [14] recommends the N2 method. This method combines the pushover analysis with the demand spectrum. The displacement capacity of the structure and the seismic demand displacement must be intersected to obtain the performance point, which is the base parameter of the global seismic assessment [15]. The pushover analysis is a static non-linear analysis that consist of applying a horizontal incremental load until the collapse of the structure is reached. The result of this analysis is a capacity curve that represent the base shear with respect to the horizontal displacement of the control node, which is located on the top of the structure.

The masonry wall structure was modelled with the Equivalent Frame Model [16], using the Tremuri software [17]. In this model, the URM walls are divided in macro-elements to form an equivalent frame. The model is composed of piers and spandrel elements assembled through rigid nodes. The formulation used to model the elements is defined from the dissipative mechanism observed in real masonry structures affected by seismic actions. This model considers the possibility of flexural-rocking, shear-sliding and diagonal-cracking shear failure modes, allowing to simulate the non-linear in-plane behaviour of URM walls with acceptable accuracy [18].

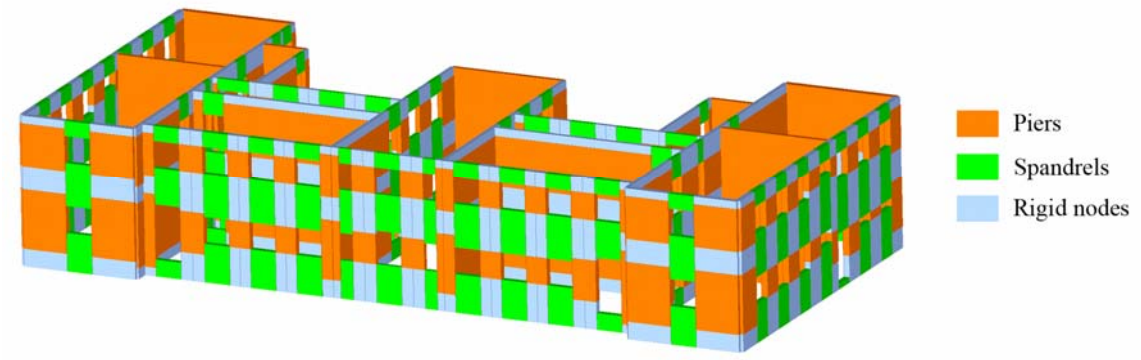

Figure 2: Three-dimensional view of the case study building model in Tremuri.

The seismic demand is defined in terms of a response spectrum, obtained from the EC8-1[19] and the Spanish annex [20]. The seismic action in Huelva is defined by the reference peak ground acceleration (a_{gR}) whose value is 0.12g according to the Spanish update of the seismic hazard maps [21]. Other parameters used to obtain the response spectrum are the importance factor and the soil coefficient. The importance factor depends on the use of the building. School buildings have an importance of class III, so the corresponding importance factor is 1.3. Regarding the soil coefficient, the type of soil has been defined from a geotechnical study performed in a near location. This study established that the soil is composed by a layer of silt-sand with medium-low compactness. According to the dynamic penetration test (DPSH) performed, the type of soil was determined as B, thus the corresponding soil coefficient is 1.2.

2.3 Damage assessment

The seismic performance of the reinforced buildings may be compared in terms of fragility curves. These curves describe the probability of reaching a given state of damage in a defined seismic scenario. The curves are defined by a lognormal function (Eq. 1) that expresses the probability of reaching or exceeding a defined damage state, given the spectral displacement.

$$P[d_s|S_d] = \Phi\left[\frac{1}{\beta_{ds}}\right]\ln\left(\frac{S_d}{\overline{S}_{d,ds}}\right) \quad (1)$$

Where S_d is the spectral displacement; d_s is the damage state; Φ is the standard normal cumulative distribution function; β_{ds} is the standard deviation of the natural logarithm of spectral displacement for damage state *ds;* and $\overline{S}_{d,ds}$ is the median value of spectral displacement at which a building reaches the threshold of damage state d_s.

The damage states considered according to the RISK-EU project (Eq. 2) are: slight damage ($S_{d,1}$), moderate damage ($S_{d,2}$), severe damage ($S_{d,3}$) and complete damage ($S_{d,4}$). The damage limit states were obtained from the idealised bilinear capacity curves. These states were defined by the yielding and ultimate displacements, as it is proposed in [22].

$$\begin{aligned} S_{d,1} &= 0.7\ S_{dy} \\ S_{d,2} &= 1.5\ S_{dy} \\ S_{d,3} &= 0.5\ (S_{dy} + S_{du}) \\ S_{d,4} &= S_{du} \end{aligned} \quad (2)$$

Then, the damage states probabilities were obtained by intersecting the fragility curves and the target displacements. Finally, the damage index (DI) or the mean damage value were calculated to represent the global expected damage in the structure with each reinforcement technique. The DI may be obtained from Eq. 3 [23]:

$$DI = \sum_{i=0}^{n} i \times P(d_{s_i}) \quad (3)$$

where n is the number of damage states, and $P(d_{si})$ is the probability that a damage state i occurs. The DI values range between 0 (no structural damage) and 4 (complete damage).

2.4 Strengthening technique

School buildings are usually characterised by numerous openings in the external walls. The presence of openings weakens the building under seismic action. Therefore, the reinforcement strategy chosen consisted in strengthening the openings, installing a steel encirclement in the building windows. A steel profile was fixed in the outer perimeter of the windows, with the possibility of adding a grille covering the whole surface of the window. The doors were not reinforced due to the difficulty of fixing the lower profile under the flooring. In any case, there are not as many doors as windows in these buildings. The advantages of this technique are that it is non-intrusive, easy to install (and remove) and cost-effective.

Six types of reinforcement were tested. The first three types consist on the installation of L-profiles of sizes L100.10, L150.10 and L200.15, respectively, on the windows perimeter (Figure 4a). The last three types are window grilles. Grille 1 includes an L100.10 profile in the perimeter and horizontal tubular profiles of 60x40 mm covering the windows surface (Figure 4b). Grille 2 combines a perimeter steel plate of 45x5 mm, horizontal 12 mm bars and two diagonal 12 mm bars (Figure 4c). Finally, Grille 3 was designed as the combination of a perimeter steel plate of 45x5 mm and seven diagonals 10 mm bars in both directions (Figure 4d).

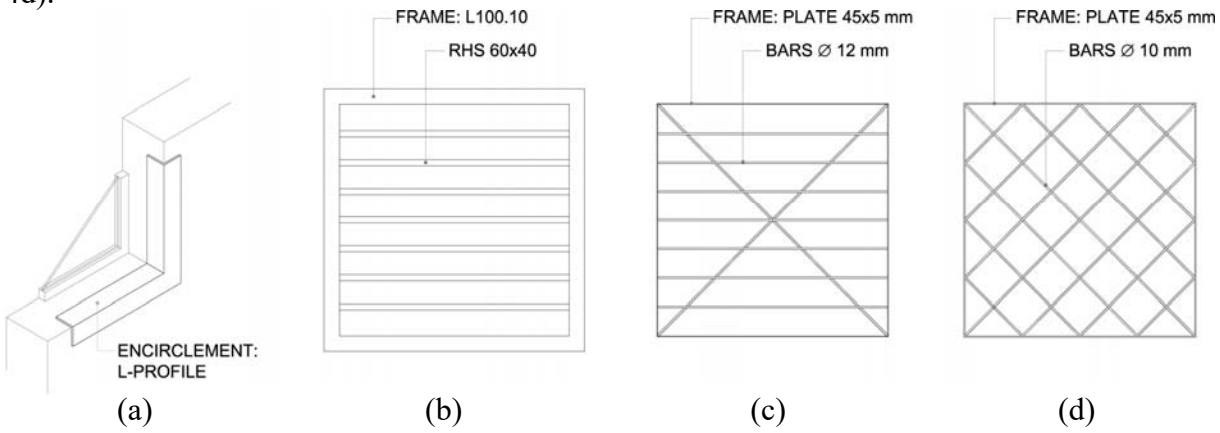

Figure 4: Reinforcements types: encirclements with L-profile (a), Grille 1 (b), Grille 2 (c) and Grille 3 (d).

The type of steel used in all reinforcements is S275JR steel both for profiles and bars. Their installation includes removing the windowsill, setting the encirclements or grilles (fixed with mechanical anchoring), and placing the windowsill back again. All six types of reinforcements integrate well with the architecture of the building.

The encirclements can be modelled in the Tremuri software, just setting this option in the window definitions. By contrast, the grilles are not included in the reinforcement library, but they can be simulated using an encirclement with equivalent rigidity. This equivalent encirclement was obtained applying a constant horizontal load to the grille and finding a profile which provided the same displacements.

3 RESULTS

3.1 Unretrofitted building

The results obtained from the seismic performance-based assessment of the unretrofitted building are presented hereafter. To obtain the capacity curves, a pushover analysis was performed in the two main orthogonal directions of the building (+X, -X, +Y and –Y), considering two lateral load patterns (uniform and triangular). Moreover, the existence or absence of an accidental eccentricity of 5% of the maximum size of the building (positive or negative)

was considered. A total of 24 different analyses were carried out and the worst-case combination for each direction was selected.

In Figure 3, it can be observed that the capacity curves in both directions X and Y are quite similar in terms of capacity. Regarding the ductility, defined by the ratio between ultimate and yielding displacements, the building presents a larger ductility in the X direction.

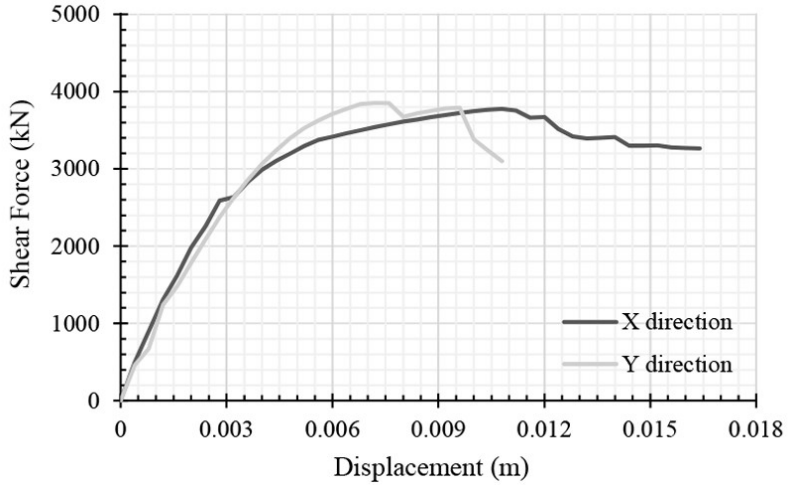

Figure 3: Capacity curves of the reference building in both directions X and Y.

After that, the performance points were calculated according to the N2 method. The main parameters used in the analysis are defined in the following paragraphs. Their values are summarized in Table 2.

	Γ	T^*(s)	μ	F_y^*/m^*(g)	q^*	$\mathbf{d_u^*/ d_t^*}$
X direction	1.20	0.24	3.34	2.47	1.72	**0.99**
Y direction	1.29	0.23	3.28	2.59	1.64	**0.70**

Table 2: Parameters and results of the analysis of the reference building.

Γ is the transformation factor, required to convert the parameters of the Multi Degree of Freedom (MDOF) system into an equivalent Single Degree of Freedom (SDOF) system and vice versa.

T^* is the period of the idealized equivalent SDOF system

μ is the ductility, the ratio between ultimate and yielding displacements.

F_y^*/m^* is the limited structural strength, the ratio between the ultimate strength and the mass of an equivalent SDOF system.

q^* is the ratio between the acceleration of the structure with unlimited elastic behaviour ($S_e(T^*)$) and the limited structural strength (F_y^*/m^*).

The results of the analysis, in terms of the ratio between ultimate displacement (d_u^*) and target displacement in the equivalent SDOF system (d_t^*) are also shown in table 2.

The ultimate limit state (ULS) safety verification according to the EC8-3 consist in checking that the ratio d_u^*/ d_t^* is higher than 1. It can be observed that this condition is not satisfied either in X or Y direction, although the results in Y are significantly worse. Non-compliance of the safety conditions indicated that the building required to be retrofitted.

3.2 Retrofitted building

Figure 5 shows the results of the pushover analysis in terms of capacity curves in X and Y directions for the retrofitted building (with all six types of reinforcements) and the unretrofitted building (reference building).

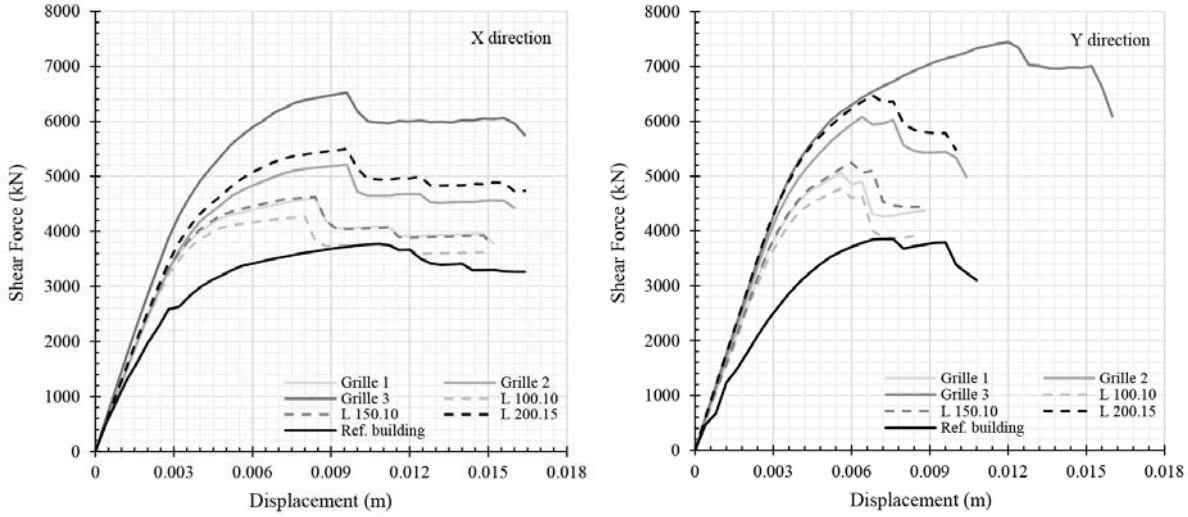

Figure 5: Capacity curves for each reinforcement technique, X direction (left) and Y direction (right).

As mentioned in the previous section, the performance points were obtained intersecting the capacity curves and the seismic displacement demand, as established in the N2 method. In Figure 6, the performance points of the reference and the reinforced buildings are shown.

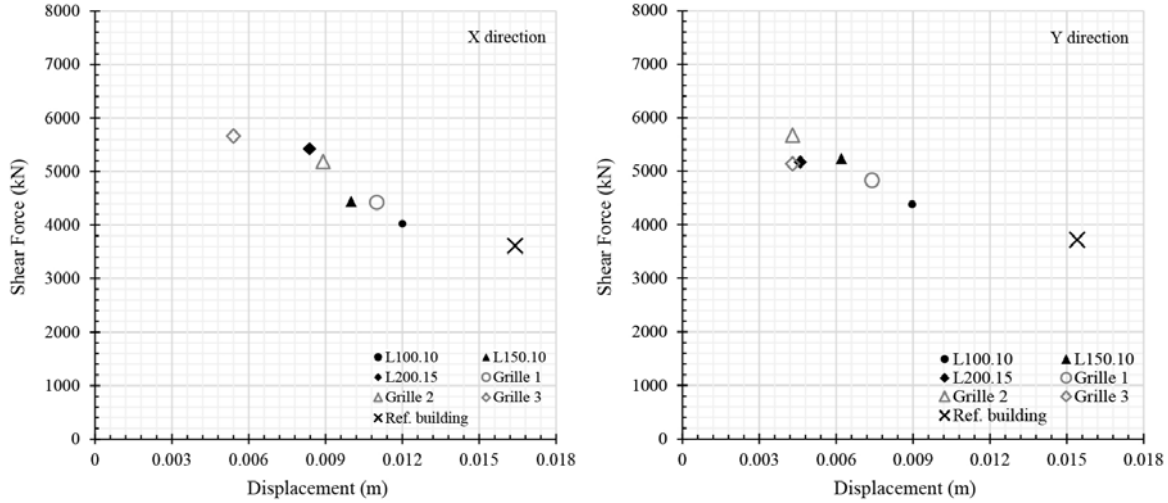

Figure 6: Performance point for each reinforcement technique in X (left) and Y direction (right).

In Table 3, the results of the N2 method are summarized. They are the target displacements (dt), obtained for the elastic response spectra defined in EC8-1; the yielding (dy) and ultimate (du) displacements. The ductility (μ) of each reinforcement type was calculated as the ratio d_u^*/d_y^*. Finally, the ratio d_u^*/d_t^*, that allowed to verify the ULS safety according to the EC8-3 was obtained.

		d_t^*	d_y^*	d_u^*	μ	$\mathbf{d_u^*/ d_t^*}$
X direction	Ref. building	1.37	0.40	1.36	3.40	**0.99**
	L100.10	1.00	0.31	1.23	3.97	1.23
	L150.10	0.90	0.34	1.26	3.71	1.40
	L200.15	0.69	0.41	1.35	3.29	1.96
	Grille 1	0.92	0.35	1.26	3.60	1.37
	Grille 2	0.76	0.42	1.32	3.14	1.74
	Grille 3	0.44	0.35	1.34	3.83	3.05
Y direction	Ref. building	1.19	0.36	0.83	2.31	**0.70**
	L100.10	0.69	0.28	0.65	2.32	**0.94**
	L150.10	0.48	0.33	0.67	2.03	1.40
	L200.15	0.34	0.30	0.75	2.50	2.21

4 ANALYSIS OF RESULTS

The results in terms of capacity curves show that both the encirclements alone and the window grilles were effective in both X and Y directions. Observing the curves, it can be noticed that all reinforcements provide a noticeable increase in both strength and rigidity.

For the unretrofitted condition, the building capacity was similar in X and Y directions, although in X the ultimate displacement of the structure was higher, indicating higher ductility in X. This may be due to the fact that the piers in the X direction walls are slenderer than those in the Y direction walls. Slenderer piers lead to a predominant flexural response, with higher values of drift. Otherwise, thick piers (predominant in the Y direction) tend to produce shear failure and lower values of drift. The same results were obtained experimentally in [24] and similar conclusions were reported in [6].

Even though all retrofitting techniques improve capacity, the enhancement is greater in Y than in X in all cases. In X direction, the maximum shear force increased between 11% (L100.10 encirclements) and 57% (Grille 3). In Y direction, the enhancement ranged between 24% (profile L100.10) and almost 100%, in the case of Grille 3.

Figure 6 shows the performance point of the reference building and the six reinforcement cases. In all cases, in line with their capacity improvement, the reinforced buildings presented a great decrease of the displacements as compared to the reference building. This reduction was from 25% to 69% along the X axis, and from 38% to 69% along the Y axis.

Table 3 presents the results of the N2 analysis in terms of the target d_t^*, ultimate d_u^* and yielding displacements d_y^*. Observing the ductility values, it can be noted that in most cases the retrofitting produced only a slight improvement in both directions. Even in some cases (e.g., L150.10 in Y), the ductility decreased when the reinforcement was applied. In general, the building presented a less ductile behaviour in the Y direction, but here once again the Grille 3 reinforcement proved very effective, producing an increase of 80% in ductility over the reference building. Regarding the ULS safety verification, it can be checked that every retrofitting case except L100.10 (Y direction) satisfied the condition $d_u^*/d_t^*>1$. The improvement ranged from 38 to 76% in the X direction. In the Y direction, the gain was in most cases up to 100% or 200%. A 400% was even reached in case of the Grille 3.

In Figure 7, the DI for the different reinforcement techniques can be compared. On one hand, it can be observed that adding the L100.10 encirclement produced a minimal decrease of DI in both axis and did not changed significantly the building´s behaviour. Adding Grille 1 produced a slight improvement in behaviour with a small reduction of the DI, down to severe

damage. On the other hand, the addition of L150.10 profiles provided a significant reduction of damage in Y direction, although the gain was minimal in X direction. Furthermore, applying the L200.15 encirclement or the Grille 2 led to significant improvements in both directions, especially in Y, where the DI was reduced below to moderate damage. Finally, the Grille 3 is the reinforcement that produced the best results. In this last case, the DI was reduced below moderate damage in the X direction and below slight damage in the Y direction.

In terms of DI, the behaviour of the unretrofitted building was slightly better in the X direction. Nevertheless, all reinforcements provided higher enhancements in the Y direction with the exception of the L100.10 case. This can be explained observing the building geometry. Firstly, there is symmetry in the plan building in the Y axis but not in the X axis. Moreover, despite the fact that there are similar number of openings in both directions, they are distributed uniformly in the Y direction, but not in the X direction, which increase the lack of symmetry in this direction. Thus, the vulnerability in the Y direction is mainly caused by the presence of openings in the walls, and can be substantially reduced with these retrofitting techniques. On the contrary, in the X direction, the vulnerability of the building is produced by many factors, including lack of symmetry and the irregular distribution of openings. As a consequence, the reinforcement of openings in the X walls is not as much effective as in the Y walls.

5 CONCLUSIONS

This work is framed in the PERSISTAH project, which aims to analyse the seismic vulnerability of primary school buildings located in the region Algarve-Huelva. In the present paper, the seismic vulnerability of a URM primary school building located in Huelva was assessed. The main goal was to develop a simple, effective and affordable technique to retrofit a large number of buildings. The seismic performance of the building with different retrofitting techniques was assessed using the N2 method, as recommended by the EC8-3. Nonlinear static analyses were performed to obtain the capacity curves of the building including the retrofitting techniques. Moreover, the fragility curves were determined to obtain the probability of reaching or exceeding each damage state. Finally, the DI for each retrofitting technique model was obtained and compared.

The results showed that the unretrofitted building presented a high seismic vulnerability and did not satisfy the EC8-3 ULS verification. Therefore, to avoid future damage in the event of an earthquake, a retrofitting technique based on reinforcing the wall openings was proposed. Six different reinforcement scenarios were tested, three of them with encirclements and the other three with grilles. The results showed that the seismic behaviour of the building improved considerably when the reinforcements were applied. In particular, a noticeable increase in capacity and an important decrease in the performance point values were observed. Regarding the EC8 ULS safety verification, the results showed that all retrofitting techniques have been effective, except in the case of the encirclement with L100.10 profile.

In terms of damage level reduction, it can be concluded that, in general, all reinforcement techniques improved the seismic behaviour of the building. On one hand, the encirclements led to enhance the seismic performance of the building, provided that the profile size is appropriate. As for the grilles, the results have shown that adding grilles composed by horizontal tubular profiles did not enhance significantly the damage level of the structure. On the contrary, including the diagonal bars has proved much more effective. Furthermore, it was found that a higher number of diagonal bars produced a higher improvement in the damage level. Consequently, the Grille 3 reinforcement, in which all bars are placed in a diagonal pattern, resulted the most suitable design. In this case, the architectural integration is better due to the use of a plate in the perimeter, instead of an L-profile. Moreover, the reinforcement of Grille 3

has the best cost-benefit ratio since the plates and bars included require less steel than the encirclements with L profiles. Furthermore, this has resulted to be the most optimal and efficient retrofitting technique to improve the seismic behaviour of the URM primary school buildings studied in Huelva and the Algarve.

Abstract

In recent years, the consideration of earthquake-induced expected annual loss (EAL) has become a topic of great interest within the earthquake engineering community. Since the introduction of performance-based earthquake engineering (PBEE) in the 1990s, the principal goal of seismic design has been the verification of limit states in addition to the use of meaningful metrics of seismic performance that respond to the diverse needs and objectives of owner-users and society. However, the need for more focus on the control of earthquake-induced losses at a design stage is also of importance and interest. One possible solution for this gap may be to use a conceptual design framework that employs EAL as a design metric, serving as a first design step to identify suitable typologies and geometrical layouts. The objective of such an approach, which would require very little building information at the design outset, is to identify a number of feasible building typologies, in terms of lateral force resisting system, and associated structural geometries. This study implemented such a novel EAL-based design methodology, recently proposed, for a reinforced concrete (RC) frame as a parametric case study within the European context. A sensitivity study on the use of storey loss functions was also done to identify their compatibility with and impact on the framework at different performance limit states. Furthermore, effectively controlling the structure's ultimate limit state whilst also arriving at practical design solutions was seen to be an issue that requires further development. An alternative method to control collapse risk during design whilst also maintaining control on the EAL of the structure was therefore identified. As such, a conceptual design framework that focuses on both the economic losses and life safety in a direct and quantifiable manner has been identified to further implement the principles of PBEE in design practice.

Keywords: Performance-Based Earthquake Engineering; Conceptual Design; Reinforced Concrete; Expected Annual Loss; Storey Loss Functions.

1 INTRODUCTION

Current seismic design guidelines have a two-fold performance objective: the protection of human lives and the limitation of earthquake-induced damage. Hence, it is important to limit the likelihood of structural collapse, which is obtained by providing sufficient strength and ductility, in addition to proper detailing and capacity design, ensuring a controlled and stable ductile mechanism during strong seismic shaking. Additionally, damage limitation can be controlled during more frequent events. Neglecting damage control at a design stage can have severe consequences during an earthquake as both structural and non-structural damage, in conjunction with the interruption of building use, may entail disproportionally high economical losses compared to the costs of the structure itself. These aspects partially form what has become known as the Pacific Earthquake Engineering Research (PEER) PBEE methodology initially outlined by Cornell and Krawinkler [1]. This PBEE methodology [2,3] is an approach to quantify the performance of a given structural system. It utilises a fully probabilistic framework, employing methodologies with a solid scientific basis to improve seismic risk decision-making and expresses the levels of performance in terms of metrics meaningful to stakeholders and building owners. New guidelines like FEMA P58 [4] were developed, which allow the performance of existing buildings to be quantified in terms of metrics like expected annual loss (EAL) and mean annual frequency of collapse (MAFC). However, due to its iterative and cumbersome nature, more simplified options to take EAL into account have been sought.

O'Reilly and Calvi [5] recently proposed a novel conceptual seismic design (CSD) framework that employs EAL as a design metric and requires very little building information at the design onset. The framework encompasses the idea that designers may start with the definition of a required or limiting value of EAL and arrive at a number of feasible structural solutions without the need for any detailed design calculations or numerical analysis. Initially, the building performance definition is transformed into a design solution space using a number of simplifying assumptions. Subsequently, with a suitable structural response backbone, a number of feasible building typologies and associated structural geometries are identified. It is important to note that the methodology forms a stepping stone prior to further member detailing and robust design verifications, such as that outlined in FEMA P58.

This study aims to describe a detailed implementation of the CSD framework [5] and provide further insight by means of a parametric study. Serviceability limit state parameters are initially varied to see their effect on the design EAL and an alteration of the design solution space. A study on the use of storey loss functions (SLFs) is then carried out for their modification to overcome their incompatibility with the CSD framework at the ultimate limit state, in view of it not affecting the EAL. Finally, an approach to consider target collapse safety to define prospective structure's dynamic and strength characteristics is discussed, which could potentially solve the issues identified during the sensitivity study on SLFs.

2 CONCEPTUAL SEISMIC DESIGN

In order to implement the CSD framework shown in Figure 1, some simplifying assumptions are needed initially. First, SLFs are used to convert expected loss ratios (ELRs) to design peak storey drift (PSD) and peak floor acceleration (PFA). Three limit states were utilised: fully operational limit state (OLS); serviceability limit state (SLS); and ultimate limit state (ULS). Two limit state intensities, SLS and ULS, are considered to characterise the structure's elastic and ductile non-linear behaviour, respectively. The OLS performance point

describes the point when direct monetary losses begin to accumulate due to building damage, which can be thought of as an initial threshold akin to the excess amount on an insurance policy. The ULS performance point describes the point of building's full monetary replacement cost (Figure 3).

Current codes define the seismic design problem primarily in terms of ensuring life safety of its occupants. Therefore, mitigation of collapse is of primary importance and ensuring satisfactory performance at frequent levels of shaking is also checked. These are termed as '*no-collapse requirement*' and '*damage limitation requirement*' in the current version of Eurocode 8 (EC8) [6] and are suggested to correspond to ground shaking return periods of 475 and 95 years, respectively, with possible modifications to account for building importance class. New Zealand's NZS1170 [7] defines two limit states: serviceability and ultimate similar to EC8 and prescribes design return periods of 25 and 500 years, respectively, once again with the possibility of modification for different importance classes. The recently revised design code in the US, ASCE 7-16 [8], outlines a slightly modified approach where the building is designed using input as a fraction of the maximum considered event (MCE). The seismic hazard is determined from a series of maps outlining risk-targeted spectral values, which are found for a target risk of structural collapse of 1% in 50 years (~5,000 year return period). It uses a generic structural fragility curve along with some other adjustments following an approach outlined by Luco *et al.* [9] but has recently been noted by Vamvatsikos [10] to perhaps not be the most ideal approach. In this study, these general recommendations provided above for the definition of limit state return period will be followed for the case study application in Section 3 and parametric studies in Section 4.1.

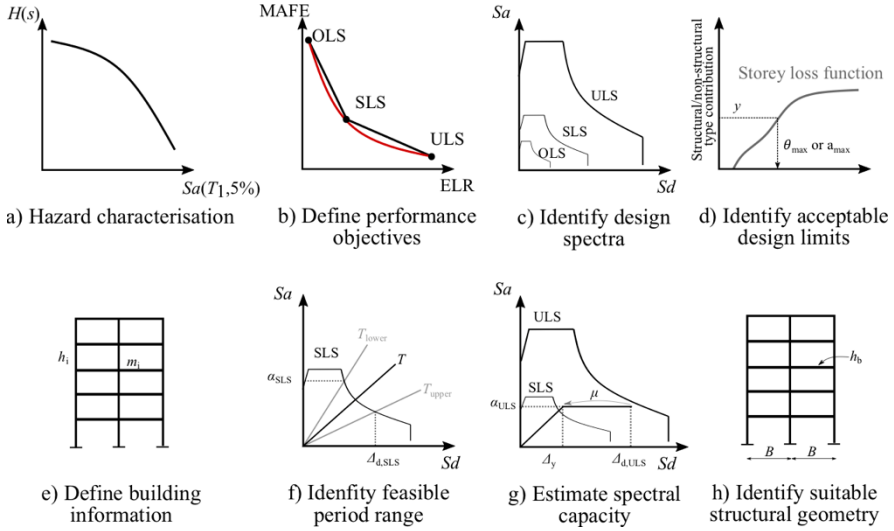

Figure 1: Overview of CSD framework for RC frames [5].

The CSD framework [5] is separated into two distinct parts: the identification of performance requirements, and the identification of feasible structural solutions. An overview of the framework for an RC frame is described in Figure 1. The first part includes: a) the site hazard initially identified with a uniform hazard spectra (UHS) for different return periods; b) performance objectives are set to establish the design loss curve characterised by an expected loss ratio (ELR, y), and corresponding mean annual frequency of exceedance (MAFE, λ), for each limit state. The loss curve is then integrated for the definition of design EAL, which has to be met by the subsequent obtainment of design solutions (Figure 3); c) using the MAFE for each limit state and the return periods of the UHS to be designed for, design spectra are identified; d) with the identification of design spectra, SLFs are used to relate expected monetary

losses to design parameters like the maximum PSD, θ_{max}, and maximum PFA, a_{max}, along the height of the building. The vertical axis in Figure 1(d) represents the ELR, y, contribution from PSD or PFA sensitive structural or non-structural elements.

The second part includes the following steps: e) minimal building information is needed, such as the number of storeys, n, seismic mass, m_i, and storey heights, h_i; f) at SLS, θ_{max} and a_{max} are converted to spectral displacement and acceleration limits, $\Delta_{d,SLS}$ and α_{SLS}, respectively. These are then used to identify the feasible initial secant to yield period range, where the initial period, T_1, of the sought structure must lie; g) knowing the design displacement at ULS, $\Delta_{d,ULS}$, and the required ductility, μ, the bilinear backbone curve is identified; h) and finally a suitable structural geometry from the established yield displacement, Δ_y, knowing that the yield displacement is a function of structural geometry and material properties. In the case of RC frames, the bay width, B, and the beam height, h_b, are computed. Overall, the framework works as an initial screening for suitable design before detailing and verification of the structure.

3 CASE STUDY APPLICATION

The CSD framework summarised in the previous section was used for a case study application herein. The goal of the study was to define certain performance objectives and come up with a set of design solutions in terms of bilinear backbone behaviour and required structural dimensions. No detailed verification analysis of these designs was carried out. Reasonable assumptions were made during the design process, since some information was not readily available. Minimal building information was necessary to implement the CSD framework. For the case study building discussed herein, a four-storey building with a floor area of 200m^2, seismic floor loading of 8kPa and roof loading of 7kPa was considered. The storey height was taken as 3.5m. The target EAL for the case study RC frame was predefined as 0.7%. With the already identified building performance requirements and minimal global characteristics of the possible building, a number of feasible design solutions were identified.

3.1 Identify site hazard

For the first step, the site hazard curve, H, was identified. Peak ground acceleration (PGA) was adopted along with EC8's type 1 design spectrum and soil type C was assumed. A higher fidelity second-order hazard model [11] was adopted instead of the first-order model initially utilised by O'Reilly and Calvi [5] to give a more accurate representation of the hazard, as described by Equation 1:

$$H(s) = k_0 \exp\left(-k_2 \ln^2 s - k_1 \ln s\right) \tag{1}$$

where the coefficients k_o, k_1 and k_2 were found to be 4.61E-05, 2.384 and 0.169, respectively, via a least-squares regression of the SHARE model [12] for a site in L'Aquila, Italy; and $H(s)$ is the hazard function representing the MAFE of a certain IM value s equal to PGA (Figure 2).

3.2 Define building performance objectives

Design performance objectives for the case study building are identified in Table 1. The values of return period, T_R, and ELR are decided. Then $H=1/T_R$ is used to determine the MAFE from Equation 2:

$$\lambda = \sqrt{p} k_0^{1-p} \left[H\left(\hat{s}\right)^p \right] \exp\left(\frac{1}{2} p k_1^2 \beta_s^2 \right)$$
$$p = \frac{1}{1 + 2k_2 \beta_s^2} \tag{2}$$

where $\hat{s}$ is the median value of s for a given limit state exceedance. Through the integration of the refined loss curve of Figure 3 and Equation 3, the EAL is computed and verified against the target one.

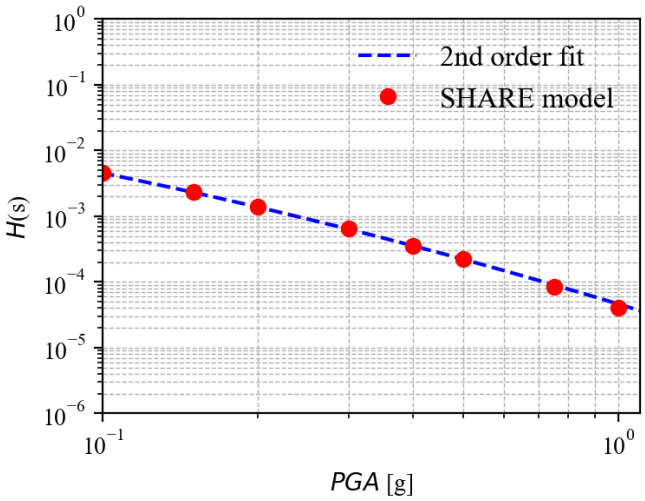

Figure 2: Second-order fit of a hazard curve for *PGA* at L'Aquila.

	OLS	SLS	ULS	Source
y	1%	25%	100%	User choice
T_R [years]	10	225	1600	User choice
H	1.00E-01	4.44E-03	6.25E-04	$=1/T_R$
β	0.1	0.2	0.3	Eurocode 8
λ	1.00E-01	4.65E-03	7.31E-04	Equation 2
EAL		0.64%		Equation 3
PGA [g]	0.01	0.10	0.28	Equation 1

Table 1: Design performance objectives defined by an ELR at each limit state, necessary to compute their respective MAFE and the design intensities.

Dispersions, β_s, were assumed based on those recommended in Appendix F of the recent draft of the revised Eurocode 8 [6] and are therefore deemed to be suitable for the present scope of illustration. In Figure 3, the EAL may be computed as the area beneath the approximate loss curve and is shaded in red. It is important to pay careful consideration since while the difference in area between the approximate and refined loss curve may appear insignificant, this is a result of the log scale of the vertical axis in Figure 3. However, it is possible to have an area between the two curves resulting in an EAL overestimation of up to 50% when compared to the refined curve. This can be overcome by using a closed-form expression with the same functional form of the refined loss curve as suggested by O'Reilly and Calvi [5]:

$$\lambda = c_0 \exp\left[-c_1 \ln y - c_2 \ln^2 y \right] \tag{3}$$

where the coefficients c_0, c_1 and c_2 can be fitted to pass through the three limit state points shown in Figure 3. The EAL was then evaluated as the area beneath this closed-form expression and is expected to be more representative of the actual EAL using more refined analysis. The ELR's were taken as y_{OLS}=1%, y_{SLS}=25% and y_{ULS}=100%, for the case study building. The values for the OLS and ULS limit states were based on the same consideration by O'Reilly and Calvi [5] whereby the OLS point is intended to represent the point at which the losses begin to accumulate and ULS when the losses reach the value of the building. The SLS point was chosen here and the sensitivity of the EAL to this value will be discussed in Section 4.1. The design EAL was established as the area under the refined curve, which was obtained as 0.64%, less than the target EAL (0.7%).

From each of these design limit state return periods, the design PGA was identified by inverting the hazard model in Equation 1 in terms of PGA. In the revised Eurocode 8, the 1600-year return period for the ULS corresponds to the significant damage limit state, so it was assumed to represent the complete replacement of the structure. In case of different design codes being used with differing minimum design requirements, such as NZS1170 or ASCE 7-16, the design return period of 2500 years is required at ULS, which may need to be accommodated as well.

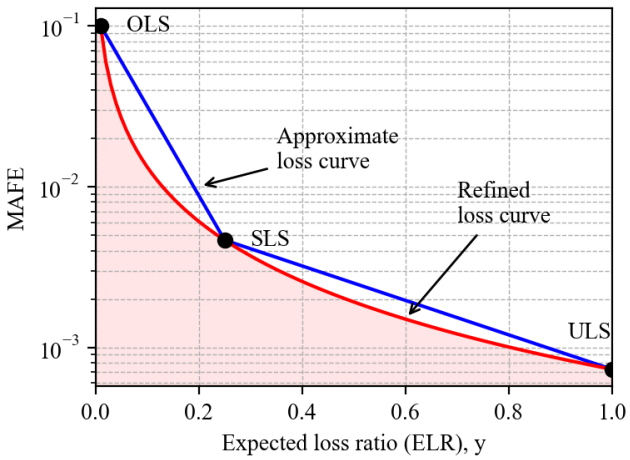

Figure 3: Approximate and refined loss curves, used to establish the design EAL shaded in red.

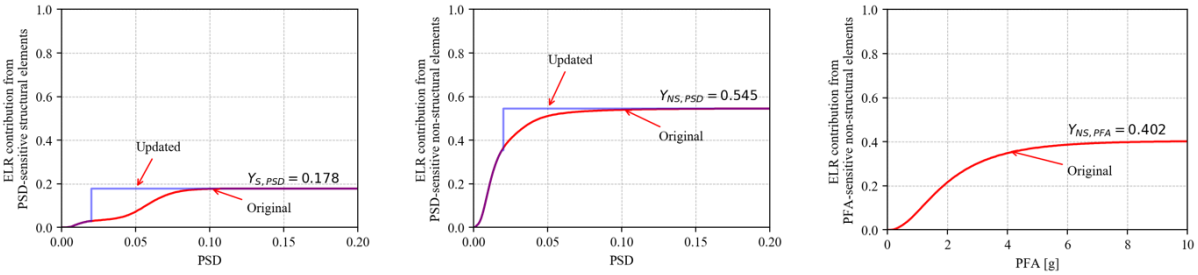
3.3 Identify structural design parameters

In order to convert the design loss ratios at both SLS and ULS into structural design parameters, storey loss functions (SLFs) were utilised and adopted from the literature [13]. Office occupancy was assumed and, for simplicity, only the typical SLFs were adopted (Figure 4). Considering the SLFs, the current formulation of CSD is not entirely compatible with their use when ELR is equal to 100% at ULS, since these functions' formulations tend to asymptotically increase towards large structural demand values of 15% storey drift (Figure 4), which are not realistic in design. To address this, a limiting value of 2% for PSD was adopted here, based on a sensitivity study presented in Section 4.2. Furthermore, some future developments to address this aspect relating to ULS performance are also envisaged in Section 4.3.

To link the ELR at each limit state to a structural demand parameter via the SLFs, as illustrated in Figure 4, the relative weights or contributions of the different component groups to expected loss, *Y*, were required. The ELR at each limit state is described by Equation 4:

$$y_{S,PSD} + y_{NS,PSD} + y_{NS,PFA} = y \tag{4}$$



(a) PSD-sensitive structural elements

(b) PSD-sensitive non-structural elements

(c) PFA-sensitive non-structural elements

Figure 4: SLFs adopted from [13].

which is the sum of all sources of loss resulting from PSD-sensitive structural ($y_{S,PSD}$) and non-structural ($y_{NS,PSD}$) elements and PFA-sensitive non-structural ($y_{NS,PFA}$) loss contributions given in Figure 4. From Equation 4, the following expressions in Equation 5 can be written:

$$\begin{aligned} y_{S,PSD} &= yY_{S,PSD} \\ y_{NS,PSD} &= yY_{NS,PSD} \\ y_{NS,PFA} &= yY_{NS,PFA} \end{aligned} \tag{5}$$

meaning that the individual values of the damageable element group loss was computed as a product of the target ELR, y, and its relative weighting, Y, shown in Figure 4. By entering the vertical axis in Figure 4, these returned two values of θ_{max} and one value of a_{max} not to be exceeded in order to maintain that level of expected loss for that limit state. Taking the more critical of the two θ_{max} values at SLS, which will almost always be the non-structural-based value, the design demand parameters were established and are illustrated in Figure 5 and listed in Table 2.

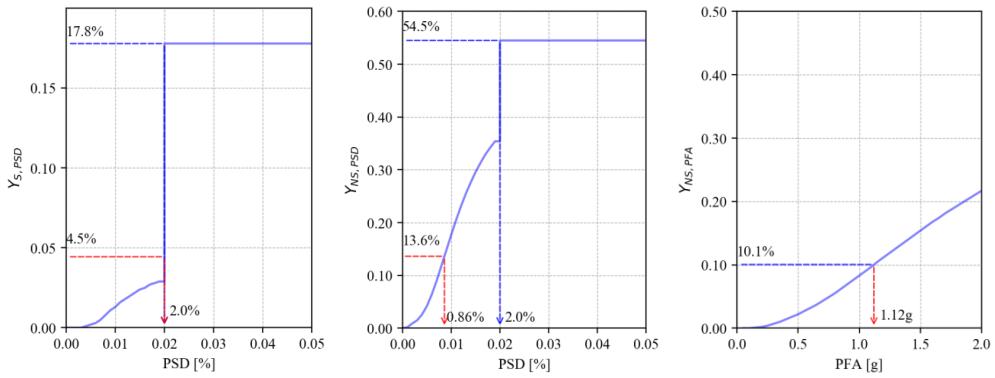


Figure 5: Illustration of the SLFs, and the identification of the design parameters for the SLS (red) and ULS (blue).

Structural demand parameter	SLS	ULS
PSD	0.86%	2.00%
PFA	1.12g	-

Table 2: Summary of structural design parameters for both limit states.

3.4 Compute spectral values

The identified values of θ_{max} and a_{max} at the SLS then needed to be converted to design spectral accelerations and displacements, $\Delta_{d,SLS}$ and α_{SLS}, respectively, as per Figure 1 (d). An equivalent single degree of freedom (SDOF) system is then employed in CSD to characterise a first-mode dominated multi-degree of freedom (MDOF) system. This is similar to the approach adopted in displacement based design (DDBD) [14] where the displacement of the equivalent SDOF system is given by Equations 6 and 7:

$$\Delta_d = \frac{\sum_{i=1}^{n} m_i \Delta_i^2}{\sum_{i=1}^{n} m_i \Delta_i} \tag{6}$$

$$\Delta_i = \omega_\theta \theta_{max} H_i \left(\frac{4H_n - H_i}{4H_n - H_1} \right) \tag{7}$$

where n is the number of storeys, m_i is the mass, Δ_i is the displaced shape at storey level i, ω_θ is the higher mode reduction factor and H_i is the i^{th} storey's elevation above the base. Detailed calculations are given in [5]. Unlike the PSD profile, PFA cannot be assumed to be first mode dominated, however, since the process of identifying a spectral acceleration, *Sa* for various building solutions assumes that the structure remains in the elastic range of response, some simplifications can be made. Combining the first few modes using square-root-sum-of-the-squares (SRSS) gives the PFA profile along the height, a_i, with a maximum value of a_{max}. For the case study building of RC frame with 4 storeys, the PFA may be approximated by a single coefficient γ defined as in Equation 8:

$$\alpha_{SLS} \approx \gamma a_{max} = 0.6 a_{max} \tag{8}$$

Initial parametric studies on the elastic modal properties of structures suggested that values of γ for low rise structures of 4 storeys of RC frame typology be around 0.6. Future research should look to improve this conversion, or at least refine this coefficient for different typologies of different number of storeys. For the purposes of CSD discussed here, they were deemed reasonable.

Table 3 lists the spectral acceleration and displacement for the case study building.

θ_{max} [%]	$\Delta_{d,SLS}$ [m]	a_{max} [g]	γ	α_{SLS} [g]
0.86	0.074	1.12	0.60	0.67

Table 3: Conversion of θ_{max} and a_{max} to spectral values at the SLS.

3.5 Quantify feasible initial secant to yield period range for SLS

The range of feasible initial secant to yield periods was identified using the equivalent SDOF spectral limits as presented in Table 3, which are illustrated in Figure 6, and the upper period bound, T_{upper}, for the RC frame in discussion was found to be 1.74 seconds. No lower period bound, T_{lower}, was identified, which is due to the fact that 0.67g of spectral acceleration is too high with respect to the maximum value of the spectrum at SLS (Figure 6). These bounds basically imply that the structure may be as stiff as needed since the SLS spectrum does not have enough spectral acceleration to exceed the PFA limits, while its flexibility will

be limited so that it does not undergo into excessive PSD. Hence, the period range is quite large, meaning that many potential design solutions could be accommodated. The damping was assumed as 5% for the case study RC frame.

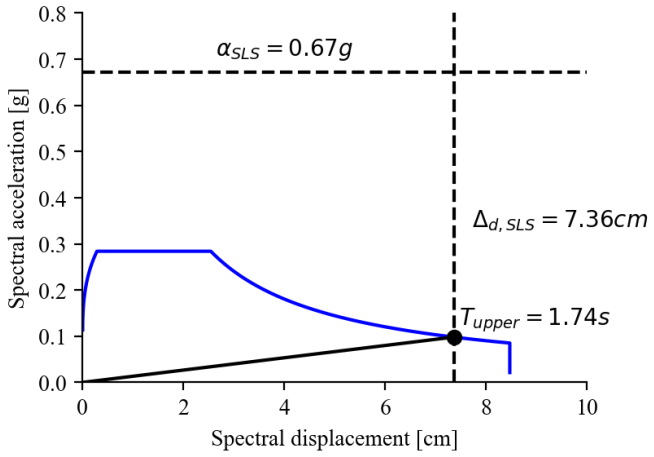

Figure 6: Identification of permissible initial secant to yield period range based on PFA and PSD limits for the SLS.

3.6 Establish required system strength and ductility

At the ULS, where the goal is to limit excessive PSD and provide a margin of safety against collapse during strong shaking, the effects of system non-linearity need to be accounted for. Figure 7 presents the permissible period range identified within the points 1 and 2, the trialled value of lateral strength capacity and the design solution space shaded in grey. It is important to note that for the case study building, point 2 is not representative since essentially there is no limit to the lower bound of the period range.

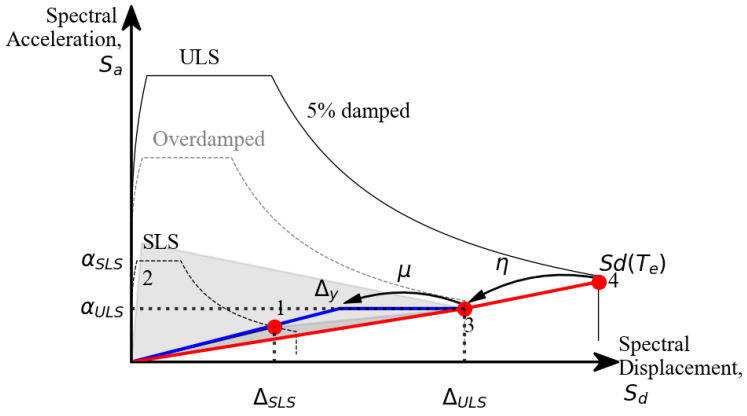

Figure 7: Identification of design solution space shaded in grey considering the permissible period range and the trialled value of lateral strength capacity (adapted from [5]).

For the given ULS spectrum and target design displacement, $\Delta_{d,ULS}$, a suitable SDOF system behaviour needed to be established. As noted by O'Reilly and Calvi [5], one way of doing this for the ULS, whilst still maintaining control over the initial period, is to simply trial a value of lateral strength. Then, by computing how much spectral reduction capacity would be required via non-linear behaviour, the structure's required ductility demand could be computed. This approach simply reworks the general DDBD approach, as the design displacement

and ULS spectrum are known but differs since the lateral strength is trialled and a compatible structural geometry is found (via the required yield displacement). DDBD, on the other hand, functions by commencing with a fixed structural geometry (meaning the yield displacement is known) and for the required ductility with respect to the design displacement and ULS spectrum, the lateral strength is found.

In this example, the approach described in [5] is followed but potential developments are described in Section 4.3. To account for the amplification in the structure's spectral capacity via non-linear behaviour of the structure, the effective period, T_e, passing from the origin through point 3 to point 4 was considered. In other words, the relation between linear and non-linear behaviour was found via a displacement modification factor (DMF) to the elastic design spectrum. As stated earlier, the design maximum PSD at ULS was 2.0% which gave a design displacement at ULS, $\Delta_{d,ULS}$, of 0.171m. Given $\Delta_{d,ULS}$ and the spectral displacement of the elastic response spectrum at T_e, $Sd(T_e)$, the required DMF, η, was determined from Equation 9.

$$\eta = \frac{\Delta_{d,ULS}}{Sd\left(T_e\right)} \tag{9}$$

Priestley *et al.* [14] outlined various expressions for different structural systems characterised by different hysteretic models representative of different structural systems and the one for RC frames was utilised here. From this relation, the required ductility, μ, was found by knowing the required spectral modification factor, η.

3.7 Compute structure backbone behaviour

With the knowledge of permissible period range, the design displacement, the lateral strength and the required structural ductility, the structure's backbone behaviour that respects these conditions was defined. The minimum required ductility already identified was then used to work back to find the yield displacement of the system, Δ_y, as per Equation 10.

$$\Delta_y = \frac{\Delta_{d,ULS}}{\mu} \tag{10}$$

The final bilinear backbone of the structural system was identified and is illustrated in Figure 8, where it was assumed that the second-order geometry effects, or P-Delta effects, were balanced out by the post-yield hardening of the structure to result in an elastic-perfectly plastic system.

The final values of yield displacement and lateral capacity are listed in Table 4. The base shear coefficient, *C*, is reasonable but the required initial period of the RC frame of 4 storeys is quite high to satisfy the design constraints. However, it is important to note that given a large range of allowable initial periods as identified earlier, a stiffer structure would have been obtained and this design scenario presented here was one of the many possibilities. This is a reflection of the current constraints imposed by the CSD at the ULS, where the advantage of being able to identify structural layouts is hampered by the fact that it tends to result in very flexible systems, as was the case in this example. Further consideration of the ULS performance that moves away from a single intensity-based verification of one PSD level (i.e. 2% PSD at 1600 years) should be pursued to arrive at a more risk-consistent approach to collapse safety. This would bring both CSD approach to a reasonable point whereby the losses via EAL and collapse safety are handled in a comprehensive manner. This was a limitation of CSD noted by O'Reilly and Calvi [5] and will be discussed further in Section 4.3

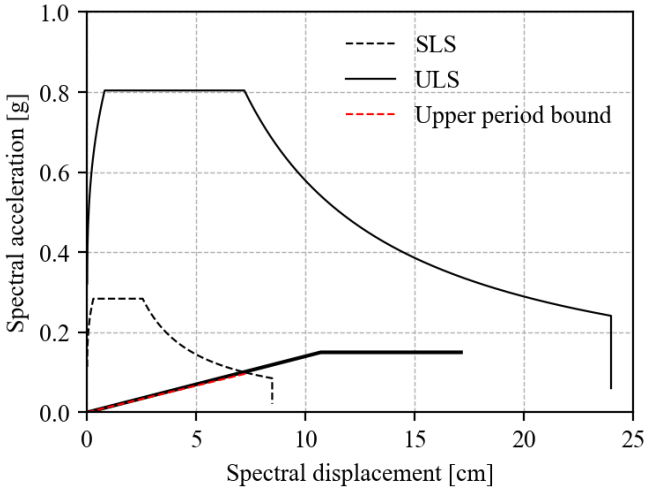

Figure 8: Required backbone response for the case study building design solution, where the period limits show how the design conditions have been respected.

a_{ULS} [g]	$\Delta_{d,ULS}$ [cm]	T_e [s]	$Sd(T_e)$ [cm]	$\eta_{required}$	Δ_y [cm]	$\mu_{provided}$	T_1 [s]	V_b [kN]	C
0.15	17.1	2.14	24.0	0.71	10.7	1.60	1.69	811	0.13

Table 4: Identification of structural system parameters to respect the design constraints, which fall within the design solution space

3.8 Identify structure layout

The final step of the design process was the identification of required geometry for the RC frame. In order to make use of the identified backbone leading to an acceptable building performance, defined in terms of expected loss, two parameters were required: the lateral strength and the yield displacement. As the lateral strength is a function of the member strengths, it can be easily adjusted by modifying the dissipative zone capacities. Structural geometry and material properties were required to establish the yield displacement. As the yield displacement was already known, the final dimensions and material properties of the structural system were identified as they are independent of the lateral strength [15].

For an RC frame with a ductile beam-sway mechanism, the yield drift, θ_y, has been shown by Priestley *et al.* [14] to be:

$$\theta_y = \frac{0.5\varepsilon_y B}{h_b} \tag{11}$$

where B is the bay width of the frame and h_b is the beam section height. Assuming a reinforcement of yield strength 350MPa and 200GPa of Young's modulus and a beam height of 0.5m, a bay width of around 6m would be required. Knowing the lateral load resisting system, structural geometry and the design base shear for the system, the structure can be detailed by providing enough capacity to ensure a ductile and stable mechanism. The resulting structural system would be representative of the backbone identified in Figure 8 and should satisfy the performance goals initially defined in terms of EAL described in Section 3.2.

4 DISCUSSION

Using the design framework summarised in Section 2 and implemented in a case study application in Section 3, additional studies on essential characteristics of the CSD framework were conducted. The goal was to understand whether the methodology could be improved in relation to the definition of the ULS performance and the sensitivity of the EAL to the SLFs. As before, the RC bare frame with office occupancy described in Section 3 was the reference design used for comparison throughout the discussion.

4.1 Influence of SLS parameters

One of the first studies regarding the definition of the performance objectives listed in Table 1 was on the sensitivity of the design EAL to the choices made regarding the return period of ground shaking, T_R, and the level of ELR at the SLS. The same values of y and T_R assumed for the OLS and ULS in Table 1 were maintained and the EAL was computed for numerous combinations of y_{SLS} and $T_{R,SLS}$. A summary of these design scenarios is presented in Figure 9. In essence, the hazard curve relates PGA (right axis) to T_R (left axis), and the SLF relates θ_{max} (top axis) to ELR (bottom axis). By increasing the y_{SLS} and $T_{R,SLS}$, the EAL, represented in green shades, will essentially stay constant. While, if the y_{SLS} is increased only or $T_{R,SLS}$ is decreased only, then the EAL will increase. Figure 9 then also shows the design solutions depending on $T_{R,SLS}$ and y_{SLS}. Only the upper bound results are shown, since the design indicated no lower period bound. The empty solution space represents an area where the solutions are beyond practicality, e.g. having high base shear coefficient, C, or high required bay width, B.

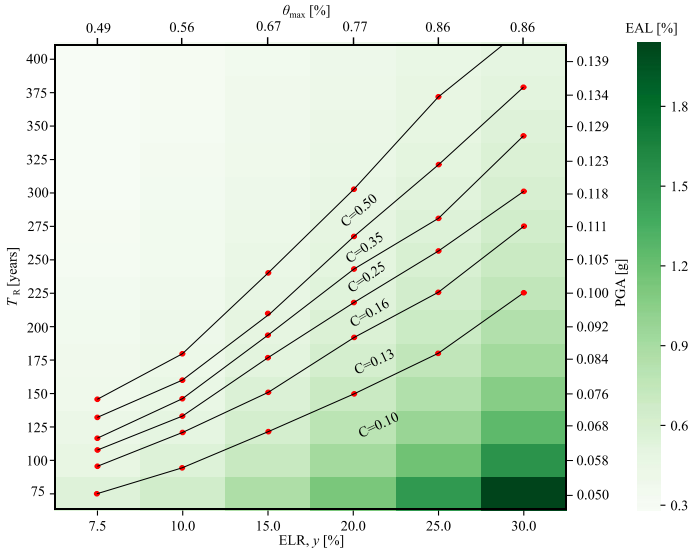

Figure 9: Impact of varying y_{SLS} and $T_{R,SLS}$ on the design EAL.

The study carried out on the variation of SLS parameters, showed high sensitivity of EAL to the SLS parameters. Additionally, the lower period range limit will be highly dependent on the *PGA* and subsequently $T_{R,SLS,}$ while the upper period range limit will be highly dependent on the θ_{max} and subsequently y_{SLS}. The curves defining C represent structures with an initial period equal to the upper period range limit and conditions imposed by each pair of $T_{R,SLS}$ and y_{SLS} below the curves can be satisfied by a structure with C equal to the curve value. Hence, the curves depend on an upper period range limit. Higher y_{SLS} and lower $T_{R,SLS}$ imply higher upper period range limit. For the study, the y_{SLS} was kept constant, while the $T_{R,SLS}$ was in-

creased sequentially, leading to a decreasing upper period range limit further constraining the design solution space, which resulted in the curves defining *C* boundaries.

4.2 Sensitivity study on SLFs

When using the SLFs as per Figure 4, the PSD at ULS for ELR=100% will be in the order of θ_{max}=10 to 20%. This value of θ_{max} may make sense purely from a monetary loss accumulation point of view, but is clearly unfeasible from a collapse performance perspective. To implement the CSD with these SLFs, a decision was made to limit θ_{max} to a certain limit similar to what ASCE 7-16 [8] prescribes to provide a level of life safety against collapse in their designs. This approach of utilising SLFs for the definition of the SLS design parameters but simply limiting the PSD to 2% at the ULS was adopted in the case study described in Section 3. The goal of the sensitivity study described here is to understand what impact this decision actually has on the design EAL. The SLF for PFA sensitive non-structural elements was not modified as the CSD methodology does not utilise the PFA at ULS.

Figure 10 shows the steps of the sensitivity study for the modification of SLFs for the CSD methodology. Initially, an original EAL was calculated through the employment of the SLF curves of the PSD-sensitive structural and non-structural elements adopted from Ramirez and Miranda [13]. Then a cut-off vertical line (in blue) representing a PSD value was gradually lowered, where the cut-off line describes a value of the PSD above which the ELR is assumed 100% times the respective weight of the element, Y_{PSD}. With each version of SLF, a corresponding EAL value was computed and then compared to the original one. The procedure was repeated until the error, ε_{EAL}, increased beyond 0.2% and the final updated SLF with the corresponding PSD cut-off line was used in the CSD presented herein.

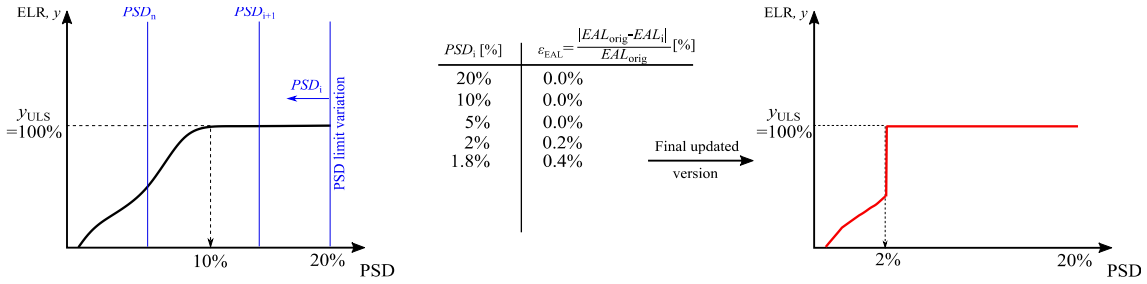

Figure 10: Sensitivity study on the modification of SLFs for the CSD methodology by the variation of PSD until EAL error, ε_{EAL}, is beyond 0.2%

The preliminary limit value obtained through the sensitivity study was 2% for PSD. By using the original and updated curves shown in Figure 4, the EAL variation error was found to be below 0.2%. Hence, the inclusion of such a limitation of PSD when utilising SLFs at ULS does not significantly impact the design EAL. Therefore, it can be concluded that the limitation of the PSD to 2% at ULS similar to what is done in the US with ASCE 7-16 [8], for example, with the aim for designing for collapse safety does not have any major impact on the design EAL that has been focused on up until now in CSD. Should the nature of determining the performance goals in CSD change from utilising EAL solely for the definition of the SLS limits and establishing an initial period range and then other possible criteria related to strength or ductility be utilised to protect against collapse, these two performance definitions will not have any major interaction with other and can be treated quite separately.

4.3 Consideration of collapse performance in design

As shown in the previous section, SLS and ULS performance can be handled with separate criteria without any major interference between them. With regards to collapse safety, MAFC, λ_c, may be used and a potential procedure to incorporate this in the CSD framework is described in Figure 11. The reasons for this are also illustrated in Figure 11(a) and are as follows. At ULS, a situation may occur where $\Delta_{d,ULS}$ is equal, or very close, to $Sd(T_e)$, meaning that the required DMF and consequently the ductility, μ, will be limited or equal to 1 (red point in Figure 11(a)). This will essentially result in designs with very long periods and limited ductility demand. Consequently, a high bay width will be required to provide a yield displacement equal to the required one. An alternative would be to neglect the condition of DMF equality, as also briefly discussed in O'Reilly and Calvi [5], and provide the structure with ductility higher than 1 (in blue in Figure 11(a)), which would then result in a lower bay width.

Alternatively, this could also be achieved by using MAFC to design for collapse safety in a more risk-consistent manner, as described a follows. An SDOF with period T that falls within the already identified period range [T_{lower}, T_{upper}] and an anticipated ductility capacity μ is considered. Knowing the yield lateral spectral acceleration, Sa_y, the dynamic performance of a trialled SDOF up to complete collapse can be quantified via SPO2IDA tool [16], as shown in Figure 11(b). Knowing the collapse fragility and the hazard curve, these may be integrated to get the MAFC, λ_c, where the collapse fragility defined in terms of R (Figure 11(b)) is transformed to spectral acceleration Sa by using a transformation factor, Γ, to a collapse fragility of the actual MDOF system (Figure 11(c)). By setting a target collapse safety to be respected by the resulting design, the base shear coefficient can be found for a given ductility, μ, and initial period, T_1. By varying T_1, a satisfactory base shear coefficient curve can be plotted in Sa versus Sd and the feasible structural solutions may be found (Figure 11(d)). It is noted that this approach is not too dissimilar to the yield frequency spectrum method [17] but here just the collapse behaviour is focused on, in addition to maintaining a degree of control on the EAL via the initial period range.

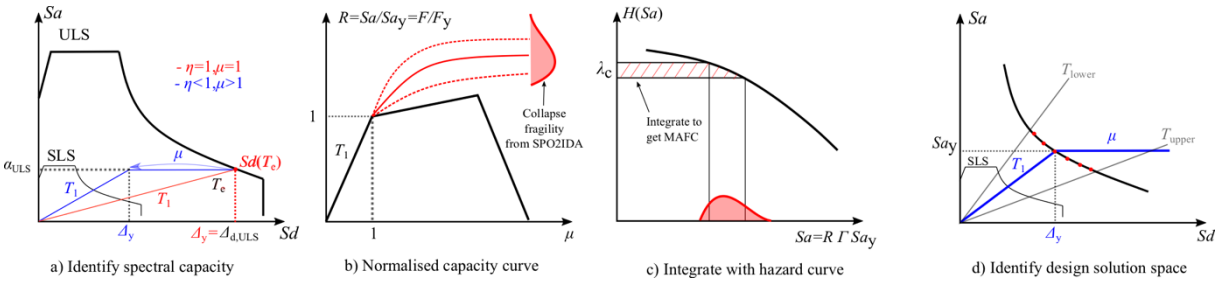

Figure 11: Potential development of the CSD framework to incorporate MAFC as a design variable.

The red dots in Figure 11(d) represent several of the numerous feasible design solutions within the period range that satisfy the collapse safety criterion. This approach would help to avoid the issue of SLFs identified in the previous section and overcome the difficulties explained in Section 3.6.

5 CONCLUSIONS

A novel CSD framework utilising EAL was used to identify feasible structural solutions aligning with the conceptual objectives of performance-based design. The general procedure with a case study application for an RC moment resisting frame was presented herein for its illustration. A number of assumptions were made: first, SLFs were used to convert ELRs to design PSD and PFA. At the ULS, where a collapse prevention requirement has to be met, the

PSD was cut-off at 2% and corresponds to the requirement brought forth by ASCE 7-16 [8]. Two limit state intensities, SLS and ULS, were utilised to characterise the structure's initial elastic and ductile non-linear behaviour. At SLS, design PSD and PFA were used to define a permissible initial secant to yield period range. Subsequently, with the choice of lateral strength and the knowledge of required system ductility, the yield displacement of the system was computed. Finally, the design solution space was identified and a potential bilinear backbone identified. Based on the characteristics identified, the required dimensions of the structure were identified as part of the first phase of design.

Moreover, some sensitivity studies were carried out to further investigate some particular aspects of the CSD framework. Several notes could be made based on these studies:

- High sensitivity of EAL and period range limits to the SLS parameters, as: 1) increasing ELR or decreasing T_R results in an increase of the EAL; and 2) decreasing T_R and increasing ELR will lead to an increase of the upper period range limit, meaning that care must be taken when establishing these points in design;
- Limiting PSD to 2% (similar to what is done in ASCE 7-16 with the aim to design for collapse safety) and modifying SLFs corresponded to an error in EAL of only 0.2%, demonstrating that it does not have any major impact on the design EAL;
- To avoid observed difficulties of implementing the CSD framework at ULS, an alternative approach was pondered. This does away with the issue where the required DMF and the ductility could potentially lead to large bay widths to satisfy the yield displacement requirement. The alternative approach foresees that the ULS is no longer considered, but rather a target MAFC, which is satisfied by a system with base shear coefficient, C, for a given ductility, μ, and an initial period, T, which must lie with the period range identified for SLS.

Within future developments, the CSD framework will be improved to include the current approach for SLS, where the elastic properties of the structure are chosen to satisfy the target EAL, while a simplified collapse analysis is used to satisfy a target MAFC.

Abstract

Earthquake engineering analyses are unavoidable to obtain response of buildings to earthquakes in order to ensure for structure to withstand a given level of ground shaking and to maintain a desired level of performance. Main reasons are vagueness and uncertainties related to the ground motion and structural modeling parameters in the available data such as location, size and resulting shaking intensity of future earthquakes. The selection of appropriate seismic input is known to be a critical step while performing this kind of analysis in order to estimate seismic performance in the basis of the hazard at the site where the structure is located. Selection of recorded ground motions are in most cases based on geophysical parameters, ground motion intensity measures, and spectral matching. In this paper seismic analysis will be performed for four-story reinforced concrete ISPRA frame structure designed according to Eurocode 8 (EC8) by selecting 30 different earthquake scenario for each EC8 target spectrums in order to evaluate average maximum inter-story drift ratio. Time history analysis for every earthquake record was obtained. As a result, Inter-story Drift Ratios (IDR) as a main damage measure were presented in order to make comparison with defined performance levels of reinforced concrete bare frames.

Keywords: seismic damage assessment, earthquake records, spectral matching

1 INTRODUCTION

The seismic damage assessment is found to be a very complex problem when analyzing reinforced concrete structures. Main reasons are vagueness and uncertainties related to the ground motion and structural modeling parameters in the available data such as location, size and resulting shaking intensity of future earthquakes [1].

In order to ensure for structure to withstand a given level of ground shaking and to maintain a desired level of performance, earthquake engineering analyses are unavoidable to obtain response of buildings to earthquakes. Response of buildings stands for complex, three dimensional and nonlinear dynamic problems, thus nonlinear dynamic analysis is unavoidable. It is also known as the most accurate method to evaluate the behavior of structures during an earthquake in both probabilistic assessment and design [2].

The selection of appropriate seismic input is known to be a critical step while performing this kind of analysis in order to estimate seismic performance in the basis of the hazard at the site where the structure is located. The current best practice in record selection is reviewed for the case of the probabilistic seismic risk analysis and for the code-based design [3]. In order to quantify former uncertainties and to combine them to produce an explicit description of the distribution of future shaking that may occur at the site, Probabilistic Seismic Hazard Analysis (PSHA) needs to be conducted [4]. This seismic analysis combines different magnitudes (M) and distances (R) with predictions of resulting ground motion intensity, and thus seismic hazard at the site can be computed [5]. Ground motion selection utilizes probabilistic seismic hazard disaggregation, as a key tool for all of the following ground motion selection approaches. The goal of this procedure is to accurately estimate the response of a structure at a specified ground motion intensity, as measured by spectral acceleration at the first-mode period of the structure, $S_a(T_1)$ [6]. It is also necessary to obtain time series that are representative of the strong shaking that a particular location may experience in the future during an earthquake. Ground motions should be selected from a database of previously recorded motions [7].

For probabilistic seismic risk assessment, record selection should be regarded as a reference case. In the case of code-based seismic assessment, there is an issue in selection of the real recordings set compatible with a code-specified spectrum, whose spectra are generally non-smooth. The structural response estimates were seen to be highly dependent on the type of ground motions that can be used for the seismic structural analysis as well on the methods utilized or selection and scaling of the records. Ground motions can be divided on 1) artificial waveforms; 2) simulated accelerograms; 3) natural records [8].

Selection of recorded ground motions are in most cases based on 1) geophysical parameters magnitude (M), source-to-site distance (R), and epsilon (e); 2) ground motion intensity measures; and 3) spectral matching, which will be the main focus in this paper. Brief review on selection of recorded ground accelerations based on spectral matching for different target spectrum EC8 spectrum, Uniform Hazard Spectrum (UHS) and Conditional Mean Spectrum (CMS) will be presented. Further, seismic analysis will be performed for four-story reinforced concrete frame structure designed according to EC8 – ISPRA frame by selecting 30 different earthquake scenarios according to spectral matching in order to evaluate average maximum inter-story drift ratio. The aim is to compare obtained results from seismic analysis for each earthquake scenario in order to observe the difference of performance levels achieved by EC8 target spectrum.

2 SELECTION OF RECORDED GROUND ACCELERATIONS – A BRIEF REVIEW

Calculating ground motions based on earthquake scenarios is an invaluable tool for evaluating direct and indirect losses from specific credible earthquakes. Hazard evaluation of earthquake ground motion in most cases is done with deterministic or probabilistic approach which

would be the two representative methods for seismic hazard assessments nowadays. Both approaches need to transform the seismic event to ground motion.

Deterministic Seismic Hazard Analysis (DSHA) is an analysis that considers a worst-case scenario in terms of earthquake size and location and it is basically governed by the seismic source that has the highest threat to the site with the largest motion estimated [9]. Contrary to DSHA, if probabilistic seismic hazard analysis (PSHA) has been used, which was the first formalized by Cornell [10], then the controlling earthquake scenarios need to be obtained by disaggregation [8]. PSHA combines the probabilities of all earthquake scenarios with different magnitudes (M), source-to-site distances (R) and epsilon (ε), the number of standard deviations from the median ground motion as predicted by an attenuation equation with predictions of resulting ground motion intensity, in order to compute seismic hazard at a site. PSHA also incorporates uncertainties in ground motion predictions. To quantify ground motion in PSHA, traditionally peak ground acceleration (PGA) was used. However, today the preferred parameter is Response Spectral Acceleration (Sa) which gives the maximum acceleration experienced by a damped, single-degree-of-freedom oscillator [11]. To identify the distribution of earthquake scenario that contribute to exceedance of a given spectral acceleration (Sa), current ground motion selection is utilized by probabilistic seismic hazard disaggregation [5].

Selection of recorded ground motions can be based on 1) geophysical parameters Magnitude (M) and Distance (R); 2) ground motion intensity measures; 3) spectral matching; etc. The main focus will be on spectral matching which is the most commonly proposed earthquake record selection method by seismic codes and, as such, can be utilized in the framework of both force-based and performance based design [12]. Spectrum matched records are artificially generated time histories of ground motion acceleration, or other relevant parameter, whose response spectral shapes are matched to a predetermined target spectrum and used as input to dynamic analysis [13]. While selecting ground motion records, main aim is to select representative records of the ground motion at the site of interest and at the consistent source-to site distance. Also there will generally be a requirement to ensure that the records of ground motion conform to some specified level of agreement with the ordinates of the design response spectrum, whether records are selected by performing searches in terms of response spectral ordinates or in terms of seismological and geophysical parameters [8]. If structural response is to be estimated by selecting ground motions to match a target response spectrum, typical response spectrum associated with the specified large amplitude S_a value at a single period must be defined [14].

In the part 1 of **design code Eurocode 8** [15] following criteria are established for the selection and scaling of ground motion records in the context of demand-based assessments of buildings: 1) the mean of the zero period spectral response acceleration values calculated from the individual time histories should not be smaller than the value of $a_g S$ for the site under study, a_g being the design ground acceleration on rock and S the soil parameter; and 2) in the range of period between 0.2 T_1 and 2.0 T_1, where T_1 is the fundamental period of the structure in the direction where the record will be applied, no value of the mean 5% damping elastic spectrum, calculated from all time histories, should be less than 90% of the corresponding value of the 5% damping elastic response spectrum [3], [8].

In Eurocode 8 [15] after the elastic response spectrum, seismic input for the time-history analysis is defined. Two spectral shapes are defined, Type 1 and Type 2, where the latter applies if the earthquake contributing most to the seismic hazard has surface waves magnitude not greater than 5.5. Contrary, the former type should be used. In EC8, for the structural assessment any form of accelerograms is allowed to be used. Regardless they are natural, artificial or simulated, the main criterion that the set of accelerograms should satisfy is 2) [16].

For the past two decades, the **Uniform Hazard Spectrum** (UHS) has been used as the target spectrum in the design practice. It is computed by PSHA and constructed by selecting a frequency of exceedance for the hazard, developing the spectral acceleration at each period and plotting spectral acceleration versus period [14]. It is suggested to select seven records which are compatible with the dominant earthquake scenario at the site of interest and that scenario is represented with the magnitude (M) and the distance (R) which are key parameters obtained by disaggregation analysis [17]. In order to match the design level of the UHS, the selected records need to be scaled when it is necessary.

Baker and Cornell [6] concluded that the UHS represents nearly impossible earthquake scenario because the rate of observing a high positive ε in all periods is much lower than the rate of observing a high ε in any single period. Although the UHS is frequent target spectrum in structural dynamic analysis, it does not represent a spectrum caused by a single earthquake at a given site and thus leads to a conservative spectrum in higher hazard levels.

Conditional Mean Spectrum (CMS) has been proposed by Baker [18] as an alternative to the Uniform Hazard Spectrum (UHS) that can be used as a target spectrum in ground motion record selection. CMS provides the expected (mean) response spectrum, conditioned on occurrence of a target spectral acceleration value at the period of interest. After it is computed, CMS can be used for selection of ground motion records. With CMS spectral shape associated with the target spectral shape *Sa(T*)* is obtained. Thus ground motions that match Sa(T*) can be treated as representative of ground motions that naturally have the target Sa(T*) value. The period ranges over which the CMS should be matched must be identified to find ground motions matching a target CMS, and this period range may include the periods of higher modes of vibration as well as longer periods that are seen to affect a nonlinear structure whose first-mode period has effectively lengthened.

3 DESCRIPTION OF EXPERIMENTAL AND NUMERICAL MODEL

3.1 Experimental model

Experimental full scale model presented in Figure 1 on which seismic analysis will be performed, is a four-storey frame structure designed according to previous version of Eurocode 2 [19] and Eurocode 8 [11]. Structure is in total 12.5 m high. Structure has three frames and thus two bays in both X and Y direction. Raster of bays in X direction are 4 and 6 m, and raster of both bays in Y direction is 5 m in which direction load was applied. Materials used in construction were concrete C25/30 and the B500 Tempcore reinforcing steel with characteristic yield strength of 500 MPa.

Columns were reinforced with ϕ8-ϕ12 mm bar. The total reinforcement ratio varied from 1% to 1.9%. Longitudinal reinforcement diameter in columns carried from ϕ16 at upper storeys and ϕ20 or ϕ25 in the bottom and in some cases in the first storey. In the critical regions of columns were used stirrups ϕ10/10. For the longitudinal reinforcement in beams were used bars ϕ14 in combination with bar ϕ12. More than half longitudinal reinforcement in the beams is placed at the bottom of the beam.

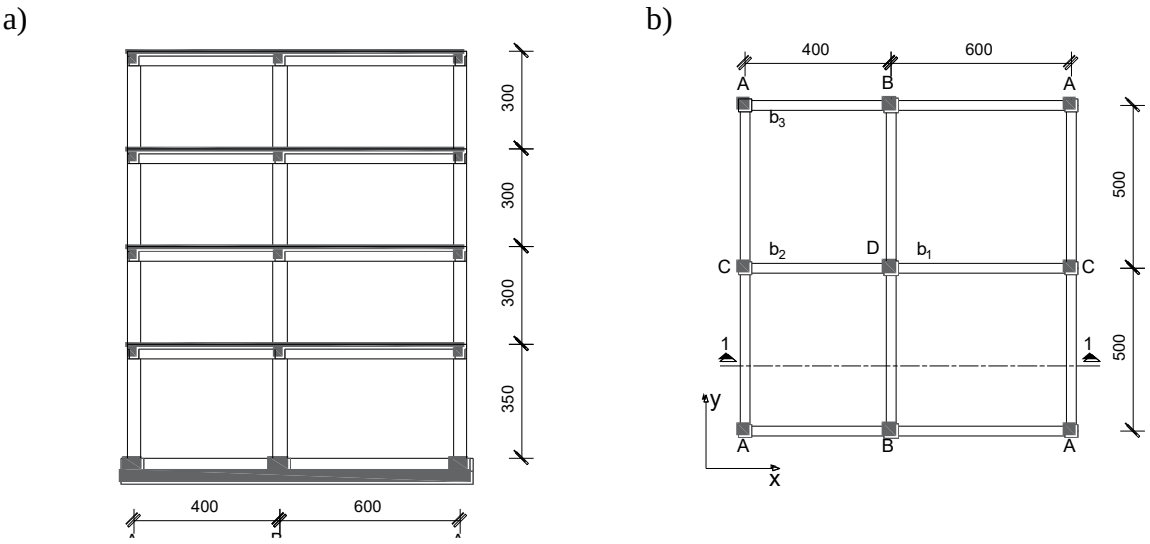

Figure 1: The four-storey reinforced concrete structure [20].

Since reinforced concrete beams and the slab are usually constructed at the same time, they act as a monolithic section. Therefore, in the seismic assessment, a contribution of slab to the stiffness and strength of beam has to be considered. In the Eurocode 8 [15] is prescribed that slab reinforcement parallel to the beam and within the effective flange width should be assumed in the design process to contribute to the beam flexural capacities, if it is anchored beyond the beam section at the face of the joint. In the Eurocode 2 [19] the values of effective width of beams for all limit states are suggested and are based on the distance l_0 between points of zero moments. It should be calculated according to next equatinos:

$$b_{eff} = \sum b_{eff,i} + b_w \leq b \tag{1}$$

$$b_{eff,i} = min \begin{cases} 0.2 \cdot b_i + 0.1 \cdot l_0 \\ 0.2 \cdot l_0 \end{cases} \tag{2}$$

$$b_{eff,i} \leq b_i \tag{3}$$

where $b_{eff}$is the beam's effective width, b_w is the width of the beam, b_i is the one half of the distance between the beams and l_0 is the distance between the zero moment points. In the seismic analysis the distance l_0 should be taken as $l_b/2$. Transversal beam spans should be taken as l_b and in Table 1 are given calculated effective widths of beams considered in analysis.

Beam	**Shape of beam**	$\boldsymbol{b_w}$ $[\boldsymbol{cm}]$	$\boldsymbol{b_{eff,1}}$ $[\boldsymbol{cm}]$	$\boldsymbol{b_{eff,2}}$ $[\boldsymbol{cm}]$	$\boldsymbol{b_{eff}}$ $[\boldsymbol{cm}]$
B1, B3, B4, B6	L	30	50	-	80
B2, B5	T	30	50	50	130
B7, B11	L	30	40	-	70
B8, B12	L	30	60	-	90
B9	T	30	40	40	110
B10	T	30	60	60	150

Table 1: The effective width of beams considered in analysis [20]

Except effective width of beams, critical region length, or plastic hinges length were determined according to Eurocode 8 [15]. As structure was designed for ductility class high (DCH)

and the behavior factor q = 5, the critical region length for beams were determined according to equation (4), and for columns according to (5):

$$L_p = 1.5\, h_w \tag{4}$$

$$L_p = max \begin{cases} 1.5\, h_c \\ 1.5\, b_c \\ 0.6 \\ L_c/6 \end{cases} \tag{5}$$

Values of concentrated masses were obtained from the self-weight of the structure, the permanent load of 2 kN/m^2 which presented floor finishing and partitions, and the live load also of 2 kN/m^2. In Table 2 are presented concentrated masses as point loads on each column and for every storey.

Column	Storey 1 m [t]	Storey 2 m [t]	Storey 3 m [t]	Storey 4 m [t]
1, 7	7.61	7.51	7.51	6.90
2, 8	11.23	11.13	11.13	10.52
3, 9	5.80	5.70	5.70	5.09
4	11.40	11.30	11.30	10.69
5	19.77	19.64	19.64	18.87
6	9.59	9.49	9.49	8.88
Σ	90.07	89.12	89.12	83.46

Table 2: Values of concentrated load masses

3.1 Numerical model

Nonlinear analysis of the ISPRA numerical model in Figure 2 has been conducted by SeismoStruct (2016) [21] in which the behavior of concrete elements was simulated with force-based plastic hinge (FBPH) elements with plastic hinges at the ends of the elements using Mander's model of confined concrete proposed by Mander et al. [22] and the Menegotto-Pinto model [23] for reinforcing steel.

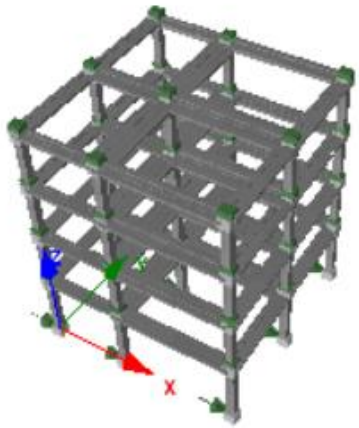

Figure 2: Numerical model in Seismostruct 2016 [21]

The accuracy of numerical model compared to the experimental one is firstly obtained by the comparison of natural periods for experimental and numerical model in Table 3.

Mode	Experiment	Numerical model	Error (%)
1	0,560	0,592	5,7
2	0,195	0,213	8,5
3	0,115	0,123	6,9

Table 3: Comparison of natural periods for experimental and numerical model

The other check of compatibility of numerical to experimental model are resulted relative errors and correlation of values obtained from numerical modelling and experimental test for displacement, and base shear. From the Table 4Table 4, it can be seen that the nonlinear numerical model also gave excellent results in terms of compatibility with hysteretic curves presented in Figure 3. The mean relative error of the observed variables (displacement, base shear) was 15.92%, while the correlation R was an excellent 0.95. That proves the compliance and applicability of the calibrated numerical nonlinear model for the parametric analysis of a model building with infilled frames according to expected behaviour.

Four-storey building ISPRA		Mean relative error [%]/correlation R
Displacement	1st floor	14.94/0.94
	2nd floor	11.11/0.95
	3rd floor	15.21/0.95
	4th floor	16.11/0.95
Base shear		17.24/0.95
Mean values		14.92/0.95

4 SELECTION OF DIFFERENT EARTHQUAKE SCENARIO

Spectral matching is the most commonly proposed earthquake record selection method by seismic codes and, as such, can be utilized in the framework of both force-based and performance based design [12]. In the past 15 years, the use of spectrum matched records has become increasingly widespread for the estimation of nonlinear structural response. Spectrum matched records are artificially generated time histories of ground motion acceleration, or other relevant parameter, whose response spectral shapes are matched to a predetermined target spectrum and used as input to dynamic analysis [13].

While selecting the ground motion records, main aim is to select representative records of the ground motion at the site of interest and at the consistent source-to site distance. Also there

will generally be a requirement to ensure that the records of ground motion conform to some specified level of agreement with the ordinates of the design response spectrum, whether records are selected by performing searches in terms of response spectral ordinates or in terms of seismological and geophysical parameters [8]. If structural response is to be estimated by selecting ground motions to match a target response spectrum, typical response spectrum associated with the specified large amplitude Sa value at a single period must be found [14]. For graphical explanation of earthquake scenario selection method, flow chart in Figure 4 is presented.

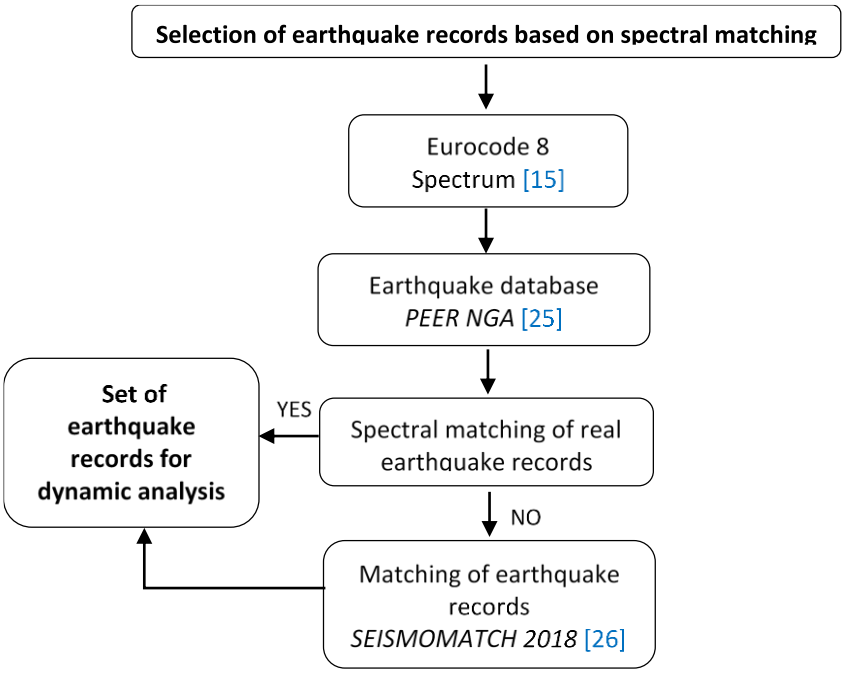

Figure 4: Flow chart of earthquake selection method

4.1 General data of used spectrums

Based on the experimental model, earthquake record from the location Friulli with longitude: 13-103365 and latitude: 46.225918 shown in Figure 5 a) was chosen for obtaining general data of used spectrum. For definition of Eurocode 8 [15] spectrum, elastic spectrum type 2 was used with expected PGA as shown in Figure 5 b) according to Hazard map for Italy.

a) b)

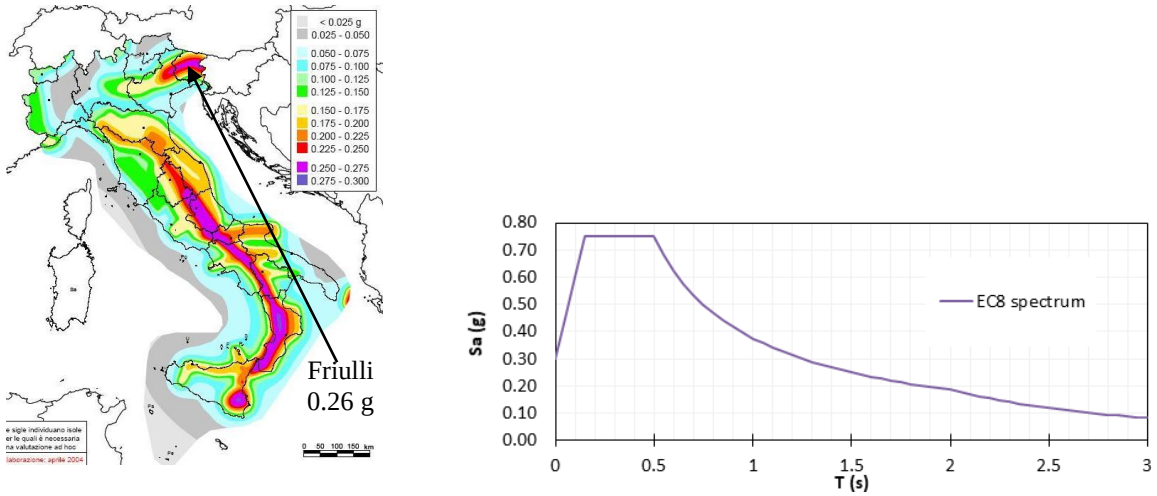

Figure 5: Seismic hazard map for Italy [35]; b) EC8 spectrum selected as target spectrums

4.2 Earthquake records set selection

Set of ground motion records was selected from PEER Ground Motions Database (The new NGA West 2 database) [25]. On Figure 6 is presented comparison of EC8 target spectrum with model spectrum obtained from PEER database.

Subfigures on left hand side are showing unscaled model spectrum, while on the right hand side are scaled model spectrum. In Table 5 are evaluated some of performance measures as Mean Absolute Error (MAE), Root Mean Squared Error (RMSE), and Mean Absolute Percentage Error (MAPE) from which can be seen that scaling model spectrums to target spectrums shows better results of performance measures.

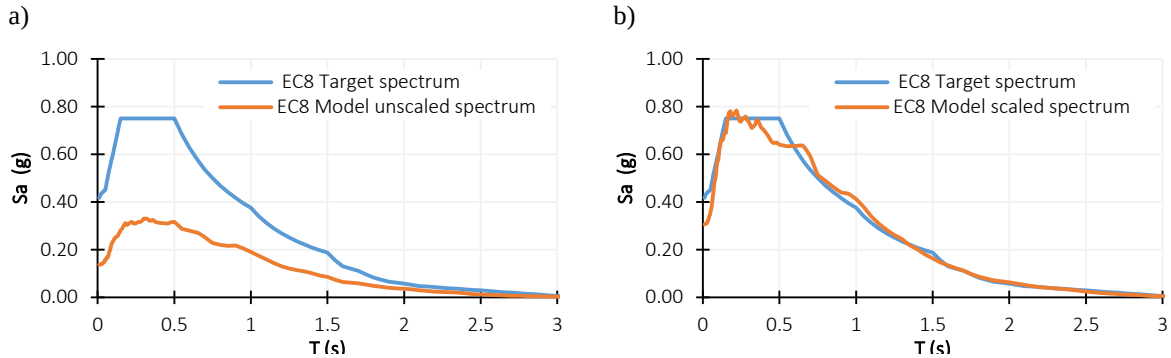

Figure 6: Comparison between spectrum obtained by PEER NGA database [25] for real (unscaled) spectrum and scaled or matched EC8 spectrum

However, comparing original spectrum obtained from the real accelerogram and target spectrum obtained from PEER NGA database [25] as shown on subfigures on the left hand side in Figure 7, great differences were observed and spectrums based on real unscaled earthquake records could not be used. Thus, real unscaled individual accelerograms were matched to target spectrum in SeismoMatch 2018 [26] to obtain mean target spectrum. Total of 30 earthquake records have been chosen (30 spectrums for 30 records). Subfigure on Figure 7 from the right hand side are presenting original and matched accelerogram.

Spectrum	Type of records	Mean absolute error (MAE)	Root mean squared error (RMSE)	Mean absolute percentage error (MAPE)
EC8	unscaled	0,24	0,49	55,31
	scaled	0,04	0,16	11,38
UHS	unscaled	0,09	0,27	44,67
	scaled	0,03	0,19	25,99
CMS	unscaled	0,03	0,15	70,84
	scaled	0,02	0,13	17,39

Table 5: Evaluation of selection of records based on real and scaled records according to performance measures

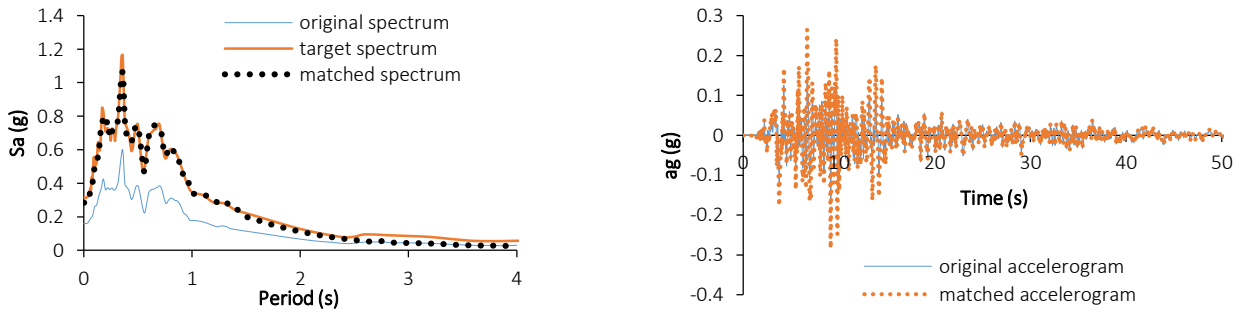

Figure 7: Example of spectral matching of earthquake records with aEC8 spectrum

Difference between the target and matched spectrum consequently have caused the change in values of performance measures Mean Absolute Error (MAE), Root Mean Squared Error (RMSE), and Mean Absolute Percentage Error (MAPE), and final shapes of evaluated spectrums on Figure 8.New, finally obtained values of performance measures are presented in Table 6.

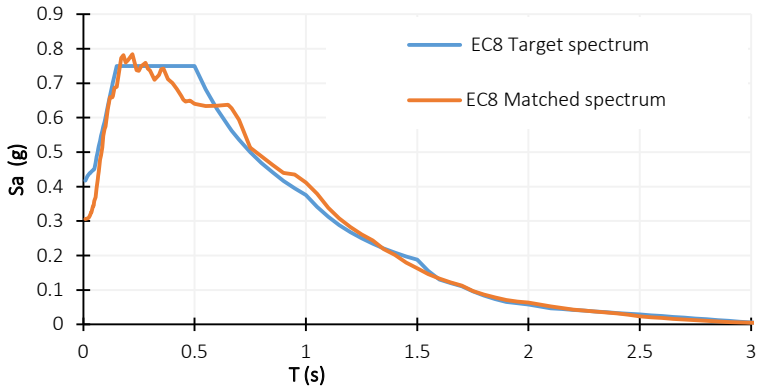

Figure 8: Example of spectral matching of earthquake records

Spectrum	Type of records	Mean absolute error (MAE)	Root mean squared error (RMSE)	Mean absolute percentage error (MAPE)
EC8	matched	0,03	0,11	9,21

Table 6: Evaluation of performance measures for matched spectrums in respect to target spectrums

5 RESULTS AND DISCUSSION

From seismic analysis are obtained results regarding Inter-storey Drift Ratio (IDR) of four-storey ISPRA building for all earthquake records and each target spectrum. These results are presented on Figure 9 and it can be seen that for target spectrum and belonging 30 matched earthquake records, average IDR is obtained.

Performance levels of structures under the earthquake loads describes the damage condition that must be satisfactory for a given building and a given ground motion. They are presenting the physical damage of buildings that may occur during the earthquake event. Damage for every structural performance level is defined by value of Inter-storey Drift Ratio (IDR) by Ghobarah [27] and description of damage condition needed to understand the physical state of the building for the end user.

a)

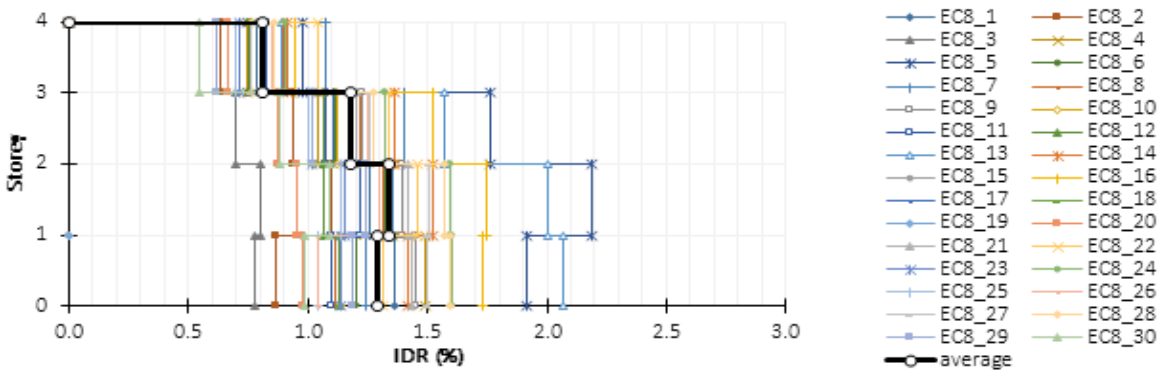

Figure 9: IDR profiles for EC8 target spectrum

Possible performance levels as shown in Table 7 are: slight damage=immediate occupancy; moderate damage=damage control; extensive damage=life safety; near collapse=collapse prevention according to HAZUS [28].

	Structural performance level	RC frames IDR(%)
	Slight damage	<0.20
	Moderate damage	<1.0
	Extensive damage	>1.0
	Near collapse	>3

Table 7: Comparison of IDR (%) according to structural performance levels and structure type [29]

In order to make an evaluation of obtained results in regard to defined performance levels and possible damage, mean IDR profiles from Figure 9 are summarized in Figure 10 with damage level limits.

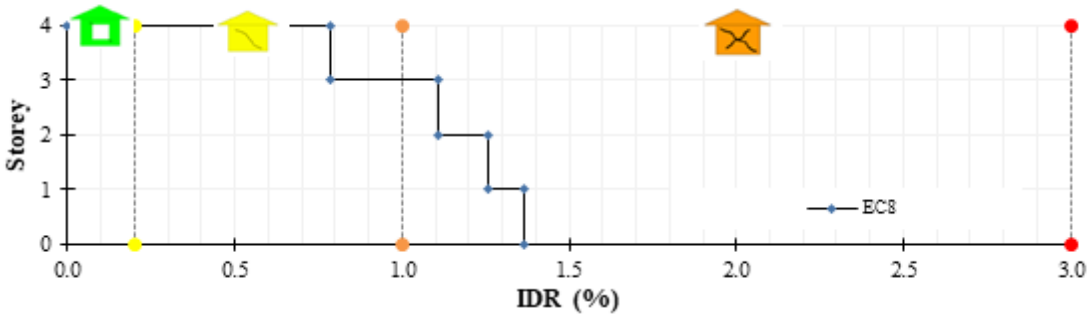

Figure 10: Mean IDR profiles for three spectrum in accordance with performance levels

Experimental results of low level (0.15 g) and high level (0.57 g) test conducted on ISPRA building [28] considering IDR are shown in Figure 10. In order to be able to compare results from the experiment and the ones obtained from seimic analysis, IDR is obtained by interpolation for PGA of 0.26 g, which is the PGA of observed location Friulli and result is shown in Figure 11. This IDR is further compared on Figure 12 with the ones obtained earlier from seismic analysis for EC8 target spectrum.

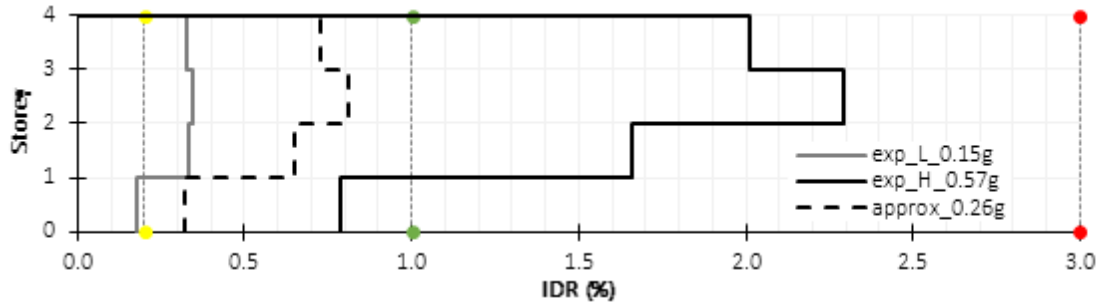

Figure 11: Mean IDR profiles for experimental results of low and high test and approximation of possible damage for 0.26g

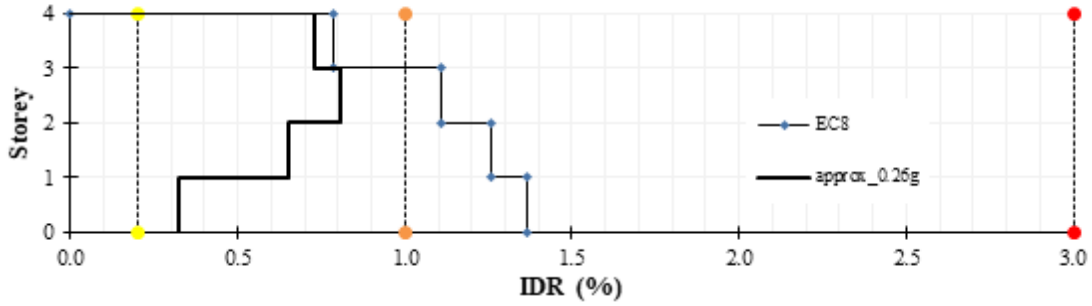

Figure 12: Comparison between approximated results for 0.26g and observed results from EC8 spectrum

6 CONCLUSION

The selection of appropriate seismic records is the one of the most critical steps while performing the nonlinear dynamic time history analysis in order to estimate the seismic performance in the basis of the hazard at the site where the structure is located. There are different ways of selecting ground motions, however in this paper 30 ground motion records are selected based on spectral matching according to EC8 spectrum.

Seismic analysis was performed on numerical model based on the experimentally tested ISPRA building. Accuracy of numerical model is obtained and approved by performance measures and comparison of displacements, base shear and hysteretic curve. Time history analysis for 30 earthquake records were obtained. As a result, Inter-story Drift Ratios (IDR) as a main damage measure were presented in order to make comparison with defined performance levels of reinforced concrete bare frames. There damage levels are defined with four limiting values of IDR. According to EC8 this IDR is within the limits that describe extensive damage.

Comparing these results with the ones from interpolation based on low and high test of ISPRA experimental model, it was concluded that IDR obtained from experimental model is lower compared to the IDR obtained for EC8 target spectrum. It can be concluded that EC8 is over conservative that can be good for design reserve, but in that case it is not efficient. However, for better results and comparison it is recommended to do larger number of numerical analysis including also conditional mean target spectrum and uniform hazard target spectrum.

Abstract

In the last years an increasing interest has been addressed to the assessment of the expected mean annual losses of single buildings as well as of building portfolio(s). Field observation of damage/failure in the aftermath of past earthquakes demonstrates that the losses related to the non-structural elements could significantly exceed the structural losses. At the same time, it is worth noting that the damage related to the non-structural elements could affect the functionality of the buildings and critical facilities. Based on these considerations, a detailed assessment of the expected annual losses requires data both on the structural and non-structural elements. In comparison to structural elements and systems, however, there is much less information and experimental data to undertake the assessment and design of non-structural elements for multiple-performance levels. Shake table testing could thus be very useful to assess the seismic performance of non-structural elements and to achieve the required information for loss estimation studies. In this paper, the results of shake table testing of acceleration-sensitive non-structural elements are presented. Equivalent single degree of freedom numerical models of the analyzed acceleration-sensitive non-structural element was developed using the results of the tests and a performance evaluation was carried out.

Keywords: Non-structural elements, shake table testing, loss estimation, fragility analysis, experimental testing.

1 INTRODUCTION

In the last years many efforts have been spent to develop advanced or simplified methodologies in order to evaluate the earthquake related losses and to ensure a desired building performance for a given intensity of seismic excitation [1-2]. Figure 1 illustrates the four steps required to perform the probabilistic seismic assessment according to the Performance-Based Earthquake Engineering (PBEE) framework [3].

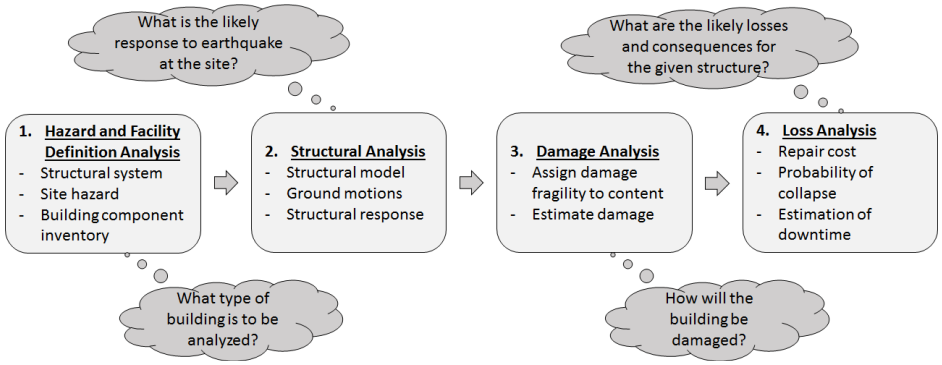

Figure 1: Overview of the four stages of PEER PBEE framework, after [3].

Within the PBEE framework the non-structural elements (NSEs) are of paramount importance, in particular in the damage (step 3) and loss analyses (step 4). During the damage analysis, the probability that a certain element (structural or non-structural) in the building will exceed a certain damage state for a given intensity level is established. At this stage, the availability of fragility functions for both structural and non-structural elements is necessary. In the literature, few experimental investigations are available for non-structural elements [4-7]. For this reason, many fragility functions are based on expert judgments. In loss estimation frameworks, the influence of non-structural elements is of paramount importance because they represent most of the total investments in typical buildings as well as because the non-structural elements show damage for low seismic intensities with respect to the structural ones [8-9]. The influence of non-structural elements has been demonstrated both looking at the damage reported during past earthquakes [10-11] as well as from loss estimation studies on buildings both at single and regional scale [12-14].

The lower seismic performance of non-structural elements is often related to the fact that, in comparison to structural elements, there is much less information and specific guidance available on the seismic design of NSEs for multiple-performance levels. The seismic qualification of NSEs by means of shake table tests could thus be a very useful tool to characterize the seismic response of the NSEs and to evaluate the performance parameters required for their seismic design. In this context, the ASCE 7-16 [15] standard in the US requires that certain critical non-structural elements must be seismically qualified to demonstrate their functionality after being subjected to design earthquake motions. The implementation of such seismic qualification procedure in the US resulted in significant benefits in terms of seismic performance of NSEs (i.e. definition of damage state, improved safety, reduced losses, etc.). According to ASCE 7-16 [15], the seismic qualification testing can be accomplished by either shake table testing, analysis or experience data.

This paper focuses on the definition of a simple procedure to evaluate the seismic performance of non-structural elements through the results of shake table tests. Shake tables tests were used both to qualify the case study non-structural element and to develop a simplified numerical model for the non-structural element of interest such that the outcomes of the testing could be reproduced and complemented with numerical simulations that in turn propagate the

effects of uncertainties/variability in the seismic input (and eventually in the non-structural element and the building). For this specific application, the developed numerical model allowed the authors to verify the performance of the tested non-structural element, when installed in a case study building. The simplified modeling approach, based on the results of shake table tests, could significantly help in the assessment of the seismic performance of non-structural elements and could be applicable to both fragility analysis as well as loss estimation frameworks.

2 CASE STUDY NON-STRUCTURAL ELEMENT

The seismic performance of a coaling machine was investigated in this study (see Figure 2). Shake table seismic qualification tests according to AC156 [16] and ISO13033 [17] were performed at the EUCENTRE laboratories using a multi-axial shaking table developed to test non-structural elements. The cooling machine is characterized by the following geometrical properties: length = 1000 mm, width = 890 mm, height = 1980 mm, operating weight = 4.51 kN. The specimen was connected to the shake table using custom interface plates designed by the staff of EUCENTRE. Every plate was connected to the shake table using four M30 bolts; threaded holes were manufactured at the Laboratory to fit the standard base connecting bolts of the tested unit (4 M10 bolts).

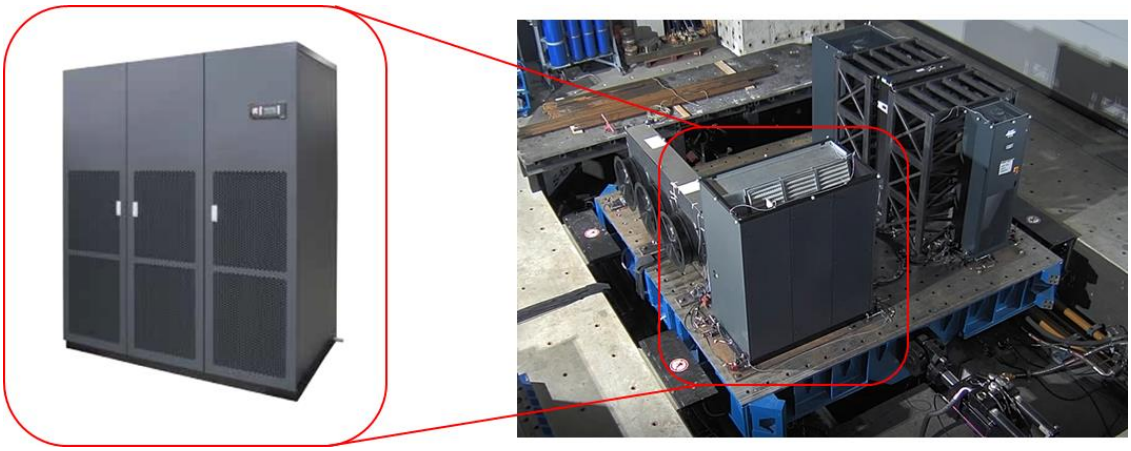

Figure 2: Tested Unit.

3 SEISMIC QUALIFICATION BY SHAKE TABLE TESTING

In this section, the main results of the experimental tests are reported. Only the results related to the shake table test performed according to ISO13033 [17] are reported. The ISO13033 document is the first document in Europe to provide recommendations about the procedures to be adopted for the verification of NSEs capacity and to ensure that those capacities exceed the seismic demands. In this study the original ISO13033 was modified and contextualized to the force-based formulation included in Eurocode 8 [18] to verify/design the non-structural elements.

3.1 Modal identification

Besides the seismic qualification tests, resonance search tests were also carried out, as specified by both AC156 [16] and ISO 13033 [17] test protocols. The resonance search was performed using white noise as input signal. The white noise consisted of a low-level acceleration (1.0 m/s^2 peak nominal) flat spectrum with frequency content from 0.25 Hz to 50 Hz, with approximately 60 seconds duration. Each axis (longitudinal and vertical) was tested separately. The white noise signal was generated using the MTS Systems Corporation Seismic Testing

Execution (STEX) software. Figure 3 shows an example of the acceleration time-histories used for the resonant frequencies search along the longitudinal direction.

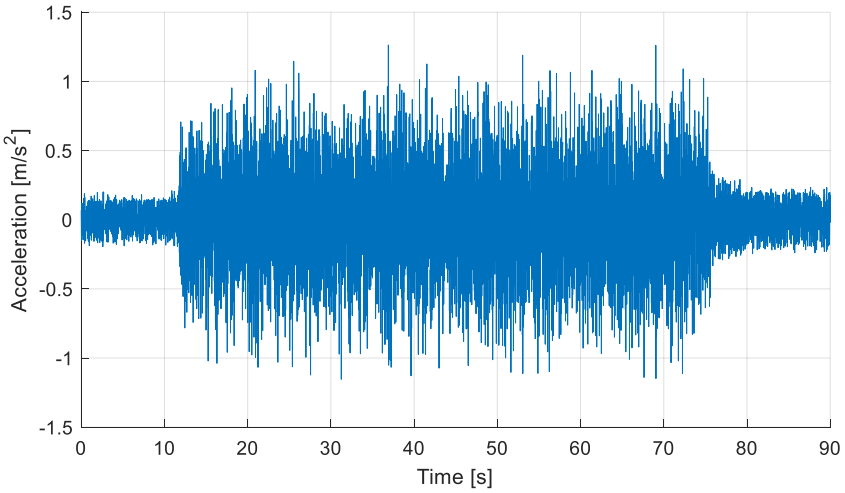

Figure 3: Time history of the white noise input for the longitudinal dof.

Data was analyzed using a transfer function algorithm with a frequency resolution of 0.0625 Hz. Based on the obtained results, the identified fundamental frequencies in the two main directions are 10.2 Hz (X direction) and 10.7 Hz (Y direction), respectively. The damping ratios were also estimated; they resulted equal to 7.1% and 6.3% respectively in the X and Y direction.

3.2 Shake table testing

The seismic qualification tests were performed according to a modified ISO13033 protocol [17] evaluating the Required Response Spectrum (RRS) for different seismic zones in Italy. Tests were conducted simultaneously in the longitudinal and vertical directions, with each direction excited by an independently (uncorrelated) generated table acceleration profile. The bi-directional testing protocol was conducted twice, in two horizontal testing directions rotated 90° from one another.

According to ISO 13033, the RRS can be evaluated for generic or specific buildings. The generic RRS can be evaluated according to the following equations:

$$A_{fleible} = k_{I(u\ or\ s)} \cdot k_{H,i} \cdot k_{R,p,flexible} \tag{1}$$

$$A_{rigid} = k_{I(u\ or\ s)} \cdot k_{H,i} \cdot k_{R,p,rigid} \tag{2}$$

where:

- $A_{flexible}$ is the design horizontal acceleration at the center of mass of flexible NSEs;
- A_{rigid} represents the design horizontal acceleration at the center of mass of rigid NSEs;
- $k_{I(u\ or\ s)}$ is the ground motion intensity factor to be provided by regional and national standards. The subscript u and s are referred to the PGA, modified to account for the soil conditions, at ultimate and serviceability limit state, respectively;
- $k_{H,i}$ is the floor response amplification factor. It is equal to:

$$k_{H,i} = \left[1 + \alpha \left(\frac{z_i}{H}\right)\right] \tag{3}$$

in which α is a parameter function of the type of seismic force-resisting system ($\alpha \leq 2.5$), z_i is the elevation of level i relative to the grade elevation, H is the average roof elevation of the structure relative to the grade elevation;

- $k_{R,p,flexible}$ is the NSEs amplification factor for flexible systems. This parameter is related to the NSEs element period, damping ratio, geometry, method of attachment, and inelastic behaviour. According to ISO 13033, $k_{R,p,flexible}$ can vary between 1 and 2.5 (or more). See ANNEX D of ISO 13033 for more information about the allowed values;

- $k_{R,p,rigid}$ is the NSEs amplification factor for rigid systems. It is assumed equal to 1.0.

The approach proposed by ISO13033 to define the RRS has been modified in order to make it compatible with the design horizontal equivalent static force evaluated according to Eurocode 8 [18]. In Eurocode 8, the spectral acceleration, S_a, used to calculate the horizontal equivalent static force to be applied to the NSE is given by:

$$S_a = \alpha \cdot S \cdot \left[3 \cdot \frac{\left(1+\frac{z_i}{H}\right)}{\left(1+\left(1-\frac{T_a}{T_1}\right)^2\right)} - 0.5 \right] \tag{4}$$

The parameter α in Eq. 4 represents the ratio of the design ground acceleration on soil type A to the acceleration of gravity g, while S is the soil amplification factor. The term in square brackets in Eq. 4 is used to replace the product $k_{H,i} \cdot k_{R,p}$ in Equations 1 and 2. This term accounts for the amplification of the peak floor acceleration due to the location of the NSEs in the building and for the spectral amplification as a function of the ratio of the fundamental period of the NSEs (T_a) to the fundamental period of the building (T_1). In order to define the spectral acceleration for flexible and rigid NSEs in the RRS, the ratio T_a/T_1 is assumed equal to 1 for flexible NSEs and equal to 0 for rigid NSEs. Based on this assumption, it is possible to reproduce the RRS by replacing Equations 1 and 2 with the following two equations:

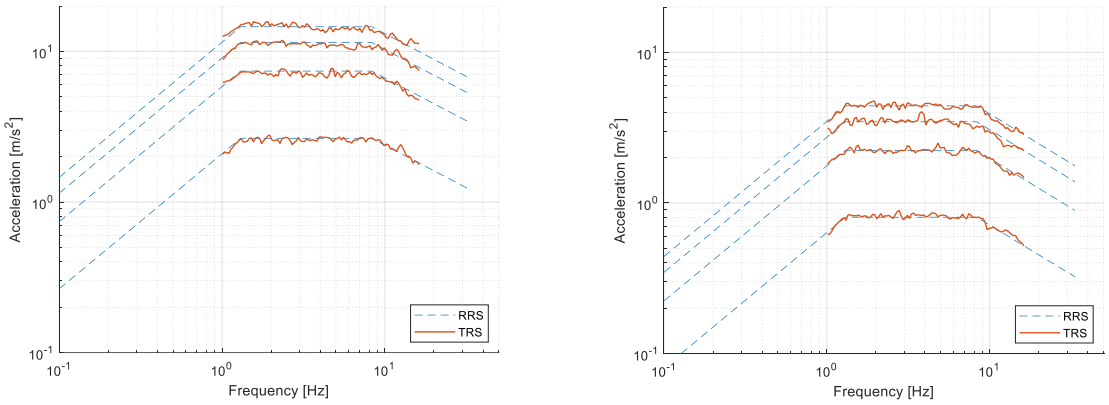
$$A_{flexible} = k_{i(u\ or\ s)} \cdot \left[3 \cdot \left(1 + \frac{z_i}{H}\right) - 0.5 \right] \tag{5}$$

$$A_{rigid} = k_{i(u\ or\ s)} \cdot \left[3 \cdot \frac{\left(1+\frac{z_i}{H}\right)}{2} - 0.5 \right] \tag{6}$$

The vertical RRS is assumed to be 2/3 of the horizontal RRS with $z_i/H=0$, as suggested by AC156 [16]. The corner frequencies are also defined according to AC156: f_0=1.3 Hz, f_1=8.3 Hz and f_3=33.3 Hz.

Four seismic intensity levels were considered for the seismic qualification tests. The selected seismic intensities are representative of the Italian context. The probabilistic seismic hazard assessment proposed by Stucchi et al. [19], that provides the horizontal peak ground acceleration (PGA) with a 10% probability of exceedance in 50 years, was used to select the seismic intensities. In particular, seismic sites characterized by the following PGA on firm soil were taken into account: 0.05g (low intensity), 0.14g (medium intensity), 0.21g (medium-high intensity) and 0.27g (high intensity).

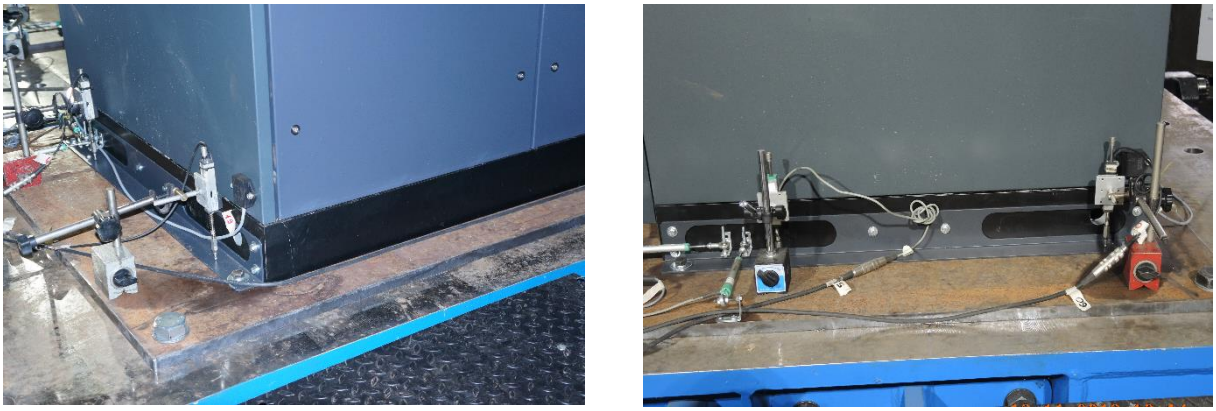
Figure 4 shows the comparison between the RRS and TRS for the vertical and horizontal testing directions. A good match between the RRS and TRS spectra is observed both for the horizontal and the vertical directions.



a) Horizontal component b) Vertical component

Figure 4: Comparison between RRS according to modified ISO13033 and TRS.

After each test, a visual inspection was undertaken to verify the structural integrity of the cooling machine as well as the presence of damage in the anchoring system. No evident sign of damage was observed after the tests for all considered intensities. Figure 5 shows photographs of the cooling machine after the test in the Y direction for the highest seismic intensity. Only a small distortion of the covering panels was observed, but the structural integrity was not compromised. A functionality test was also performed after the seismic qualification and the machine functioned perfectly.



a) Deformation panels **b) Deformation panels**

Figure 5: Visual inspection after the seismic qualification tests.

4 SEISMIC PERFORMANCE EVALUATION OF THE CASE STUDY NON-STRUCTURAL ELEMENT

The results of the shake table seismic qualification tests were used to derive an easy-to-use modeling idealization for the investigated cooling machine and to carry out seismic performance evaluation of it, when integrated in a case study structure. In what follows, account is given of the main characteristics of the studied building archetype along with a description of the ground motion sets and seismic intensity levels assumed for the assessment. Capacity modeling was then treated, leading to seismic performance evaluation of the selected non-structural element.

4.1 Case study structure

A four-story RC moment-resisting frame was designed according to Eurocode 8 [18] assuming a ductility class B (q = 3.75) and a firm soil condition. The frame was supposed to be located in construction site near Cassino, Italy characterized by a design peak ground acceleration of 0.21g (return period of 475 years). The seismic weight of each floor was defined assuming a tributary width of 5 m. The strength of the concrete (f'c) was taken equal to 32 MPa, while the yield strength of the steel was taken equal to 375 MPa. The dimensions of the frame are shown in Figure 6.

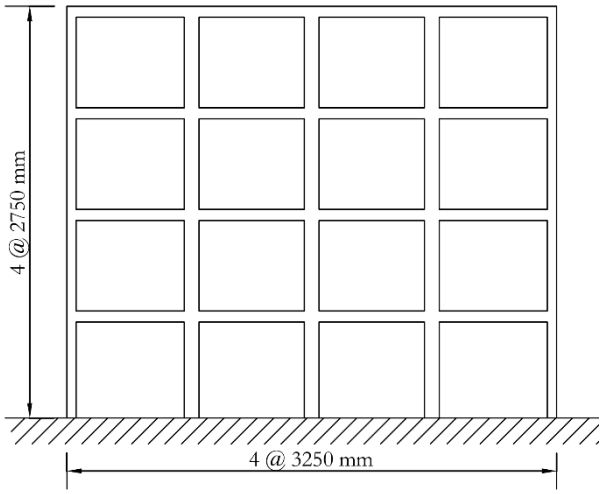


Figure 6: Case study RC frame

The model of the frame was developed using the Opensees software [20]. The numerical models were developed assuming the fiber force-based approach [21]. Inelastic beam-column fiber elements were used to model the frame members, explicitly including geometric and material nonlinearities. A distributed plasticity approach was thus adopted to simulate the spreading of inelasticity over the member length and cross section. The uniaxial confinement model proposed by Chang and Mander [22] was considered to simulate the cyclic behavior of concrete, the hysteretic rules of which were established based on statistical regression analysis on the experimental data from cyclic compression tests conducted by a number of researchers. A simple bilinear constitutive model with isotropic strain hardening was assigned to the steel rebars.

4.2 Ground motion selection

A set of 20 horizontal accelerograms at the site of the case-study buildings were selected from the PEER NGA-West database [23]. Based on a preliminary estimation of the Italian and European seismicity, the selection of the site was carried out in order to represent a medium-to-high seismicity in Italy. The selected intensity corresponds with the medium-high intensity used in the seismic qualification tests.

Hazard-consistent record selection was based on spectral compatibility (matching of the geometric mean) with a conditional mean spectrum according to the methodology proposed by Jayaram et al. [24]. This approach considers the conditional variance given a return period of spectral acceleration at the selected period. The conditional period, T*, to be used for the nonlinear time history analyses (NLTHAs) of RC frame was selected based on the results of eigenvalue analyses, and it is equal to 0.5 sec. Five return period of the seismic intensity were selected to perform the NLTHAs (50, 200, 475, 975 and 2475 years). Figure 7 shows the mean response

spectrum and all individual record response spectra for the 20 considered ground motions for a return period equal to 475 years.

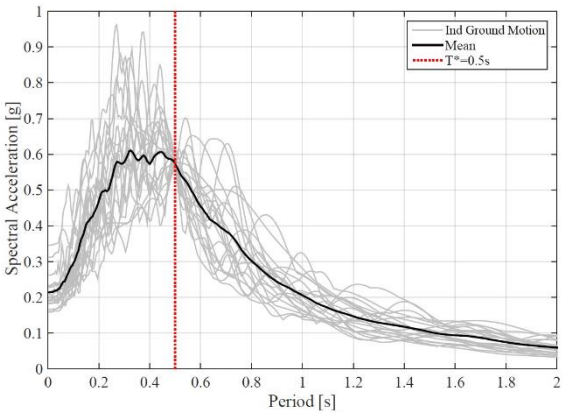

Figure 7: Mean response spectrum and acceleration response spectra of all considered ground motions for a conditional period, T*, equals to 0.5 sec

In order to perform the time history analyses tangent stiffness proportional Rayleigh damping was introduced to the 1st and 3rd modes of the structure. The inherent damping ratio was assumed to be 5.0% of the critical.

4.3 Numerical modeling of the case study cooling machine

For the purposes of this study, the non-structural element of interest was modeled as a simple bilinear idealization, with the initial elastic stiffness being computed according to test data from modal identification. More in detail, the initial stiffness of the bilinear single degree of freedom (SDoF) system was calculated as reported by Equation 7:

$$k = m \cdot (2\pi \cdot f)^2 \tag{7}$$

where m is the mass of the cooling machine and f is its fundamental frequency in the most critical of the two main directions. By taking Y-direction as reference, f equals 10.7 Hz and, hence, k equals 2078 kN/m.

Furthermore, the peak capacity of the bilinear model was assumed to correspond to the shear resistance of the 4 M10 bolts used to anchor the cooling machine to the shake table for the tests. Equation 8 reports how the total shear yield/ultimate capacity of the bolts ($V_{y/u}$) was computed:

$$V_{y/u} = 0.6 \cdot A_s \cdot n \cdot f_{y/u} = 0.6 \cdot A_s \cdot 4 \cdot f_{y/u} \tag{8}$$

where A_s is the cross-section area of the bolt, n is the number of bolts, and $f_{y/u}$ is the yield/ultimate stress of steel. The class of the bolts is 4.6, meaning that f_y is equal to 240 MPa. The bilinear model is presented in the S_a-S_d format in order to easily undertake performance evaluation and compare the results with the absolute acceleration – relative displacement floor response spectra obtained by the NLTHAs. In order to convert $V_{y/u}$ in the acceleration format, the maximum shear capacity is simply divided by the seismic mass of the cooling machine.

A simple parametric study was also performed to evaluate the bilinear model varying the bolts' diameter. To this end, three diameters were considered: 6, 8 and 10 mm. Figure 8 shows the S_a-S_d relationship of the calculated bilinear models.

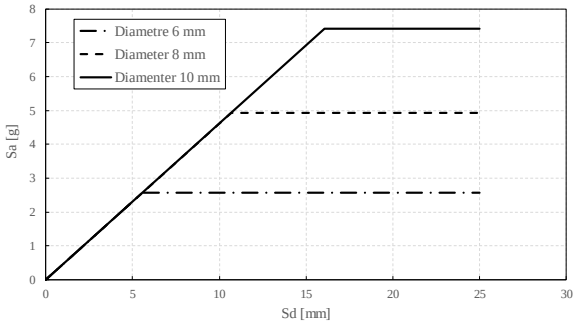

Figure 8: Bilinear model tested cooling machine

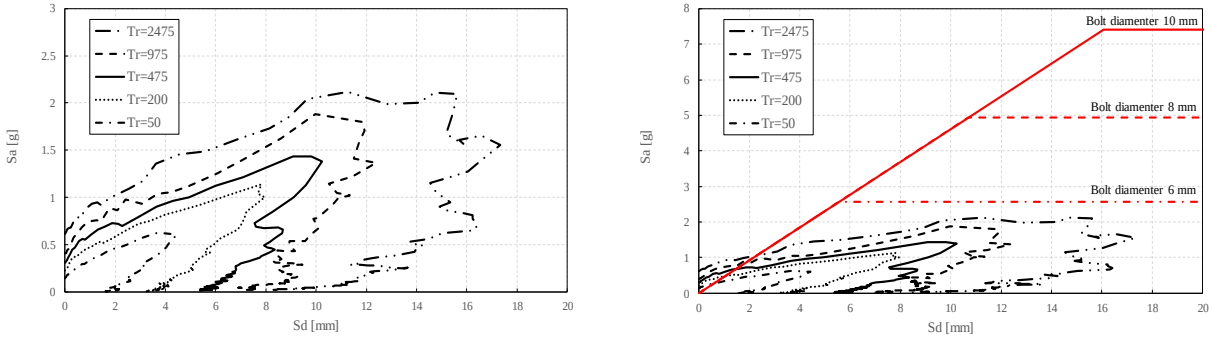
4.4 Seismic demand and assessment of the non-structural element

In order to carry out the performance evaluation, the absolute acceleration – relative displacement floor response spectra for the analyzed case study building were first calculated, for different return periods of the seismic intensities. Note that the cooling machine is supposed to be installed at the third floor of the building, and hence Figure 9a reports the median S_a-S_d response spectra corresponding to this floor. As reported in Figure 9b, all considered bolt's diameters satisfy the performance evaluation, for all considered return periods. It is worth to be noted that high return periods, such as 975 and 2475 years, are generally not considered for non-structural elements performance evaluation but are reported here as illustrative example.



a) Floor response spectra b) Performance evaluation

Figure 9: Floor response spectra and performance evaluation

As a closing remark, it is worthy of mention that the adopted assessment methodology could be also used and extended to perform fragility analysis and develop fragility functions in which probabilities of exceeding given damage state conditions are expressed in terms of spectral accelerations at the fundamental period of the non-structural elements $S_a(T_1)$. The assumption of $S_a(T_1)$ as engineering demand parameter could significantly improve the loss estimation evaluation for acceleration-sensitive non-structural elements, with respect to the peak floor accelerations, because it takes into account the dynamic amplification due to the non-structural element stiffness.

5 CONCLUSIONS

The damage observed during past earthquakes demonstrated the importance of the non-structural elements in the performance-based seismic design of buildings. However, few experimental data are available to characterize the performance on non-structural elements and to

carry out seismic performance assessment. Within this context, this paper describes the results of shake table seismic qualification tests on a cooling machine. The shake table tests were first presented and then used to define a simple SDoF bilinear model of the investigated cooling machine. The proposed mechanics-based idealization was used to undertake the performance evaluation of the case study cooling machine, when installed in a typical four-storey RC frame. The results of the assessment demonstrated the effectiveness of the proposed approach, which could be extended and applicable to fragility analysis assuming a new, and more consistent, engineering demand parameter.

Keywords: adobe walls, traditional construction, vulnerability, abaqus,simplified micro-modelling approach, concrete damage plasticity.

Abstract. *Nowadays, traditional construction methods still widespread in developing countries despite the dominance of reinforced concrete structures in urban area. These traditional methods are generally based on the use of available local materials and old techniques characteristic of each region. Since, this kind of structure is poorly studied in the literature there is a strong need to better understand their mechanical behaviour in order to optimize their design.In this paper, the shear behaviour of an adobe wall, made of natural earth materials, is modeled using a simplified micro-modelling approach in order to investigate its behaviour under cyclic loading. The concrete damage plasticity model is used for the adobe modelling while interfaces between adobes are defined using cohesive and frictional elements. Then 2D numerical simulations are performed using Abaqus/Standard. The numerical model is first used to reproduce the experimental shear cyclic behaviour of a wall.The results show the different damage patterns while all numerical data were compared with the results of the experimental test.*

1 INTRODUCTION

Adobe structure is known as one of the oldest structures in the world. This type of construction is still widely used in several countries, especially in the developing ones because of its economical advantages characterized by the low cost of the materials and it's local availability since it's mainly composed of earth and water. In addition, there is no need to high engineering skills where non experienced labour are capable to construct adobe buildings relying on the traditional construction techniques [1]. Moreover, earth construction has revived in several developed countries due to the energy and environmental issues that create an urgent need to re-adopt sustainable construction techniques [2].
However, the adobe buildings are known as fragile structures that cannot withstand earthquakes. In fact, there is only few studies on the behaviour of these structures whereas nowadays most of research are concentrating on the developing and the enhancement of the reinforced concrete constructions. Therefore, there is a strong need to improve the earth construction by analysing their vulnerability using experimental and numerical techniques.
The paper presents a numerical simulation of adobe wall under cyclic loading that will be compared to a real experimental test in order to validate its efficiency. This model will be used in the future to simulate masonry walls under dynamic loading.

2 NUMERICAL MODELLING APPROACH

A finite element model was generated in Abaqus/Standard [3] to simulate the wall behaviour where 2D was chosen over 3D modelling in order to compromise between time consuming and real wall configuration. Where another decision that must be taken regarding the representation of masonry walls.
Based on the literature [4], there is different modelling strategies that can be divided into three types depending on the desired level of accuracy, see figure 1, two of them take into account the heterogeneous nature of the masonry walls, figure 1 (b) and (c), while (d) neglects the interface and takes the wall as a one homogeneous material. Among these techniques the simplified micro modelling was adopted where adobe units are expanded to the half of the mortar thickness in each direction in order to conserve the original wall dimension. They are represented by continuum elements while the interface is represented using discontinuous elements.

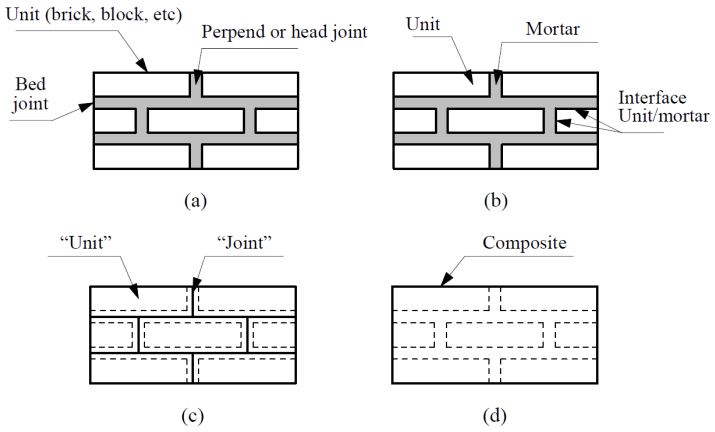

Figure 1: Modeling strategies for masonry structures: (a) masonry sample; (b) detailed micro-modeling; (c) simplified micro-modeling; (d) macro modeling.[4]

This technique was used by several studies on the masonry modelling [6, 7, 8] and it has several advantages: it gives accurate results despite of the simplified representation of the joints, since right before failure the non linear deformation occurs mostly in the joints [5]. It also allows to study the crack patterns and the shear behaviour. It should be mentioned that the CPS4R elements were using for adobe modelling in Abaqus.

2.1 Constitutive model of masonry units

The concrete damage plasticity model (CDP) was used to simulate the non-linearity of the adobes, it's based on the work of Lubliner [10], Lee and Fenves [11]. It's a continuum damage model for concrete or other quasi-brittle material which are subjected to monotonic, cyclic and /or dynamic loading [9]. It assumes that the uniaxial tension and compression response of the material is characterized by the damage plasticity where this damage is governed by the degradation of the stiffness, it's defined under unixial loading as:

$$\sigma = (1 - d)E_0(\epsilon - \epsilon^{pl}) \tag{1}$$

where $\sigma, \epsilon, \epsilon^{pl}, E_0$ are respectively, stress, strain, plastic strain, the (undamaged) modulus and d is the damage variable that can take from zero, for the undamaged material, to one when it's fully damaged. The model allows also the stiffness recovery, it's more evident when the load changes from tension to compression where the tensile cracks closure occurs resulting the recovery of the compressive stiffness, figure 2.

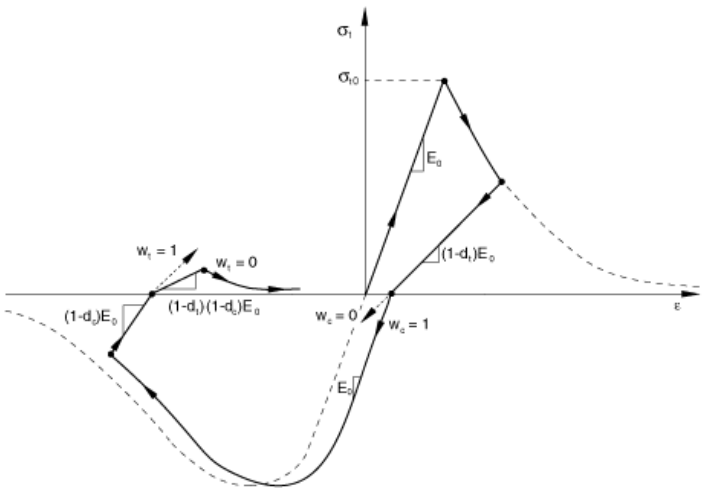

Figure 2: Response of the CDP material under uniaxial load cycle(tension and compression)[9]

In this work, most of the material properties of the adobe units were calibrated based on the experimental compression and tension tests [12]. The elastic properties are shown in the table 1 while the table 2 shows the CDP parameters that were calibrated by Agüera & al [13].Moreover, the compression-tension behaviour was introduced as a stress-strain values where compressive and tensile strengths are respectively equal to 6.4 and 0.48 MPa. Hence, the damage factor is identified using the following formula[10]:

$$d = 1 - \frac{\sigma}{f} \tag{2}$$

f is either the compressive or the tensile strength of the material.

Mass density (Kg/m^3)	E modulus (GPa)	Poisson coefficient
200	4	0.2

Table 1: Elastic characteristics of adobe.

Dilation angle	Eccentricity	fb0/fc0	k	Viscosity parameter
7	0.1	1.16	0.66	0.0005

Table 2: CDP characteristics of abode units

2.2 Surface-based cohesive model for joints

The surface based cohesive model was chosen to create the link between the units in order simulate the interface response. The interaction is defined based on a traction separation law [9] that allows to simulate the joint failure caused by normal tensile cracking, in plane and out of plane shear sliding. This law assumes initially linear traction-separation behaviour which is defined in terms of an elastic matrix K that relates the nominal shear stresses t and the separation vectors δ:

$$t = \left\{ \begin{array}{c} t_n \\ t_s \\ t_t \end{array} \right\} = \begin{bmatrix} K_{nn} & 0 & 0 \\ 0 & K_{ss} & 0 \\ 0 & 0 & K_{tt} \end{bmatrix} \left\{ \begin{array}{c} \delta_n \\ \delta_s \\ \delta_t \end{array} \right\} = K\delta \tag{3}$$

This linear law is followed by a failure mechanism which consists of a damage initiation criterion that refers to the beginning of the cohesive degradation at the interface contact and a damage evolution that ended with total joints failure. In this study the maximum stress was adopted to initiate the degradation of the cohesive bond, it's when the maximum contact stress ratio reached the value of one, see equation 4. The cracks propagation in the joints impose a stiffness degradation that affect the contact stress according to equation 5 where D is the damage coefficient that starts from 0 and it reaches 1 when the joints failure occurs. D is calculated in Abaqus based on a linear softening evolution, equation 6, by specifying the maximum value of the effective separation δ_m^{max} which is attended during loading history.

$$max \left\{ \begin{array}{c} \langle \frac{t_n}{t_n^0} \rangle ; \frac{t_s}{t_s^0} ; \frac{t_t}{t_t^0} \end{array} \right\} = 1 \tag{4}$$

$$t = (1 - D)K\delta \tag{5}$$

$$D = \frac{\delta_m^f (\delta_m^{max} - \delta_m^0)}{\delta_m^{max} (\delta_m^f - \delta_m^0)} \tag{6}$$

Moreover, the friction between adobes is defined by Coulomb friction model. The sliding begins after the failure of the cohesive bond and when the shear stress attends the critical sliding stress which is defined by the coefficient of friction μ and the normal compressive stress. The following table shows the different linear and non linear properties for joint interfaces, the rigidities are calculated based on the equations 7 [4] and the other parameters are deduced experimentally based on Casagrande tests:

μ	$K_{nn}(N/m^3)$	$K_{ss}(N/m^3)$	$K_{tt}(N/m^3)$	t_n^{max}(kPa)	C (kPa)	δ^{max} (mm)
0.9	102E9	43E9	43E9	200	13.9	1.56

Table 3: Properties for the joint interfaces.

$$K_{nn} = \frac{E_u E_m}{h_m(E_u - E_m)} \tag{7}$$

$$K_{ss} = K_{tt} = \frac{G_u G_m}{h_m(G_u - G_m)} \tag{8}$$

E_u and E_m are the Young's modulus, G_u and G_m are the shear modulus, respectively, for adobe and mortar and hm is the thickness of the joint.

3 MODEL OUTPUT AND DISCUSSION

The configuration of the FE model in Abaqus/Standard is showed in the figure 3. The model includes the wall which is composed of the adobe units and the contact is applied at their edges. The other two parts(base and top) are the metallic supports where they used to impose the boundary conditions like in real experimental test.

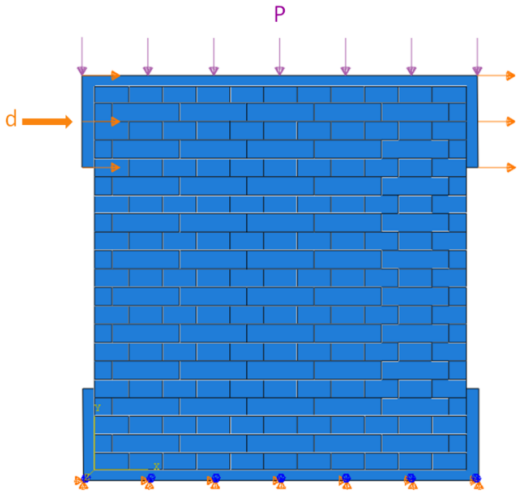

Figure 3: Numerical model of the adobe wall

The base support was fixed and on the surface of the top one a normal pressure loading P of 88 kN per surface was applied. Finally a cyclic loading (horizontal displacement d) was

imposed at the edges of the upper support. The wall has been meshed using the CPS4R elements where the number of elements in each unit vary between 4, 6 or 14 depending of their dimension, where 1506 is the total number of elements.

The figure 4 shows the damage pattern of the real experiment [12] and the numerical simulation at the end of the loading. In both cases, the cracks begin from the top and go down to the bottom of the wall in the two directions which is due to the high shear stress triggering the failure of the joints contact and creating an X shape pattern.

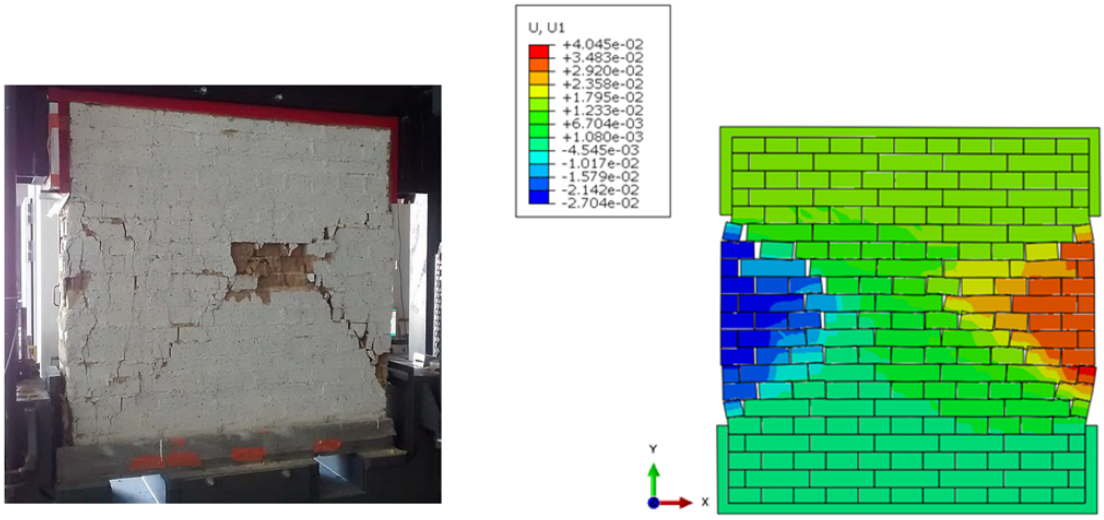

Figure 4: Crack patterns of the experimental and the numerical simulation(lateral displacement in m) of the wall

In addition, a comparison between numerical and experimental hysteresis loops is represented in the figure 5 where it shows the horizontal force (kN) in function of the displacement (mm). An asymmetrical loop is obtained from the experimental test where the positives peak forces attend 45.9 kN while the negative ones are limited at 23 kN. It can be assumed that this asymmetry is due to the cracks generation and the failure of several joints right from the beginning of the test, it makes the wall less resistant in a direction than the other one where the wall preserve it's resistance for several cyclic loading. As it's shown in the same figure the numerical simulation represents fairly enough the positive side of the experimental results than the negative one. Moreover, the experimental forces attend high values right from the beginning of the test which is not the case for the numerical forces. Therefore, the numerical wall withstand the first cycles where a symmetrical hysteresis loop is obtained.

The maximum numerical force is equal to 48.34 kN which is relatively close to the experimental value mentioned above. The effective stiffness K_{eff}, eq. 9, is calculated in function of: F_{eff} which is the maximum obtained force and d_{cr} its corresponding displacement. K_{eff} corresponds to the stiffness at the moment of the first cracks creation. The experimental stiffness is equal to 58.14 kN/mm while the numerical one is 10.35 kN/mm, and it also shows that the cracks start at an early stage experimentally while it's not the case for the numerical model.

$$K_{eff} = \frac{F_{cr}}{d_{cr}} \tag{9}$$

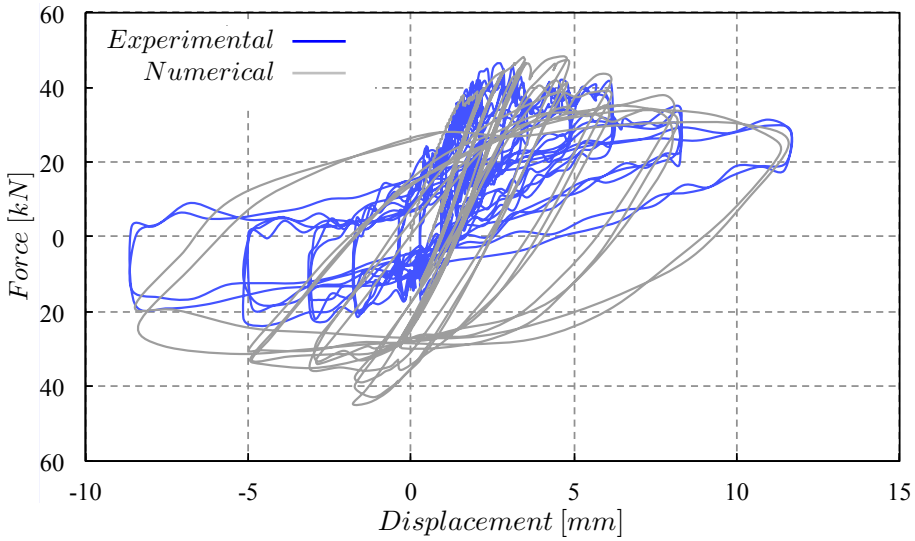

Figure 5: Hysteresis loop of experimental and numerical results, the horizontal force is presented in function of the horizontal displacement

The final graph, figure 6, represents the dissipated energy, in Joules, of each cycle. For the experimental results, the energy starts to dissipate from the first cycles and increases progressively with the increasing of the applied displacement. However, the numerical dissipated energy is negligible at the beginning, it starts to increase after the ninth cycle.

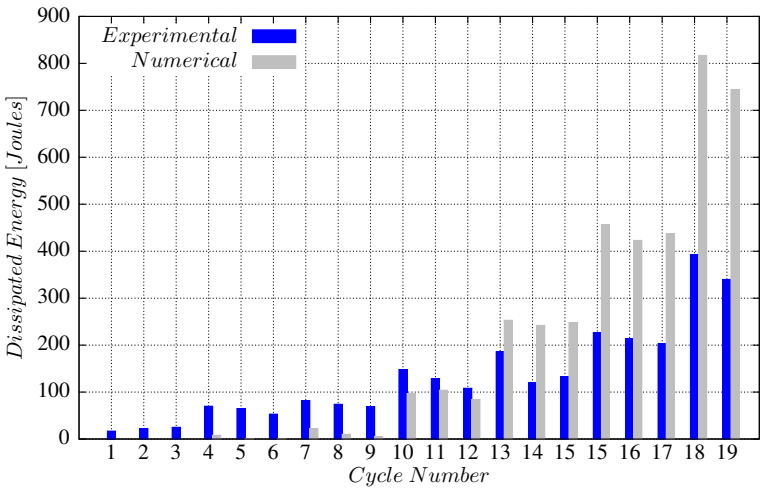

Figure 6: Comparison between the experimental and the numerical dissipated energy of each cycle.

All the results above indicate that the damage of the wall occurs at an early stage in the experimental test compared to the numerical one.

4 Conclusion

The numerical model is able to describe the adobe walls behaviour under cyclic loading. The simplified micro modelling is accurate enough to describe and predict the damage pattern

while the comparison of force-displacement curves was done only on the positive part of the values because of the asymmetrical shape of the experimental hysteresis loop. The forces and the dissipated energies show that the damage starts earlier in the experimental test than in the numerical model.
Therefore, additional analysis must be done on the experimental test and their results in order to specify and implement the exact boundary conditions in the numerical model. Moreover, 3D modelling will be performed to represent the real configuration of the wall and thus to improve the numerical results. In future, the model will be used to perform dynamic simulations that will allow to study more precisely the masonry walls behaviour.

THE INFLUENCE OF THE STEEL GRADE ON THE PROBABILISTIC THEORY OF PLASTIC MECHANISM CONTROL FOR STEEL MOMENT RESISTING FRAMES

Alessandro Pisapia[1*], Vincenzo Piluso[1]
[1] University of Salerno

e-mail: alpisapia@unisa.it, v.piluso@unisa.it

Abstract

This work aims at the extension of the Probabilistic Theory of Plastic Mechanism Control (P-TPMC) for Steel Moment Resisting Frames (MRFs) to other steel grades. P-TPMC is based on the application of First Order Reliability Method and Ditlevsen Bounds, which represents the reliability method for series systems, considering as random variable the yield strength of steel members. As in previous work, only the S275 steel grade has been investigated in this paper the analyses are extended to a different grade of steel, in particular, S235 and S355, to evaluate its influence on the failure probability of TPMC. Finally, a simple relationship to computing the value of the overstrength factor needed to include the importance of random material variability in the application of TPMC is proposed.

Keywords: Theory of Plastic Mechanism Control, collapse mechanisms, moment resisting frames, stochastic frames, probability of failure, series systems.

1 INTRODUCTION

In the seismic design of structures, modern seismic codes [Eurocode 8, AISC] [1],[2] provide simplified design rules to prevent unsatisfactory collapse mechanisms. In particular, in case of Moment Resisting Frames (MRFs), the use of the so-called beam-column hierarchy criterion is suggested, but it is widely demonstrated it is only able to prevent soft storey mechanism not assuring the development of a collapse mechanism of global type. The Theory of Plastic Mechanism Control (TPMC) [3]-[5] has been developed to design structures able to show a collapse mechanism of global type after aseismic events. This design procedure is based on the extension of the kinematic theorem of plastic collapse to the concept of mechanism equilibrium curve. Besides, the design conditions to be satisfied to prevent all the undesired collapse mechanisms, up to an ultimate displacement compatible with the local ductility supply of structural members, are derived. Up to now, TPMC has been successfully applied to deterministic structures having different seismic resistant schemes both for steel structures [5]-[15] and reinforced concrete structures [16]. However, even in the case of structures designed by TPMC, undesired collapse mechanisms could occur when the effects of random material variability are taken into account. The Theory of Plastic Mechanism Control has been extended to the case of stochastic MRFs to account for the influence of random material variability on the collapse mechanism of steel structures subjected to horizontal seismic forces. The method proposed evaluates the probability of failure in the attainment of a collapse mechanism of global type. It constitutes the probabilistic version of the Theory of Plastic Mechanism Control (TPMC) [17]-[19]. It is important to underline that, within structural reliability analysis and within the contest of failure mode control, the term “failure” denotes the attainment of a collapse mechanism different from the global one. In fact, many experimental investigations made by shaking table test [20]-[22] or Incremental Dynamic Analyses (IDA) [24]-[29] have shown that different failure mode can occur in structures under destructive earthquakes, and the reliability of having a collapse mechanism of global type sometimes is very low. Through the probabilistic procedure, it was possible to define an overstrength factor to apply to the deterministic version of TPMC with a given success probability, taking account the effects of random material variability.

In this work, a parametric analysis has been carried out to develop a mathematical relationship for computing the overstrength factor as a function of the main features of the analysed MRFs and with a fixed reliability value in the application of the deterministic version of Theory of Plastic Mechanism Control.

2 THEORY OF PLASTIC MECHANISM CONTROL

It is well known that under earthquake excitation, it is necessary to assure adequate global ductility and high energy dissipation. In the design of MRFs, it is important to guarantee the development of a global mechanism, where the dissipative zones are concentrated at beam ends and at the base of the columns of the first storey, avoiding the development of partial failure mechanisms, as depicted in Figure 1. For this reason, in the nineties, a theory on the plastic mechanism control has been proposed by Mazzolani et al. [3]. In particular, this theory is based on the extension of the kinematic theorem of plastic collapse to the concept of mechanism equilibrium curve. Therefore, for each collapse mechanism, it is possible to define the equilibrium curve as follows:

$$\alpha = \alpha_0 - \gamma\delta_u \tag{1}$$

where α is a collapse multiplier of structures, α_0 represents the first order multiplier, γ is the slope of curve depending on the second-order effects, and finally, δ_u is the ultimate displacement of the structure. Eq. (1) is provided by the equality between the internal work of

the plastic hinges and the external work of the horizontal forces. Remembering that, in the rigid-plastic analysis, the collapse multiplier is the smallest of the kinematically admissible multipliers, to assure the collapse mechanism of global type, it is necessary to satisfy the following design condition:

$$\alpha^{(g)} \leq \alpha^{(t)} => \alpha_0^{(g)} - \gamma^{(g)}\delta_u \leq \alpha_{0.i_m}^{(t)} - \gamma_{i_m}^{(t)}\delta_u \;\; for\; t = 1,2,3\; and\; i_m = 1,2,\ldots n_s \qquad (2)$$

where "g" indicates the global mechanism while "t" represents a generic collapse mechanism different by the global type and i_m is the generic storey of the structure. Eq.(2) assures that the curve of the global mechanism type is located below those corresponding to all the other undesired mechanisms until the ultimate displacement δ_u, compatible with the ductility supply of the dissipative zones, as depicted in Figure 2.

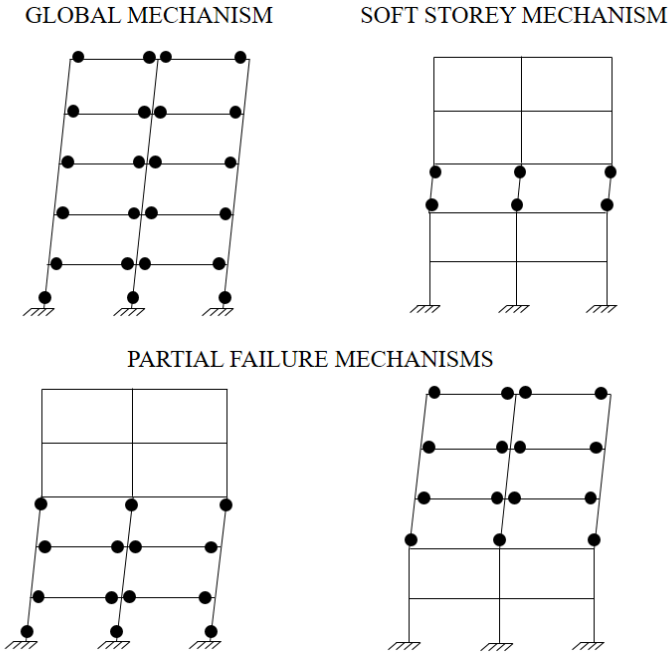

Figure 1: Collapse mechanism typologies.

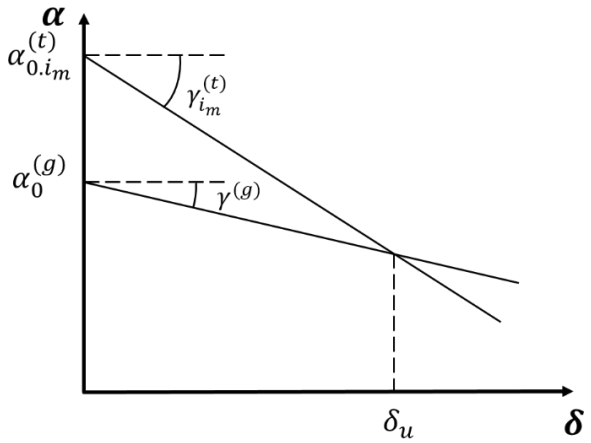

Figure 2: Design Condition of Theory of Plastic Mechanism Control (TPMC).

3 PROBABILISTIC VERSION OF TPMC

An advanced method for designing MRFs showing at collapse an assured probability of developing a collapse mechanism of global type is herein proposed. It means that the failure in the attainment of the design goal means the development of an undesired mechanism different

from the global one. Therefore, as reported in Figure 2, the failure is achieved when the mechanism equilibrium curve corresponding to any unwanted mechanism is located above the one corresponding to the global mechanism.

3.1 Definition of the failure events according to TPMC

Seeing the problem from the failure point of view, we can rearrange the design condition needed to prevent undesired collapse mechanism reported in Eq. (2) representing the occurrence of any failure event. The failure events, thus identified, are random events constituting a series system of binary components. Each failure event can be expressed by means of the following safety margin parameter $E_{i_m}^{(t)}$:

$$E_{i_m}^{(t)} = \left(\alpha_{0.i_m}^{(t)} - \gamma_{i_m}^{(t)}\delta_u\right) - (\alpha_0^{(g)} - \gamma^{(g)}\delta_u) < 0 \quad (3)$$

The safety margin is negative when "failure" occurs, i.e. an undesired mechanism develops. The number of the considered inequalities is equal to the whole number of collapse mechanisms different from the global one. Starting from the above consideration, in order to apply the reliability series method, some preliminarily assumptions are made:

1. Plastic moments of members are jointly Gaussian random variables because of random variability of steel yield strength;
2. Second order rigid-plastic analysis is carried out to include the influence of second order effects;
3. Horizontal seismic forces are deterministically distributed according to the first vibration mode of the structures evaluated following code provisions;
4. Vertical loads are assumed as deterministic quantities;
5. Plastic moments of columns are independent of the axial load.

3.2. FORM Method and Ditlevsen Bounds

As mentioned in a previous section, the failure events are events located in series, for this reason, it is possible to study the problem from the point of view of series system reliability [31],[32]. First Order Reliability Method (FORM) [32] and Ditlevsen Bounds [30] are applied to estimate the probability of failure. In particular, through FORM method it is possible to define the probability of failure of the single event, while Ditlevsen Bounds represent the Lower and Upper bounds of the failure probability of the TPMC, taking into account the correlation of random variables.

Following, the probabilistic procedure is reported. In particular, the random variables are collected into a vector **x** whose expectation and covariance matrix are respectively given by:

$$\boldsymbol{\mu}_{\mathbf{x}} = E[\mathbf{x}] \quad (4)$$

$$\boldsymbol{C}_{\mathbf{x}} = E[(\mathbf{x} - \boldsymbol{\mu}_{\mathbf{x}})(\mathbf{x} - \boldsymbol{\mu}_{\mathbf{x}})^T] \quad (5)$$

When the limit state condition defines a manifold surface $\mathrm{G}(\mathbf{x}) = 0$ constituted by n hyperplanes (being *n* the number of failure events), it means that any failure event is defined by a limit state function linear in **x**. The linearity of the expectation operator *E*, allows an easy determination of the first two moments of **G** as a function of the random vector **x**:

$$\mathbf{G}(\mathbf{x}) = \mathbf{a_0} + \mathbf{B}^{\boldsymbol{T}}\mathbf{x} \quad (6)$$

where $\mathbf{a}_0$ is a vector representing known quantities and **B** is a matrix of deterministic coefficients. Starting form Eq. (4) it is possible to obtain:

$$\boldsymbol{\mu}_{\mathbf{G}} = \boldsymbol{E}[\mathbf{G}] = \mathbf{a_0} + \mathbf{B}^{\boldsymbol{T}}\boldsymbol{E}[\mathbf{x}] = \mathbf{a_0} + \mathbf{B}^{\boldsymbol{T}}\boldsymbol{\mu}_{\mathbf{x}} \quad (7)$$

where $\boldsymbol{\mu}_G$ is a vector of mean values and $\boldsymbol{\mu}_{\mathbf{x}}$ is a vector containing the expected values of random variables of vector x. From Eq. (5), is possible to obtain the matrix of covariance $\boldsymbol{\sigma}_{\mathrm{G}}^2$ as:

$$\boldsymbol{\sigma_G^2 = E[(G - \mu_G)^2] = B^T E[(x - \mu_x)(x - \mu_x)^T]B = B^T C_x B} \quad (8)$$

where $\mathbf{C_x}$ is the matrix of second-order moments of random variables. Given the above, the Cornell reliability indexes corresponding to the different failure events are collected in the vector $\boldsymbol{\beta}_C$ [33], which is computed as the ratio between the mean value and the standard deviation of G.

$$\boldsymbol{\beta_C = \frac{\mu_G}{\sigma_G} = \frac{a_0 + B^T \mu_x}{\sqrt{B^T C_x B}}} \quad (9)$$

The theoretical justification of the above-reported index lies in the fact that when the distribution of **x** is jointly Gaussian than G is also Gaussian, being a linear combination of Gaussian variables. In this case, the distribution of G is completely defined by $\boldsymbol{\mu}_G$ and $\boldsymbol{\sigma}_G$. For this reason, the vector collecting the probability of the failure events given by Eq. (3) of the event $\boldsymbol{p}_f$ is expressed in this way:

$$\boldsymbol{p_f = \Phi\left(-\frac{\mu_G}{\sigma_G}\right) = \Phi(-\beta_C)} \quad (10)$$

which establishes a bi-univocal relationship between the Cornell indexes and the failure probability of the events constituting the series system.

However, because the events, i.e. each row of the **B** matrix, are correlated, it is needed to account for the correlation between each couple of events. To this scope the correlation coefficients ρ_{ij} have to be computed:

$$\boldsymbol{\rho_{ij} = \frac{b_i^T C_x b_j}{\sqrt{(b_i^T C_x b_i)(b_j^T C_x b_j)}}} \quad (11)$$

where $\mathbf{b}_i$ and $\mathbf{b}_j$ are the i-th and j-th row of **B** matrix. The values of ρ_{ij} ranges between -1 and 1. Concerning the whole series system identified by the failure events given by Eq.(3), the failure probability P_f can be approximated by the individual components failure probabilities P_{fi} which are the elements of the vector provided in Eq. (10) and of their intersection up to the second order using upper and lower bounds, so-called Ditlevsen bounds, which are generally close enough to provide an acceptable estimate [30],[32].

The failure probability has the following lower bound:

$$P_f \geq p_{f1} + \sum_{i=2}^{n} max\left\{p_{fi} - \sum_{j=1}^{i-1} p_{f.ij}, 0\right\} \quad (12)$$

and upper bound:

$$P_f \leq \sum_{i=1}^{n} p_{f.i} - \sum_{i=2}^{n} \max_{j<1}\{p_{f.ij}\} \quad (13)$$

where $p_{f.i}$ is the i-th component of the vector $\boldsymbol{p}_f$. However, the bounds require the calculation of joint probabilities of every pair of elements *i* and *j* by means of the following equation by exploiting the Cornell index and the correlation factors:

$$\boldsymbol{P_{f.ij} = \Phi_2(-\beta_i; -\beta_j; \rho_{ij})} \quad (14)$$

The joint probabilities can be computed according to the following equation:

$$p_{f.ij}(y_1;\, y_2; \rho_{ij}) = \Phi(y_1)\Phi(y_2) + \int_0^{\rho_{ij}} \frac{exp\left[-\frac{y_1^2 + y_2^2 - 2y_1 y_2 \rho^2}{2(1-\rho_{ij}^2)}\right]}{2\pi\sqrt{1-\rho^2}} d\rho \quad (15)$$

where a change of base is needed according to Cholesky decomposition of covariance matrix leading to:

$$\begin{bmatrix} y_1 \\ y_2 \end{bmatrix} = \begin{bmatrix} 1 & 0 \\ \rho & \sqrt{1-\rho^2} \end{bmatrix} \begin{bmatrix} -\beta_1 \\ -\beta_2 \end{bmatrix} \tag{16}$$

The mathematic procedure to define the Lower and Upper bounds for the failure events given by in Eq. (3), is provided by Piluso et al. [17].

4 CALIBRATION OF OVERSTRENGTH FACTOR

In a previous section, the procedure to compute the probability of failure of Theory of Plastic Mechanism Control is provided. Now, a procedure to define the overstrength factor γ_{ov} to apply to the deterministic version of TPMC is presented, considering the random material variability.

So, the following design procedure can be suggested, starting from the assumption that the maximum bending moment which the beams can transmit to the columns is given by $\gamma_{ov} M_b$ where M_b is the nominal plastic moment, while γ_{ov} is the overstrength factor to be calibrated according to the step reported in the flowchart (Figure 3).

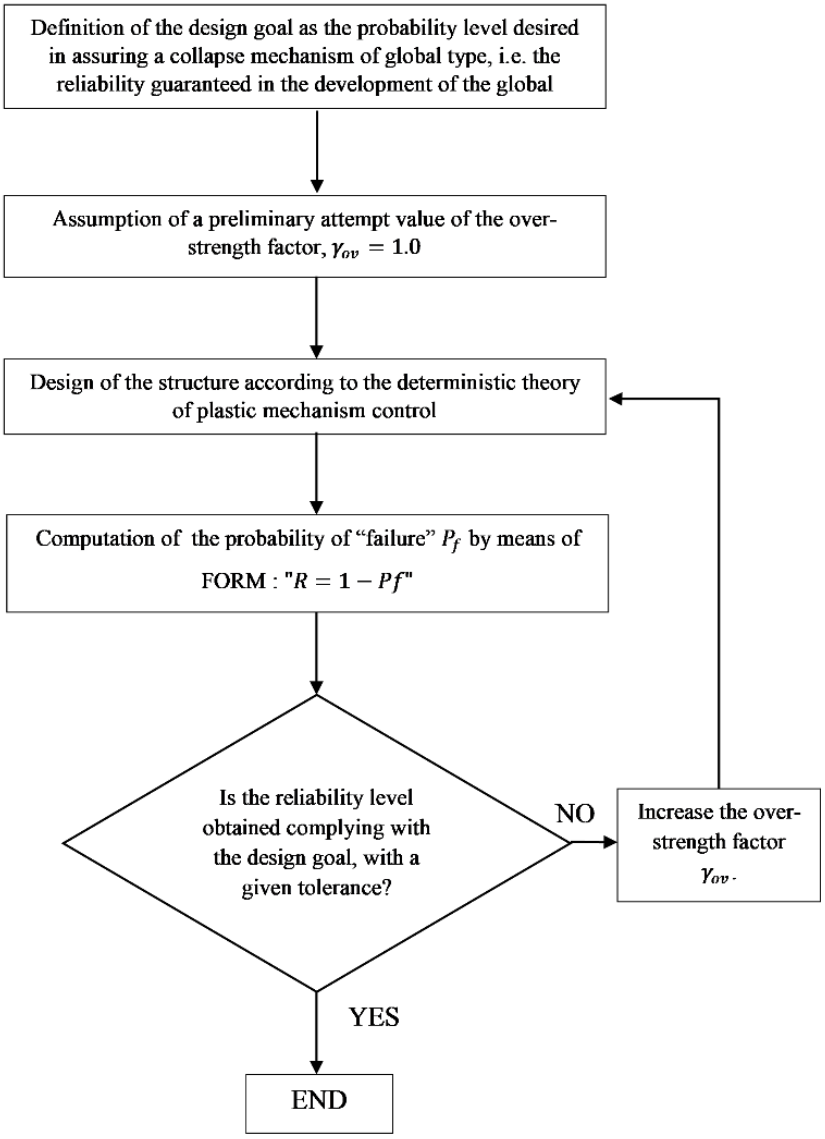

Figure 3: Design procedure flowchart.

5 PARAMETRIC ANALYSES

The parametric analyses have been performed to achieve a predefined level of reliability in the attainment of the design goal, i.e. the development of a collapse mechanism of global type. To this scope, 27-moment resisting steel frames have been considered by varying the number of storeys n_s, of bays n_b and the steel grade. The plastic moments of beams and columns are considered Gaussian random variables depending on the randomness of material properties. Moreover, three values of the coefficient of variation equal to 0.05, 0.10 and 0.15 have been accounted for. The parametric analysis has been repeated for increasing values of γ_{ov} aiming to its calibration. The analyzed moment resisting frames has a bay span equal to 6.00 m and an interstorey height equal to 3.50 m. The beams are the same for each frame, and they are designed to withstand distributed gravity loads whose values are $G_k = 15.00\ kN/m$ and $Q_k = 6.00\ kN/m$ for permanent and live load, respectively. Concerning the non-seismic load combination, the maximum gravity load acting on the beams is equal to $q_v = 1.3G_k + 1.5Q_k = 28.5\ kN/m$. The selected beam section is IPE 330. As the results of deterministic TPMC are not influenced by the magnitude of the seismic forces but are only sensitive to their distribution, a triangular distribution of the horizontal seismic forces has been assumed. Successively, for each frame, the plastic moments of the columns are defined according to the deterministic TPMC which is applied for increasing values of the overstrength factor assigned to the beam plastic moments. The resulting frames are analyzed using the stochastic approach herein presented, i.e. the corresponding lower and upper bounds of the probability of failure are computed. The results gained by means of such parametric analyses provide the variation of the probability of failure as a function of the overstrength factor adopted for the beams in the deterministic design and of the coefficient of variation, as depicted in Figure 4 to Figure 6.

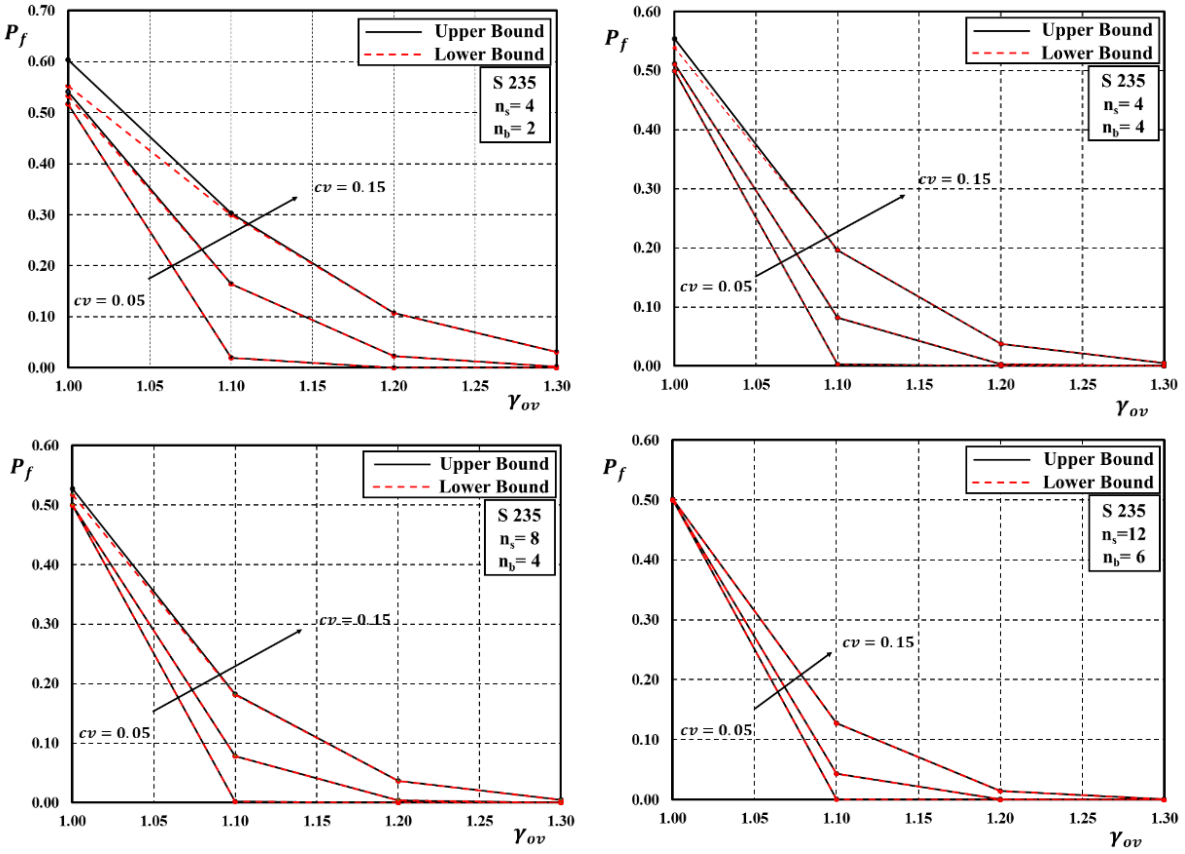

Figure 4: Upper and Lower bound of the failure probability for steel grade S235.

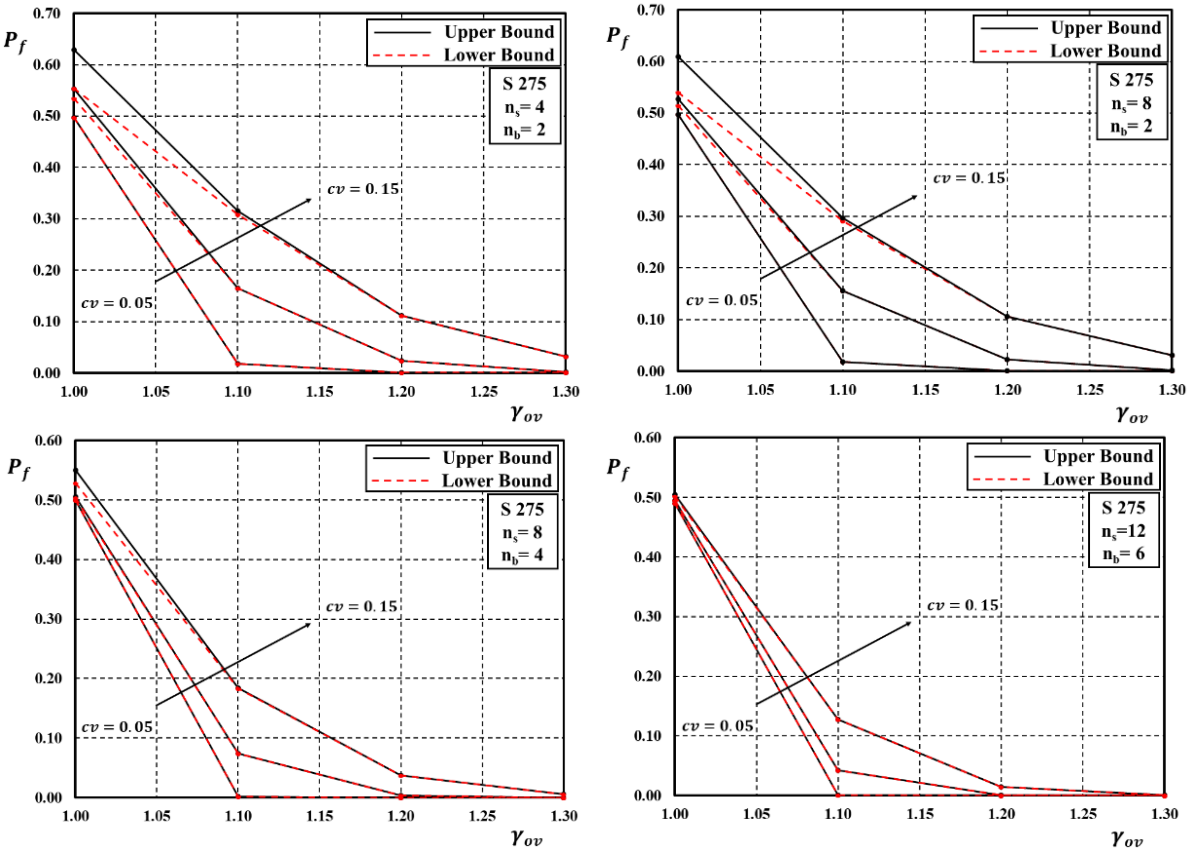

Figure 5: Upper and Lower bound of the failure probability for steel grade S275.

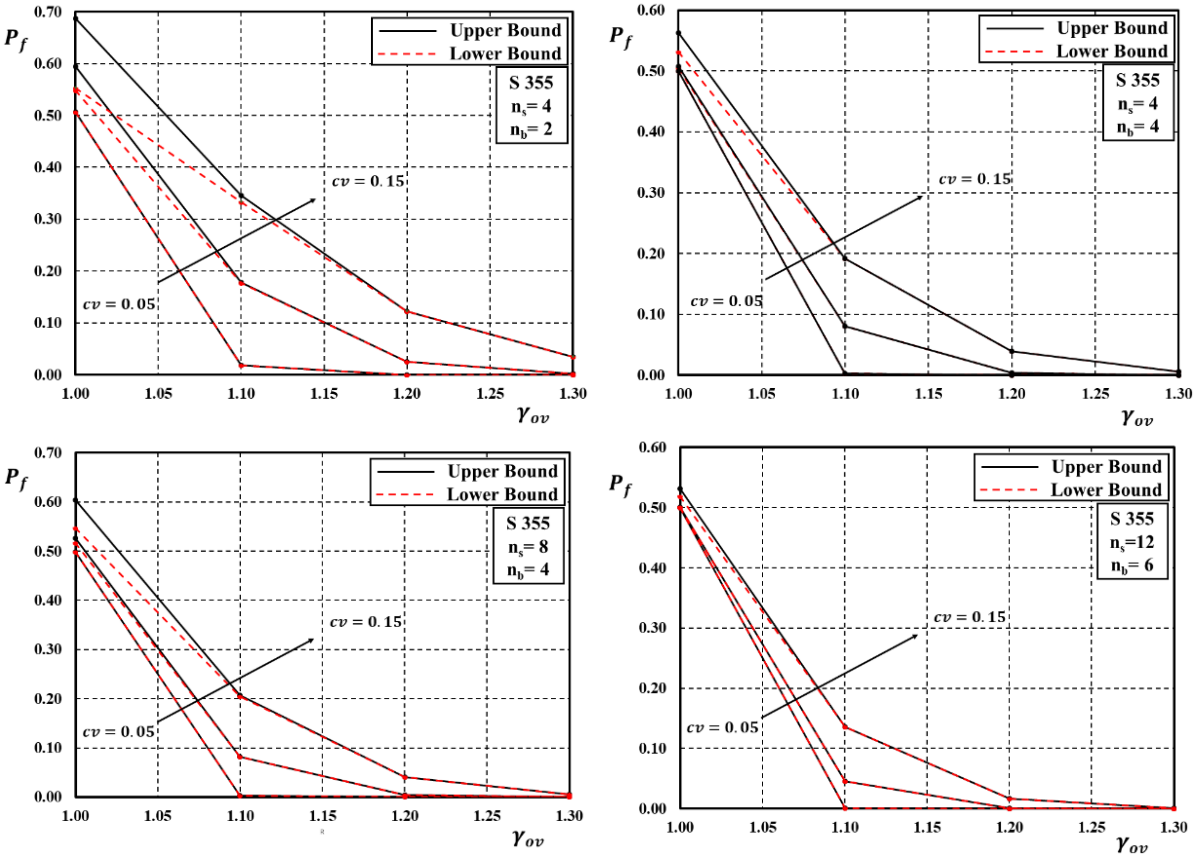

Figure 6: Upper and Lower bound of the failure probability for steel grade S355.

6 DEFINITION OF MATHEMATIC RELATIONSHIP

A mathematical relation can be suggested to compute the overstrength factor to apply the deterministic version of TPMC for fixed reliability level. Starting from the parametric analysis, previously described, it was easy to observe:

1. both the upper and lower bounds of the failure probability increase as the coefficient of variation of the yield strength cov increase, independently of the overstrength factor adopted in the design.
2. Independently of the coefficient of variation, both the upper bound and the lower bound of the probability of failure decrease as the overstrength factor adopted in the design is increased.
3. The value of the overstrength factor γ_{ov} decreases when the number of bays n_b increases, for fixed values of the number of storeys n_s and the failure probability.
4. Finally, for fixed values of the failure probability, the coefficient of variation cov and the number of bays n_b, the overstrength factor γ_{ov} results is not very influenced by varying the steel grade and the number of storeys n_s.

For these reasons, a mathematical formula has been developed with reference only Upper Bound of failure probability and with fixed reliability level R ($R = 1 - P_f$). In Table 1, the overstrength values are reported for a different number of bays n_b and coefficient of variation cov for a fixed value of R equal to 95%:

	Number of bays " n_b"		
cov	2	4	6
0.05	1.1148	1.1104	1.1096
0.10	1.3334	1.3201	1.3152
0.15	1.3846	1.3432	1.3200

Table 1: Values of the overstrength factor for reliability level of 0.95.

In Eq. (17) the mathematical relationship is provided, while the coefficients C_i are reported in:

$$\gamma_{ov} = [C_1(n_b)^{C_2}](cov)^2 + [C_3(n_b)^{C_4}](cov) + (c_5 n_b + c_6) \quad (17)$$

C_1	C_2	C_3	C_4	C_5	C_6
-34.2282	0.0502	9.8668	-0.012	0.0024	0.7075

Table 2: Coefficients of Eq.(17).

The comparison between the overstrength factor resulted by Eq. (17) and the values of γ_{ov} obtained by parametric analysis is provided in Figure 7. It is immediate observing that the accuracy of the mathematical formula proposed by the authors, is very high. The linear correlation coefficient R^2 is equal to 0.9977, while the standard deviation and the relative maximum error are equal respectively 0.0016. In the end, the corrective factor of regression has been computed at the 95% fractile, that is 1.0027.

7 CONCLUSIONS

- This work aims at the extension of the Probabilistic Theory of Plastic Mechanism Control (P-TPMC) for Steel Moment Resisting Frames (MRFs) to other steel grades
- Parametric analyses have been carried out starting from the Probabilistic version of Theory of Plastic Mechanism Control.

- The analyses were performed by varying the steel grade, the number of bays, number of storeys and the coefficient of variation of the stochastic variable.
- For a specific value of the reliability equal to 95%, a simple mathematical formula is defined to estimate the overstrength coefficient to apply to the deterministic version of TPMC, considering the material randomness.

Abstract

The decision-making process for seismic risk is affected by the assessment/design procedure adopted and rigorous methodologies have been developed to estimate performance metrics relevant to stakeholders to take informed decisions. Input data for loss estimations of buildings are typically floor accelerations and inter-storey drift ratios, generally obtained from: 1) simplified evaluations, based on linear models and static analysis, 2) more accurate non-linear static analyses, or 3) more complex and time-consuming non-linear history analyses.
Considering that non-linear static analyses are arguably the best compromise between accuracy and simplicity, this paper proposes the application of an analytical non-linear static procedure, based on the Simplified Lateral Mechanism Analysis (SLaMA) of the NZSEE 2017 Guidelines, for the cost/performance-based evaluation of Reinforced Concrete structures. In order to validate the accuracy of the method, multi-storey case-study buildings are analyzed using different structural analysis methods (the proposed SLaMA-based approach vs. numerical Pushover vs. Time-History) and through sophisticated or simplified loss assessment methodologies (FEMA P-58, 2012; D.M. n.65, 2017).
The results in terms of Expected Annual Losses from the SLaMA-based approach are quite satisfactory - increase of 7-18% or 3-7% compared to numerical Pushover results from probabilistic or simplified loss estimations, increase of 20-40% compared to numerical Time-History results - and, in general, more accurate than static analyses results, even though no numerical modelling is needed. Therefore, the SLaMA-based method can be a promising tool for a daily use of practicing engineers for a rapid evaluation of economic losses for both the seismic assessment of existing buildings and the initial feasibility studies of new structures.

Keywords: Cost/performance-based, SLaMA procedure, Pushover analysis, Time-history analysis, Expected Annual Losses.

1 INTRODUCTION

Seismic design philosophy is based on controlling the building response under low-to-high intensity earthquakes, including either structural and non-structural components. Traditionally the design aimed to prevent the damage of these elements under low-intensity earthquakes, to reach repairable conditions in medium-intensity shakings and to avoid building collapse under high-intensity earthquakes. However, past earthquakes (e.g. Northridge 1994 and Kobe 1995, confirmed by more recent events such as Christchurch earthquake 2010-2011) highlighted very high economic losses in terms of repair costs and business interruption even for code-compliant buildings, leading in the mid-1990s to the development of the performance-based earthquake engineering (PBEE) concept [1, 2].

Vision 2000 [3] is one of the first documents where there is evidence of this new philosophy. Different structural and non-structural performance levels at various intensity demands (frequent, occasional, rare, and very rare) are described and classified as fully operational, operational, life safety, and near collapse, thus design objectives for building typologies are identified through the combination of performance levels and seismic hazard. Following this original concept, a series of additional documents were published considering the same design philosophy and representing the first generation of PBEE [4, 5, 6]

Nevertheless, the initial PBEE procedures were deterministic-based and affected by many shortcomings, such as the relations between engineering demand and component performance based on relations measured from laboratory tests or assumed considering engineering judgement [7]. Therefore, a more rigorous and probabilistic methodology was developed by the Pacific Earthquake Engineering Research (PEER) Center and its framework is summarized in Figure 1.

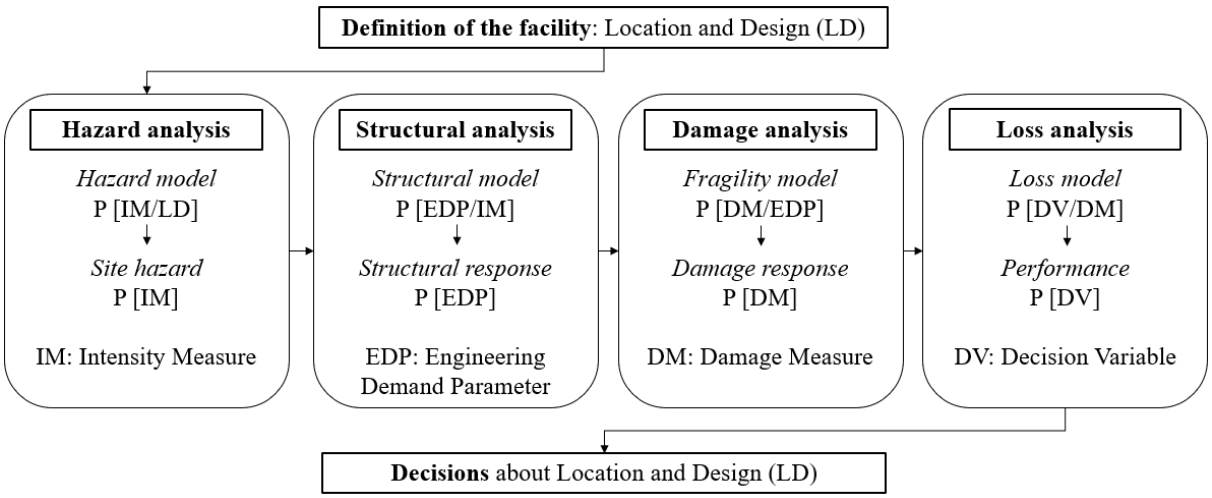

Figure 1: Performance-Based Earthquake Engineering (PBEE) methodology (modified after [8]).

The PEER methodology allows the direct evaluation (estimation) of performance measures such as economic losses, downtime and casualties that are relevant to stakeholders to manage decisions about seismic risk mitigation. The comprehensive framework includes the description, definition and qualification of different variables considering all the inherent uncertainties in the earthquake performance assessment. The process starts with the definition of the ground motion hazard (*Intensity Measure*) which affects the structural response, then the building structural response can be evaluated in terms of accelerations, deformations or other quantities (*Engineering Demand Parameter*). Finally, the system response is related to the

damage of each building component (*Damage Measure*) and the damage is transformed into quantities useful for decision-making processes (*Decision Variable*).

For the practical implementation of the probabilistic procedure, the US Federal Emergency Management Agency (FEMA) commissioned to the Applied Technology Council (ATC) the development of an electronic tool to apply this methodology, referred to as Performance Assessment Calculation Tool (PACT) and provided with the publication of the FEMA P-58 Document [9].

The application of the PBEE procedure is primary for the seismic loss evaluation of new buildings as well as for taking decisions on intervention/retrofit strategies of existing structures, particularly in the initial feasibility studies of the building/intervention. However, the fully probabilistic procedure can be time-consuming in its implementation, because it also requires the definition of numerical models to evaluate the building response through non-linear static and dynamic analyses. For this reason, this paper presents the application of an analytical procedure for non-linear static analysis, based on the Simplified Lateral Mechanism Analysis (SLaMA) of the NZSEE 2017 Guidelines, that can be rapidly implemented providing acceptable results for the loss estimation and can thus be a promising tool for a daily use of engineers for a rapid yet quite reliable initial evaluation of the post-earthquake losses.

2 EVALUATION OF BUILDING RESPONSE

Structural analysis is conducted to determine the building response to earthquake shaking, obtaining values for those key parameters that are predictive of structural and non-structural damage, such as floor accelerations, floor velocities, story drift ratios and residual drift ratios.

Alternative procedures can be used to estimate the peak values of these parameters: 1) *simplified procedures*, which consider linear models and static analyses to estimate the lateral yield strength and generate median demand values, thus determining the building response at each floor through simplified and numerically calibrated formulas; 2) *non-linear static analyses*, which allow the definition of the building capacity curve from numerical modelling as well as the performance points for the various seismic intensity (i.e. Capacity Spectrum Method), giving more accurate predictions than the previous ones; 3) non-linear response (time) history analysis, that is the most sophisticated method, where the structure is numerically modelled in its full non-linear cyclic and dynamic behavior, sets of demand parameters are generated from sets of earthquake input motions and are used to develop statistics (median values and dispersions) for each parameter of interest. Among all the aforementioned analysis methods, the non-linear static procedures (pushover) are the best compromise between accuracy and simplicity.

In the recently developed New Zealand Seismic Assessment Guidelines [10] an analytical non-linear static analysis procedure has been proposed for the seismic assessment of reinforced concrete existing buildings, the Simplified Lateral Mechanism Analysis (SLaMA), that is shown schematically in Figure 2. This assessment method, mandatory for every assessment prior to carry out any numerical modeling, is able to predict the building capacity curve (pushover) through an analytical study that, starting from the local section and member analysis and through the hierarchy of strengths evaluation of subassemblies, evaluate the local and global building mechanisms.

Notwithstanding the SLaMA procedure has been primarily implemented for the assessment existing structures, in this paper the method is applied, for the sake of simplicity, to rapidly estimate the seismic response of new reinforced concrete buildings, because it can be very useful for initial feasibility studies. The proposed simplified loss-assessment method based on a SLaMA approach, can be however used and properly exploited for either assessing existing structures and comparing alternative retrofit strategies.

In the case of a new building, the procedure can be modified and simplified as follows: 1) in terms of input data, the building characteristics are not already available but obtained from a preliminary building design that aims to already respect the hierarchy of strengths determining a final beam-sidesway mechanism, as required by the seismic codes; 2) the capacity curve of such type of building mechanism is analytically determined considering the results from the section analysis evaluation; 3) finally, introducing the capacity curve into the Acceleration-Displacement Response Spectra and combining it with the demand spectra, the expected maximum accelerations and displacements at different seismic intensities can be determined.

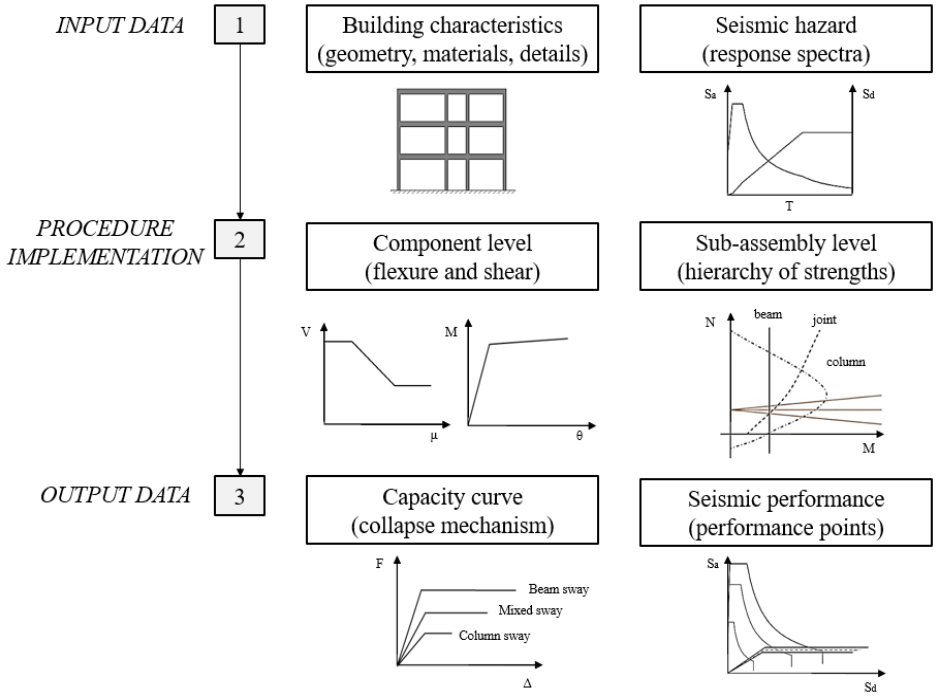

Figure 2: Framework of the SLaMA assessment procedure for reinforced concrete buildings.

3 RESEARCH MOTIVATION

In the current international seismic codes, the building design aims to guarantee the Life-Safety performance objective. However, as the reliability of design and construction practice in meeting this goal has improved, there has been an increasing demand for engineers to provide building design capable of reducing both damage and business interruption [11] and new tools able to determine these parameters in the philosophy of the performance-based earthquake engineering have been developed.

Apart from the seismic assessment process of existing buildings, the need for loss estimation in the common design process is starting to spread, therefore practical and efficient tools must be developed to be used by engineers. As alternative to more sophisticated procedures based on non-linear dynamic analyses, as previously described, more rapid estimations of post-earthquake losses can be determined through non-linear static (pushover) evaluations, especially as part of an initial feasibility study of the building design features.

This paper proposes the application of an analytical non-linear static analysis procedure, based on the Simplified Lateral Mechanism Analysis (SLaMA), for a rapid evaluation of post-earthquake losses of buildings without the need of more complicated numerical models.

A set of multi-storey case-study buildings is considered to apply and validate the proposed procedure, as described below.

4 VALIDATION OF THE SLAMA-BASED ANALYTICAL PROCEDURE

Cost/performance evaluations are implemented for a set of multi-storey buildings considering different approaches: the proposed SLaMA-based analytical procedure and numerical analyses through both non-linear Push-Over and Time-History analyses.

The numerical investigations are implemented with the aim of validating the analytical approach and confirming whether acceptable results in terms of economic losses can be expected from the SLaMA evaluation when compared to more sophisticated numerical results.

4.1 Description of the case-study buildings

The procedure is implemented considering four 5-storeys monolithic reinforced concrete buildings located in a high seismic zone in Italy (Soil type C, PGA of 0.35 g at the Life-Safety Limit State). The benchmark case-study structure has a plan configuration of 32m x 18 m, inter-storey height of 3.8 m; the building has commercial use for the first two floors, residential use for the other two floors, while the top floor is a roof. Lateral resistance against seismic action is provided by two seismic resistant four-bay frames in the longitudinal direction and two shear walls in the transverse direction. The other buildings are derived from the initial case-study structure (*Case1*) by varying: the beam span length in both seismic directions (*Case2*); the inter-storey height to 4.5 m (*Case3*); both the beam span length and the inter-storey height (*Case4*). Figure 3 presents the plan view of the benchmark building (Plan1) and its variation (Plan2), while all the case-study structures are summarized in Figure 4.

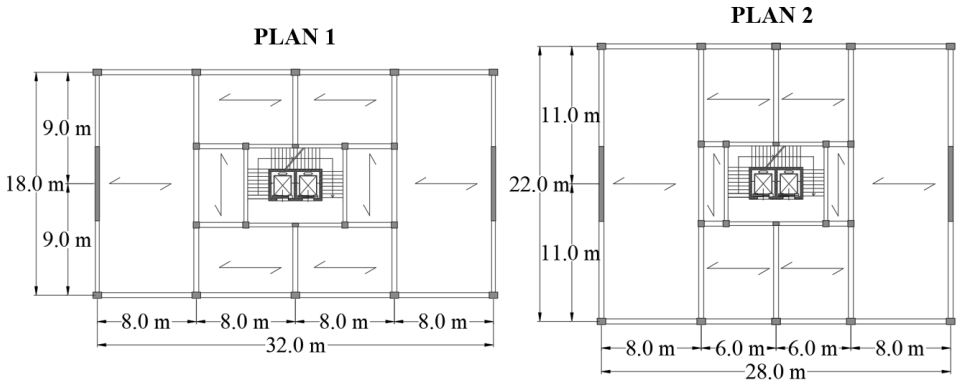

Figure 3: Plan view and dimensions of the benchmark building (left) and modified plan (right).

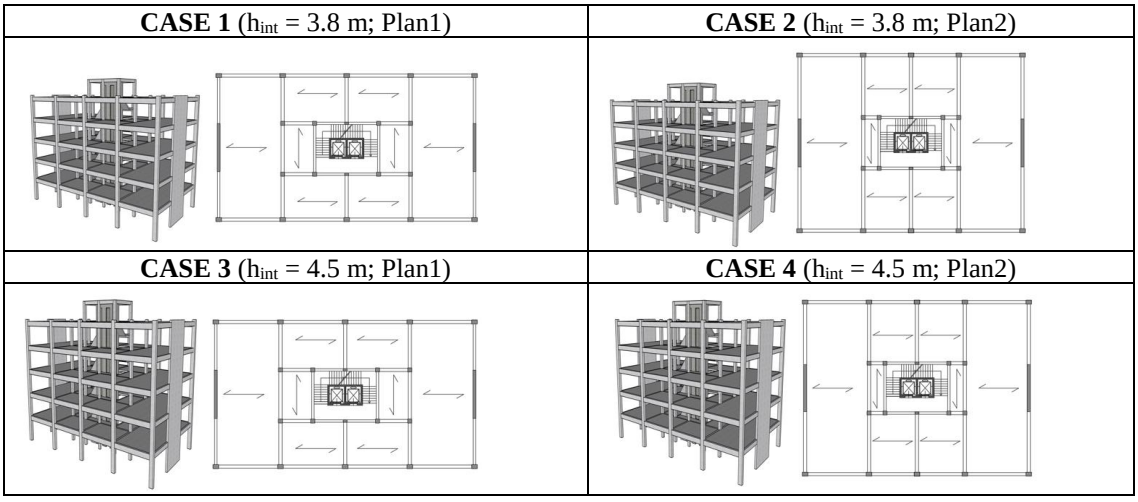

Figure 4: Case-study buildings.

In terms of dimensions of the structural members: the seismic beams and columns have same dimensions for both building plan (400 x 700 mm and 500 x 700 mm, respectively); while the wall is 6 m long, but its thickness varies depending on the plan configuration (350 mm for Plan1 and 400 mm for Plan2). Finally, the gravity beams connecting the wall are 300 x 600 mm and 400 x 700 mm, respectively for Plan 1 and Plan 2.

4.2 Building design

Referring to this structural scheme, geometry and related gravity loads, all the buildings are designed following the Direct Displacement Based Design (DDBD) procedure by [12, 13]. The DDBD procedure has been performed at the ULS limit state (Life-Safety) considering an appropriate value for the inter-storey drift limit, i.e. 2% for the frame direction and 1.2% for the wall direction for all case-study structures.

Table 1 shows the DDBD results for all the buildings in terms of yielding displacement (Δ_y), design displacement (Δ_d), effective mass (m_e), effective height (H_e), equivalent viscous damping (ξ_{eq}), effective period (T_e), effective elastic stiffness (K_e), and base shear (V_b).

Parameter	Case 1		Case 2		Case 3		Case 4	
	Frame	Wall	Frame	Wall	Frame	Wall	Frame	Wall
Δ_y [mm]	62.17	50.29	62.15	50.26	73.38	70.14	73.36	70.10
Δ_d [mm]	223.80	163.19	223.74	163.13	264.36	192.63	264.28	192.56
m_e [t]	2760.15	2627.80	2914.20	2774.46	2834.12	2698.27	2991.83	2848.42
H_e [m]	13.24	13.60	13.24	13.60	15.63	16.05	15.62	16.05
ξ_{eq} [%]	19.19	18.35	19.19	18.35	19.19	16.90	19.19	16.90
T_e [s]	2.65	1.91	2.65	1.91	3.13	2.22	3.13	2.21
K_e [kN/m]	15533.5	28383.0	16409.6	29987.5	11429.8	21705.3	12072.43	22928.2
V_b [kN]	3476.42	4631.94	3671.44	4891.99	3021.56	4181.03	3190.55	4415.01

Table 1: Parameters from the DDBD procedure for all the case-study buildings.

Distributing the base shear obtained by the DDBD throughout each structure, the internal actions in the structural members are determined, and the required steel reinforcement of each component can be designed.

4.3 Building seismic response

The building response is initially estimated through the SLaMA procedure described in the NZSEE 2017 Seismic Assessment Guidelines [10]. The seismic design considers capacity design principles, therefore it is sufficient to evaluate the capacity curves related to the beam-sway mechanism. In Figure 5 the so-obtained analytical capacity curves are presented for each building and structural direction. The ultimate limit state represents the achievement of the displacement corresponding to the first element reaching the ultimate rotational capacity.

Converting the base shear/displacement relationships into acceleration/displacement responses and considering the demand spectra from the Italian Code [14] of either elastic or ultimate limit states, the building performance points at each intensity level can be identified in the Acceleration Demand Response Spectrum (ADRS) domain. The demand spectra of the ultimate limit states (life-safety SLV and near collapse SLC) have been reduced considering the area-based equivalent viscous damping evaluated through the formulation proposed by Priestley in 2007 [12].

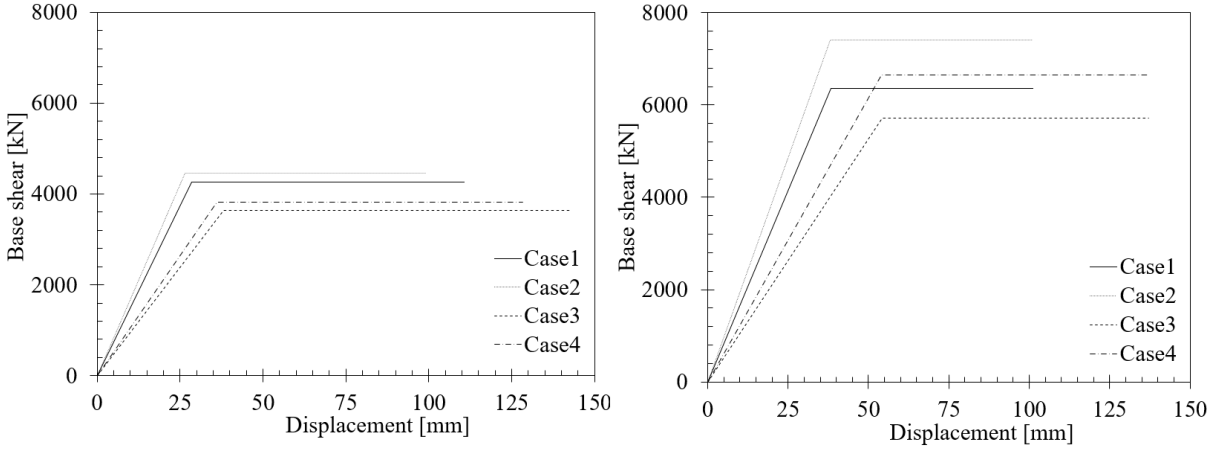

Figure 5: SLaMa-based non-linear (analytical) pushover capacity curves for the case-study buildings. Left: frame direction; Right: wall direction

The SLaMA capacity curves are compared to those obtained from numerical non-linear static analyses. The numerical models of each building are implemented using Ruaumoko 2D analysis program [15] through a lamped-plasticity approach. Therefore, the structural members are represented by elastic components where the non-linearity is concentrated within plastic hinge regions at the end sections (Giberson elements). The plastic hinges are described using proper moment-curvature relationships and a Takeda stiffness-degrading hysteresis rule.

Applying the Capacity Spectrum Method [16], where the area-based equivalent viscous structural damping is directly evaluated from push-pull analyses, the performance points can be also evaluated for this analysis approach.

As example, in Figure 6 can be found a comparison between the push-over curves and performance points obtained from both the analytical and numerical methods.

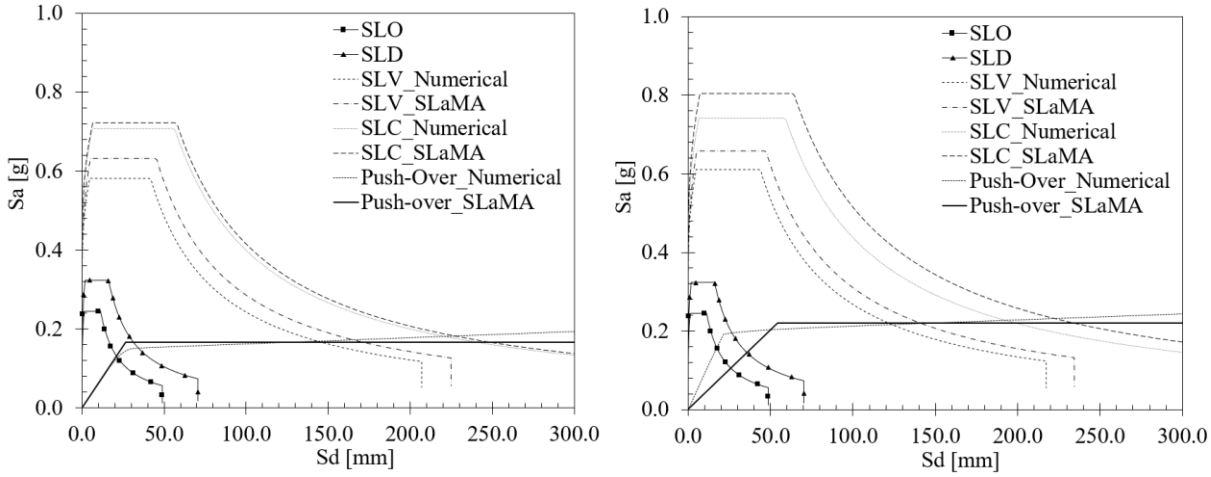

Figure 6: Analytical and numerical capacity curves in the ADRS domain for the *Case2* considering both frame (left) and wall (right) directions.

It can be observed from the previous graphs that the analytical curves well predict the building seismic behavior. The two analyses methods produce very similar performance points for all the case study-buildings in the frame directions, apart from the collapse limit state because of the increasing slope of the numerical curve and the inherent limit of the analytical curve itself which is not modeling the collapse point. Regarding the wall directions, the main differences in the performance points are obtained for the lower limit states (fully opera-

tional and operational) because of the modeling of the wall as equivalent frame which produces a very high initial stiffness when compared to the one from the analytical procedure.

In order to further validate the accuracy of the SLaMA method as a loss-modeling simplified procedure, non-linear time history analyses are also performed using sets of 7 accelerograms obtained from REXEL [17] for each seismic intensity. The accelerograms, extrapolated from the European Strong Motion database, are, thereby, properly scaled to guarantee the spectro-compatibility to each demand spectrum. For the Life-Safety intensity level, Figure 7 presents the response spectra related to the 7 accelerograms, the average and target spectra, the lower and upper tolerances, as well as the range of periods (0.15 s ÷ 2 s) selected for the spectro-compatibility to be satisfied.

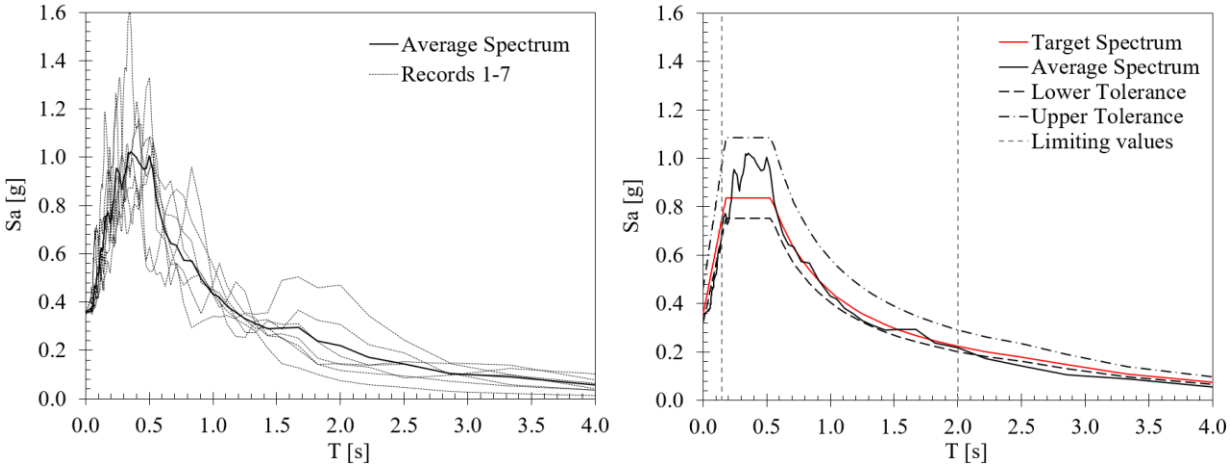

Figure 7: Spectro-compatibility at Life-Safety intensity level.

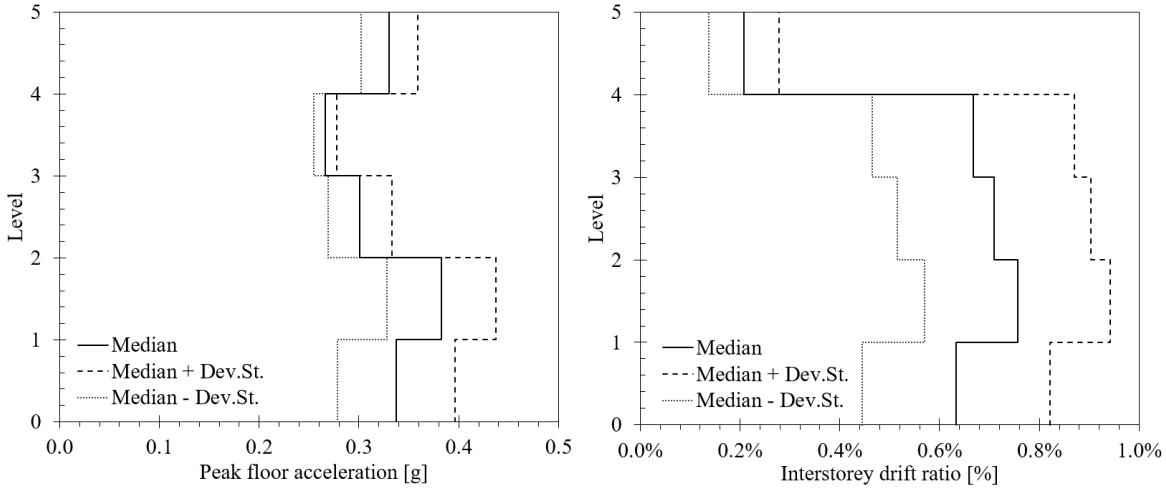
From time-history analyses a direct estimation of the floor accelerations and inter-storey drift ratios can be determined. As example, the results are presented for one case-study structure and one seismic intensity level in Figure 8. These key engineering demand parameters (EDPs) can be used as direct input data for the loss assessment investigations, while for the analytical and numerical non-linear static assessments they are estimated from the performance points, representing the behavior of the equivalent SDOF system, at each seismic intensity. In fact, considering the effective building height the EDPs at each floor can be estimated assuming proper displacement and acceleration profiles for the SLaMA procedure or the exact profiles determined from the numerical Push-Over results.



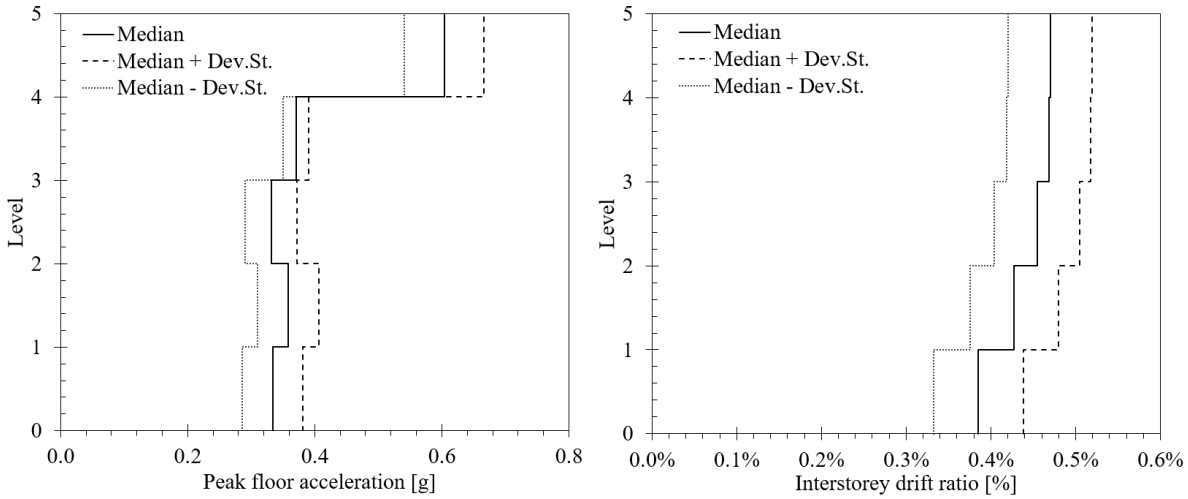


Figure 8: Time-history results for the Life-Safety demand level of *Case2*: peak floor acceleration and inter-storey drift ratio profiles for both building directions.

4.4 Loss assessment investigations: SLaMA vs numerical Pushover

Loss assessment estimations are performed using the PACT software [9] where all the case-study buildings are implemented. The input data for the analysis are: 1) the total replacement cost and time, calculated referring to 338 euro/m^3 and estimating the proper number of man-days; 2) the population model of the building, provided by the software depending on the building use; 3) the component fragilities, considering all the structural members, non-structural components, building services and contents present into the building; 4) the seismic building response, estimated using the different structural analyses methods; 5) finally, the seismic hazard, whose function is built referring to the demand intensity levels reported in the Italian Code [14] (T_R=30 years, fully operational; T_R=50 years, operational; T_R=475 years, life-safety; T_R=975 years, near collapse). Regarding the non-structural systems, it is assumed that all the structural skeletons are covered by external curtain walls, while interior components include lightweight partitions, suspended ceilings, electrical and mechanical services and contents. All the structural and non-structural components are defined using the fragility curves and consequence functions already available in the fragility database.

The results obtained for all the case-study buildings are reported in Figure 9 and Table 2.

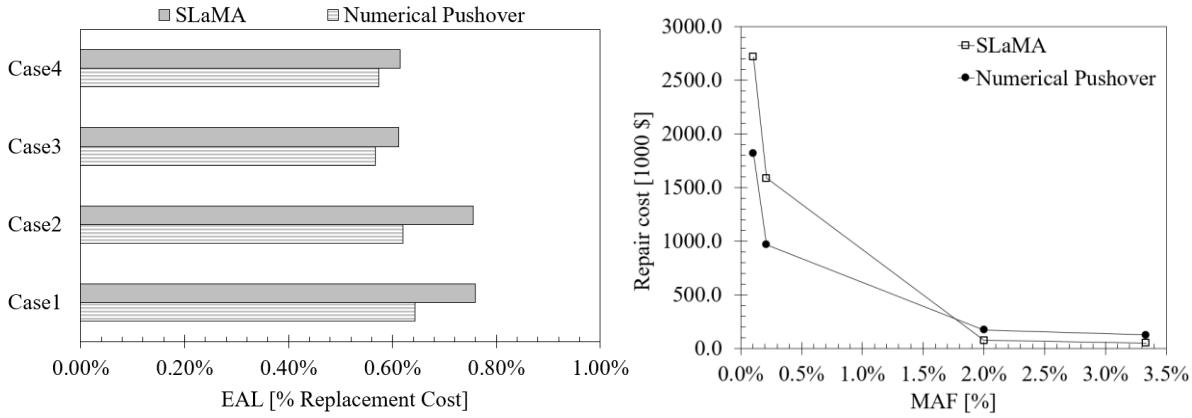

Figure 9: EAL values for all the four case-study buildings considering different structural analysis results (left) and Repair cost/Median Annual Frequency functions (right) for one case-study structure (*Case 2*).

	Case 1	Case 2	Case 3	Case 4
EAL $_{SLaMA}$ [%RC]	0.759	0.755	0.612	0.614
EAL $_{PO}$ [%RC]	0.644	0.621	0.567	0.573
ΔEAL $_{SLaMA/\ PO}$	15.16	17.79	7.31	6.70

Table 2: EAL values from non-linear static analyses results: SLaMA versus numerical Pushover (PO).

The loss estimations are carried out considering the floor accelerations and inter-storey drift ratios from: 1) for the SLaMA approach, these parameters are evaluated assuming a proper displacement profile for the building beam-sway mechanism, as suggested in NZSEE Guidelines [10], and considering the floor acceleration profile proposed by FEMA P-58 [9] for simplified procedures, 2) for the numerical analysis, the floor accelerations and inter-storey drift ratios are determined from the performance points considering both the displacement and acceleration profiles resulting from the numerical investigation. All the loss estimations have been performed, in this initial validation of the SLaMA procedure, without including the effects of the building collapse fragility or the residual drift into the results.

It can be observed that the application of SLaMA gives quite satisfactory results in terms of Expected Annual Losses (EAL) when compared to the results obtained from the numerical investigations, i.e. approximately 7-18% higher (conservative side).

Estimations of direct economic losses are also developed through the simplified procedure presented in the 2017 Italian Guidelines for Seismic Risk Classification [18]. This document describes a simple methodology to determine the expected annual losses, that is generally applied for the seismic assessment of existing buildings to investigate the benefits of retrofit strategies and regulate financial incentives provided to private owners to improve the risk/losses of their building. In this research the same approach is applied to new buildings. The building analytical and numerical capacity curves are the starting points of this procedure, which requires the determination of the median annual frequencies, MAF, associated to the achievement of specific limit states in the structure. Particularly, in this study, two limit states (Damage Control and Life-Safety) are identified taking into account just the structural behaviour (achievement of yielding and ultimate rotations of structural members) and used to estimate other limit states related to the structural and non-structural system, as explained in the Guidelines [18].

The results from this simplified methodology are presented in Figure 10 and Table 3.

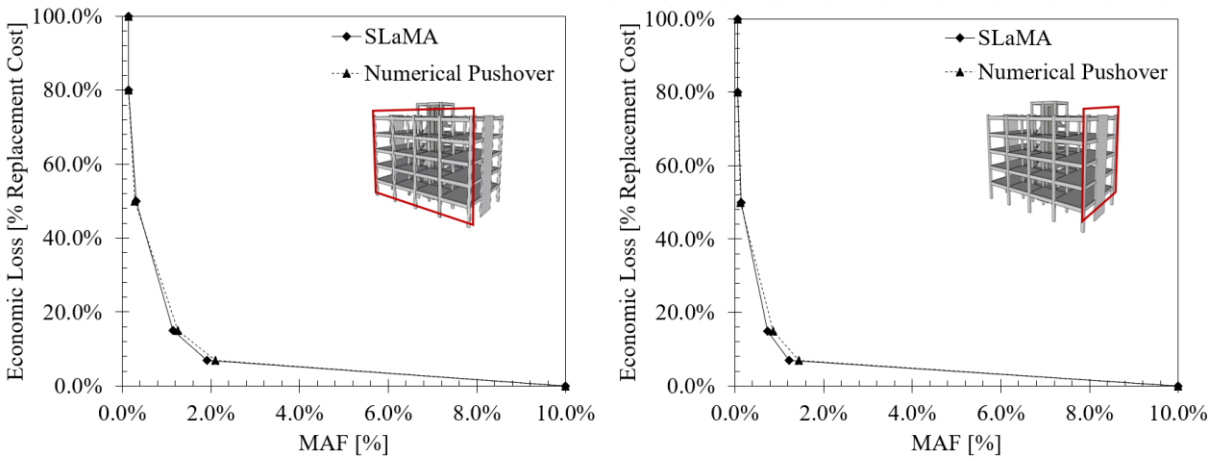

Figure 10: Economic loss/Median Annual Frequency functions estimated following the Italian Guidelines for Seismic Risk Classification [18] for *Case 2* and both building directions referring to the capacity curves obtained from SLaMA or numerical studies.

	Case 1		Case 2		Case 3		Case 4	
	X Dir.	Y Dir.	X Dir.	Y Dir.	X Dir.	Y Dir.	X Dir.	Y Dir.
EAL_{SLaMA} [%RC]	0.810	0.717	0.892	0.669	0.789	0.631	0.865	0.595
EAL_{PO} [%RC]	0.872	0.749	0.920	0.704	0.849	0.648	0.891	0.623
$\Delta EAL_{PO/SLaMA}$	7.17	4.22	2.99	4.94	7.27	2.68	2.91	4.49

Table 3: EAL (as a percentage of the Replacement Cost, RC) values from the simplified procedure [18] using the building capacity curves from analytical (SLaMA) and numerical (PO) Pushover analyses.

As it can be observed from the previous table, the differences between the EAL values from the SLaMA-based approach and numerical analysis are minor, in the range of 3-7% for both building directions. It is also noticed that the EALs associated to the numerical Pushover curves are now higher than those derived from the simplified SLaMA procedure, thus it seems that the estimation is not on the conservative side. This can be justified considering that the elastic and ultimate limit state points are identified on the numerical capacity curves respectively for lower and greater accelerations compared to the same points on the simplified elasto-plastic capacity curves. In any case, the differences are relatively low and well acceptable, thus the SLaMA method can be considered a valuable alterative tool to numerical methods for an initial cost-based building evaluation.

4.5 Loss assessment investigations: SLaMA vs Pushover vs Time-history

Loss assessment investigations are finally performed using the results from the time-history non-linear analyses, therefore the peak floor accelerations and inter-storey drift ratios from all the 7 records of each seismic intensity are directly introduced in the PACT software.

Figure 11 and Table 4 summarize the EAL values obtained from all the structural analysis procedures (analytical push-over, numerical push-over, time-history).

The percentage difference between the EAL values from SLaMA approach and Time-History analysis is in the range of 20-40%, while between numerical Pushover and Time-History results a difference of 15-30% is estimated. Notwithstanding the differences between the EAL values from the simplified SLaMA procedure and the sophisticated Time-History investigation are in this case not negligible, the SLaMA method still produces acceptable results and, in any case, more accurate than those obtained when application of linear static analysis suggested within the FEMA P-58 methodology as an alternative simplified investigation compared to the non-linear response history analysis. This statement is based on parallel work being carried out and to be presented in a future companion research publication.

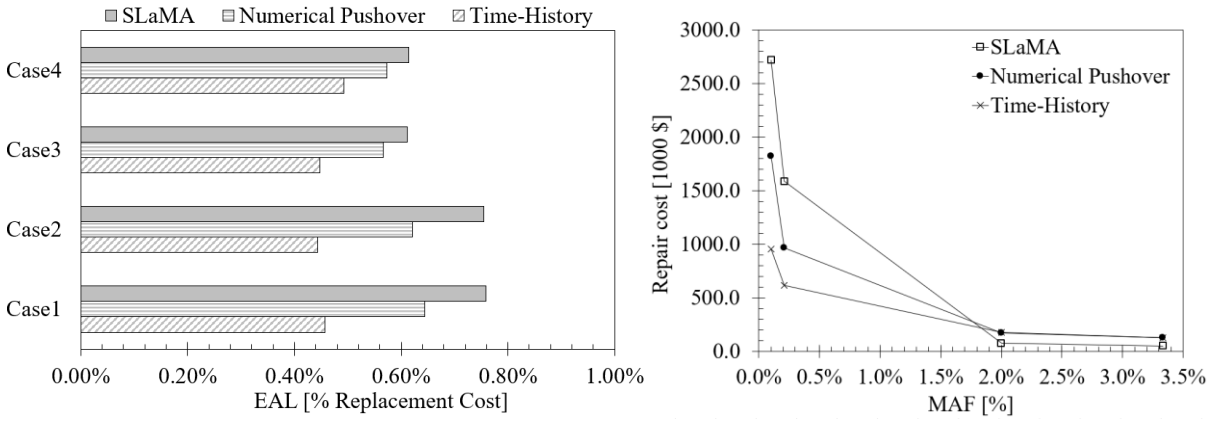

Figure 11: EAL values for all the four case-study buildings considering different structural analysis results (left) and Repair cost/Median Annual Frequency functions (right) for one case-study structure (*Case 2*).

	Case 1	Case 2	Case 3	Case 4
EAL_{SLaMA} [%RC]	0.759	0.755	0.612	0.614
EAL_{PO} [%RC]	0.644	0.621	0.567	0.573
EAL_{TH} [%RC]	0.457	0.444	0.447	0.493
$\Delta EAL_{SLaMA / PO}$	15.16	17.79	7.31	6.70
$\Delta EAL_{SLaMA / TH}$	39.76	41.18	26.84	19.75
$\Delta EAL_{PO / TH}$	28.98	28.44	21.07	14.02

5 CONCLUSIONS

In the engineering community the estimation of performance metrics, such as repair costs or downtime, relevant to management decisions for seismic risk mitigation is becoming more consolidated not only for the assessment of existing buildings and thus for the evaluation of optimal retrofit strategy, but also in the seismic design of new buildings.

Probabilistic methodologies have been proposed to implement socio-economic loss estimations, which requires as input data engineering demand parameters, EDPs, such as floor accelerations and inter-storey drift ratios. The latter are usually obtained from simplified linear or non-linear analyses, requiring the implementation of simple or more-sophisticated numerical building models. The more complex the model the more accurate are typically expected to be the results in terms of seismic response, although very time-consuming modeling and analyses are required (i.e. Non-linear Time-History analyses).

With the aim of avoiding the implementation of un-necessary complex numerical models and knowing that non-linear static procedures are a very valuable compromise between accuracy and simplicity, the paper proposes the application of an analytical non-linear static analysis procedure, based on the Simplified Lateral Mechanism Analysis (SLaMA), for the cost/performance-based evaluation of buildings.

The Expected Annual Losses of four case-study reinforced concrete buildings are estimated referring to different structural analyses (SLaMA, numerical Pushover, Time-Histories) and loss assessment methodologies [9, 18]. The results highlighted that the SLaMA-based approach can provide satisfactory and acceptable results when compared to more complex numerical procedures. The method can be a promising tool for the daily use of practicing engineers for a rapid evaluation of the post-earthquake losses and it can be suggested both for the seismic assessment of existing buildings and retrofit interventions as well as part of the design feasibility study of new reinforced concrete structures.

Notwithstanding the good results obtained from this initial study, more investigations are needed to incorporate, for example, the building collapse limit states and the effects of residual drifts, which have been neglected in the loss estimations of this initial work.

Keywords: Performance-based seismic design, Reinforced concrete structures, Moment-resisting frames, Maximum displacement estimates, Drift**.**

Abstract *A method for preliminary design of reinforced-concrete frames to satisfy predefined performance objectives is developed. It is directly based on performance targets and therefore fits in the context of emerging next-generation performance-based engineering. The key objective of the proposed method is achieving designs that are more reliable in meeting the targeted performance so that subsequent performance assessment iterations are minimized, while at the same time maintaining traditional design formats. The procedure is an adaptation of the force-based design where a force-reduction factor is still used; however, its value is calculated based on displacement parameters that are estimated at the initial design stage. Extensive parametric studies encompassing the inelastic response of regular moment-resisting frames to several ground motion records are performed, employing hundreds of nonlinear time-history analyses where the seismic records are scaled to different intensities to drive the structures to different levels of inelastic excursion. By conducting statistical analysis of the created response databank, a mathematical expression that relates the maximum displacement to some geometrical factors as well as a performance and damage metrics can be developed, while being independent of the frame section dimensions, such that it can be used at the initial stage of design. Using this estimate of maximum displacement, designers can calculate approximate values of force-reduction factors that are well correlated to performance, and then design can proceed in the conventional way.*

1 INTRODUCTION

Seismic design procedures have been in a continuing process of evolution, much more than design for any other load cases because it is difficult to replicate the complex geological nature of an earthquake in an experiment, and therefore major code changes remains an interminable requisite in response to actual performance of buildings during damaging earthquakes. Although earthquakes impose deformations on structures rather than forces, almost all current codes and standards, like Eurocode 8 (EC8) [1], still adopt the force-based design (FBD) approach for seismic design, which uses seismic forces as the primary design parameter. The main advantages of FBD are that it allows simple combination of all possible load cases being an extension of the traditional design format and that it involves linear analysis in conjunction with the familiar acceleration response spectrum. Inelastic behavior is allowed and is implicitly accounted for by dividing the ordinates of the elastic spectrum by a factor, referred to as response reduction factor (R) in American codes and behavior factor (q) in Eurocode, where its values are empirically stipulated to reflect the ductility and over-strength of the structural system [1, 2].

In the past 20 years, there has been an increasing shift in seismic design concept towards satisfying various levels of structural and nonstructural performance. Based on the increased demands from stakeholders for better accountability of new and existing designs in order to be able to make reliable economic and life-safety decisions, performance-based seismic design (PBSD) – a design whose objectives are in terms of multiple performance levels – has emerged as the future trend of seismic design. The latest approach for PBSD was first liberally described in the FEMA-445 document published by the Federal Emergency Management Agency of the United States [3], which explains how probabilities of exceeding certain values of some performance metrics can be converted to real-world losses such as casualties, time lost without operation, repair and replacement costs. The presented approach consists of three main steps: (1) defining the performance objectives, (2) performing preliminary building design, and (3) assessing the performance of the designed building; where steps (2) and (3) are iteratively repeated until the objectives in step (1) are achieved. The performance assessment stage, step (3), has been extensively studied and its methodology presented in the P-58 report [4] as a relatively long process that involves advanced structural analysis techniques and complex probabilistic approaches, however there is still limited research on efficient preliminary building designs, step (2). The FEMA-445 report acknowledges the challenge of developing such efficient design methods that can meet the desired objectives without extensive iterations and defines this challenge as the major decisive factor of the success of the whole framework of performance-based design, because otherwise the implementation process will be inefficient and uneconomical due to the length assessment process. The key requirement is that this design needs to address the system geometrical attributes as well as proportioning it in a manner consistent with the defined performance objectives [3].

The current state of knowledge renders two options for preliminary design in the context of the emerging performance-based methodology: either the aforementioned building code provisions for force-based design (FBD) or alternatively displacement-based design (DBD) that have been developed along with the growing interest in PBSD, and which use displacement parameters as the starting point of design; therefore, effectively control damage. Among the most common DBD procedures are the displacement coefficient method and the equivalent-linearization method [5]. These methods represent real seismic behavior more rationally by imposing displacement restrictions; however, they lack practicality and acceptance in the design community when compared to conventional FBD methods due to the use of the nonfamiliar displacement response spectrum, as evidenced by results of a recent survey of

practicing engineers in North America about their current seismic design practice [6]. Moreover, these procedures have other limitations, where they involve many approximations especially in adopting an equivalent single-degree-of-freedom (SDOF) representation of the structure, which does not recognize the basic differences in response due to different lateral load resisting systems. More importantly, they require a predesigned structure to get a starting estimate for the displacement demand, which renders these DBD methods more applicable to performance evaluation of existing structures for rehabilitation, rather than new designs [7]. On the other hand, concerning the applicability of the FBD method for performance-based design, it is recognized that most seismic codes (e.g. EC8 [1]) embody two performance levels in FBD: the first is the "life safety" performance level under the design basis earthquake at which strength requirements are obtained, and the second is the "serviceability or damage limitation" performance level under the frequently occurring earthquake at which deformation checks are performed. However, the latter performance level is only a final design check rather than a design criterion, which usually results in an iterative process and additionally include several approximations that can lead to inaccurate estimates of displacement [8]. Therefore, because FBD is likely to remain the mainstream of seismic design practice for some time, there is a need to adjust FBD to fit into the multi-level performance-based framework, by minimizing iterations required to achieve various performance objectives, and bringing damage and displacement control upfront at the beginning of the design process.

This paper proposes an efficient seismic design approach for reinforced concrete (RC) moment-resisting frames (MRF) based on the simple FBD scheme that can serve to meet the rising call for performance-based engineering without sacrificing practicality of application. A modification to the FBD procedure is envisaged, whereby, based on the structures' structural system and geometrical configuration, maximum roof displacement can be estimated according to preselected performance levels, and then the behavior factor (q) can be rationally calculated, so that damage and performance can be incorporated in the initial design stage. The study focuses on low-to-moderate height concrete frames with limited ductility, which is a common construction practice in some moderately seismic zones, for example, Egypt and Turkey, where the level of seismicity does not necessitate more complicated preliminary designs. The scope of this paper is presenting the computational methodology for obtaining the roof displacement estimates as associated with specific performance levels and other structural geometrical characteristics. More than 1750 nonlinear time history analyses are performed, employing rigorous models of RC members that captures both material and geometrical inelasticity which are particularly critical in case of RC structures. The results are postprocessed in order to understand the dependency of the story displacement values on the different variables chosen to be included in the displacement prediction equation for later use in the modified FBD method.

2 MODIFIED FORCE-BASED DESIGN METHOD

The basis of the designated method has been first proposed for steel moment resisting frame structures by Bazeos and Beskos [9], later developed and validated in detail specifically for PBD [10-18] and is still under refinement till present. This group of researchers have termed it the hybrid force/displacement (HFD) method. The main principle of this methodology is that it converts target limiting values of damage metrics associated with predefined performance levels to a target roof displacement that can be used to calculate a more meaningful behavior factor "q" such that ductility demands are bounded by the estimated target roof displacement ductility, and thus the design can control both strength and drift performance for several levels of seismic action. In addition to the benefit of using displacement parameters as input variables for the design process, the HFD method retains the use of conventional elastic

response spectrum analysis and design in line with current seismic codes. An initiative to apply the same procedure for composite steel/concrete structures was recently proved successful [19]. The method was also just newly extended to RC structures [20] where Piana and his co-researchers have developed a HFD method for RC structures based on numerical analyses of structures of varying height only and employing phenomenological models (lumped plasticity) to represent nonlinear behavior. The present work is an additional effort along the same frontier of applying the HFD design method to RC structures for preliminary PBD but through employing distributed plasticity fiber-element modeling to represent inelasticity along members cross sections and lengths, which, despite being much more computationally demanding, is deemed more accurate in accounting for the complex hysteretic behavior of RC structures. The steps of the envisaged modified force-based method can be summarized as follows:

(1) Selection of performance levels

According to the PBD philosophy, a performance level is defined by a pair of a post-earthquake damage and functional state objective and a level of seismic action. For example, a common multiple performance objective is: Immediate Occupancy (IO) under the frequently occurring earthquake (FOE), Life Safety (LS) under the design basis earthquake (DBE), and Collapse Prevention (CP) under the maximum considered earthquake (MCE). The DBE is given in seismic codes, while the FOE and MCE can be estimated from the DBE based on hazard studies. Limiting values of a response parameter associated with the damage level are identified based on performance-based codes for example FEMA-356 [21]. Inter-story Drift Ratio (IDR) is the chosen response parameter because there is consensus in the literature that it best correlates to damage at the global level [22-24]. IDR is defined as the relative lateral displacement between two successive floors normalized by the height between the floors

(2) Definition of building attributes

Some building characteristics such as the number of storeys, n_F, and the number of bays, n_B, are identified. The criteria for application of the FBD method as stated in the code are checked, for example, regularity in plan and elevation.

(3) Estimation of the maximum roof displacement

The maximum roof displacement, $\mu_{r,max}$, is estimated using a relationship that will be developed as a second stage of this research, given as $\mu_{r,max}= f(IDR_{max,}\ n_F,\ n_B,\ H)$, where H is the total height of the building.

(4) Elastic design under the FOE

Perform an elastic design of the frame with a behavior factor q= 1 only for strength requirement under the FOE. The resulting roof displacement serves as an estimate of the global yield displacement $\mu_{r,y}$

(5) Calculation of the behavior (strength reduction) factor, q

Based on the equal displacement rule [25], the behavior factor q is calculated based on the global displacement parameters by dividing the estimated maximum roof displacement ($\mu_{r,max}$) at the desired seismic event by the global yield displacement $\mu_{r,y}$

(6) Design of the structure

The ordinates of the elastic acceleration response spectrum are divided by the q-factor corresponding to the target deformation, and design proceeds in the conventional way.

3 DESCRIPTION OF PROTOTYPE BUILDINGS

In order to develop the expression that estimate the maximum roof displacement at the beginning of design, the performance of nine prototype RC structures varying in height (4, 7 and 10 floors) and number of bays (3, 5 and 7 bays) is studied. The structures are assumed to have the same symmetrical and square plan, as representatives of typical medium-rise RC office buildings. The floor height and bay width are fixed at 3.0m and 6.0m, respectively. The buildings are assumed to be constructed in a moderate seismic zone (featuring a design peak ground acceleration (PGA) of 0.3g).

3.1 Design and structural properties

The buildings were designed and detailed to resist combination of gravity and seismic loads, according to the Egyptian design codes ECP-203 [26], and ECP-201 [27] which are fundamentally in line with the regulations of EC8 [1]; a typical modern seismic code applicable to many countries. For gravity loading, the dead loads assumed comprise the self-weights of the concrete structural elements, typical floor finishing of 1.5 kN/m^2, and weight of masonry infill panels of 12 and 25cm thickness on interior and exterior beams respectively with a density of 18 kN/m^3. A live load of 3.0 kN/m^2 is also included. For seismic design, the lateral load resisting system is chosen as a space frame, and acceleration elastic response spectrum for shallow crustal earthquakes in non-Mediterranean areas is adopted known as Type 1 in ECP-201 [27], and as Type 2 in EC8 [1], for a "Soil Class C", which is soft soil, or dense or medium-dense sand, gravel or stiff clay as given in ECP-201[27] and EC8 [1]. Based on the norm and knowledge of reinforcement detailing in Egypt and many other countries with similar low-to-moderate seismicity, limited ductility (ordinary) frames are chosen and thus a FRF with a value of five is used in the design. Characteristic material properties are utilized, and they are presented in Table 1 using units consistent with those that will be subsequently used in the program for nonlinear time-history analysis. Gravity and seismic loading are combined using the appropriate coefficients from ECP-203 [26]. The only capacity design rule applied is that resulting from the prescribed reduction in the effective flexural stiffness of members where the reduction for beams (50%) is higher than that for columns (30%). All floors are assumed to have a solid rigid slab with a constant thickness of 150mm, and columns are selected to have a square cross-section and to be symmetrically reinforced on the four sides, in order to have equal resistance to the changing direction of earthquake loading. The reinforcement is selected minimally according to the structural analysis and code requirements, to avoid overstrength and unnecessary margins reflecting personal designers' choices. Figure 1 summarizes the notations used for the study cases together with their corresponding geometrical characteristics, and member cross-section sizes and reinforcements.

	Material parameter	Values used
Concrete	Compressive cube strength, f_{cu}	25 N/mm^2
	Modulus of elasticity, E_c	22 kN/mm^2
	Poisson's ratio	0.2
Steel (36/52)	Yield strength, F_y	360 N/mm^2
	Ultimate strength, F_u	520 N/mm^2
	Modulus of elasticity, E_s	205.9 kN/mm^2

Table 1: Material properties employed in design and time-history analysis

	Column (dimension (mm)/RNF)	**Beam** (depth (mm)/RNF)
Floors 1-4	450/8φ22 (outer) and 600/16φ20 (inner)	750 / 8φ18

	Column (dimension (mm)/RNF)	**Beam** (depth (mm)/RNF)
Floors 5-7	450/8φ22 (outer) and 450/8φ22 (inner)	650 / 7φ18
Floors 1-4	550/12φ20 (outer) and 650/16φ22 (inner)	750 / 7φ20

	Column (dimension (mm)/RNF)	**Beam** (depth (mm)/RNF)
Floors 8-10	450/8φ22 (outer) and 400/8φ20 (inner)	600 / 7φ16
Floors 5-7	550/12φ22 (outer) and 650/16φ22 (inner)	650 / 6φ20
Floors 1-4	650/20φ22 (outer) and 750/20φ22 (inner)	750 / 7φ20

3.2 Nonlinear analytical model

Taking advantage of the symmetry of the buildings with the insignificance of torsional effects, a two-dimensional nonlinear model of the structures was developed in order to simplify the post-processing of results. The simulation platform of the Mid-America Earthquake Center (MAE), called "ZEUS-NL", is selected for nonlinear Time History Analysis (THA). This

software was developed at the University of Illinois at Urbana- Champaign [28] specifically for earthquake engineering applications, based on the older analysis packages ADAPTIC [29] and INDYAS [30]. The stability and robustness of ZEUS-NL in its present or previous forms have been extensively tested and validated by many researchers [31-32]. ZEUS-NL uses the fiber analysis approach in modeling nonlinear behavior. This type of models, usually referred to as the distributed plasticity models, is considered a middle ground between the computationally efficient lumped plasticity models which represent inelasticity as a zero-length hinge with hysteretic properties, only at defined locations at ends of elements (for example SAP2000 and ETABS) and continuum analysis which monitors stress-strain behavior through every single point of the entire structure (for example ABACUS and ANSYS). The latter is unquestionably the most accurate and powerful modeling method, however because of its excessive computational demand, the fiber modeling approach is often the method of choice for research about large displacement analysis of frame structures in the inelastic range.

In distributed plasticity models, cross-sections at specific integration points along the element length are divided into fibers where each fiber is associated with a uniaxial stress-strain relationship (constitutive model) for one material. The number of section fibers needs to be defined by the user and they usually range between 100 and 200. During the entire multi-step analysis, making use of the Euler-Bernoulli assumption that plane sections remain plane after bending, fiber stresses are calculated from the fiber strains considering the migration of the position of the section neutral axis during the loading history. Then sectional stress-strain state in the form of moment-curvature relationship is obtained through the integration of the nonlinear response of the individual material fibers over the cross-sectional area, thus fully accounting for the spread of inelasticity across the whole section depth. This is followed by integrating the moment-curvature relationship of the sections along the length to obtain the moment-rotation response, and thus simulating the distributed inelasticity along the member length. This discretization process is illustrated for reinforced concrete frames in Figure 2.

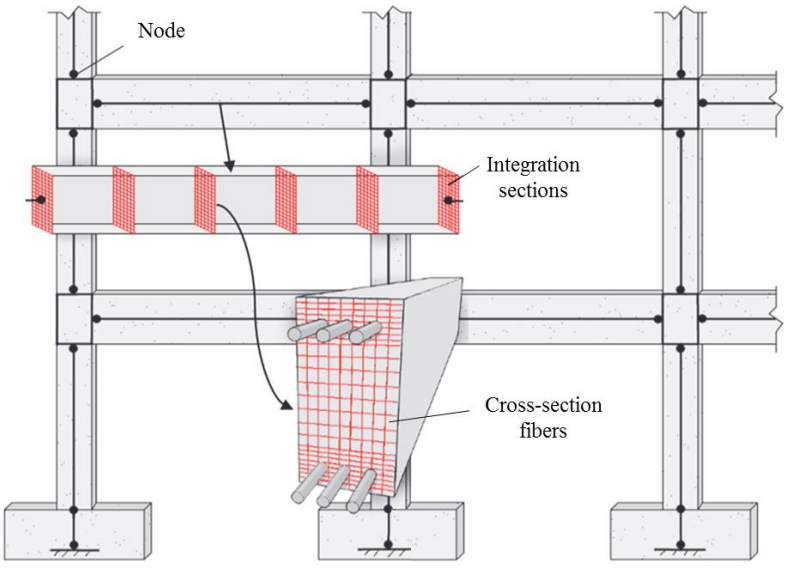

Figure 2: Fiber-element modeling of a reinforced concrete frame (after ATC, 2016 [33])

Some of the advantages of the fiber element method are that: it directly simulates interaction between axial force and bending moment; it does not need any prior moment-curvature analysis of members; and it automatically accounts for concrete cracking and growth in crack length, as well as gradual progression of steel yielding through the member cross sections and

lengths. Also, local buckling of steel reinforcing bars or steel webs and flanges can be reasonably modeled by incorporating it in a steel constitutive model that degrades the structural properties of the steel elements when they reach a certain critical buckling stress. The model can also impose equilibrium in the deformed state of the structure and thus represent geometrical nonlinearity and P-delta effects.

3.3 Material models

Concrete is represented using the uniaxial nonlinear concrete model that has a balance of simplicity and accuracy. This model adopts the constitutive relationship formulated by Mander et al. [34] integrated with the improved cyclic rules proposed by Martinez-Rueda and Elnashai [35] which can predict the continuing cyclic degradation of strength and stiffness and helps to achieve better numerical stability in case of large displacements analysis. Two separate concrete material models are used for the core concrete (confined) and cover concrete (unconfined) to reflect the different confinement factors included. The model assumes constant active confinement pressure throughout the entire stress-strain range, which is considered as the maximum confining pressure that occurs at yielding of transverse reinforcement.

The steel reinforcing bars (longitudinal bars) are modeled using a bilinear (elasto-plastic) model with a kinematic strain-hardening rule for the yield surface assumed as 0.5% of the elastic initial stiffness [36].

3.3.1. Cross-sections

The cross-sections of each element are defined based on their design details and the material models chosen. In order to account for the slab contribution to beam stiffness and strength, all beam sections are modeled as T-section with effective flange width equals to threefold the slab thickness on each side, corresponding to the specifications of ECP-203 [27] in case of seismic loading and amounting to 1.15m. Columns are modeled using square sections. ZEUS-NL built-in section models for RC T-section and RC Rectangular section are used to model beams and columns respectively as shown in Figure 3. Each structural member is modeled using several elements having different cross sections to reflect the change in reinforcement detailing along the member length. The cross-section definition covers the actual arrangement of longitudinal reinforcement while the arrangement of transverse reinforcement is approximated through the confinement factor in the constitutive material model discussed in section 3.2.1. Figure 3 also illustrates the discretization of the cross-section into fibers at the material level. The accuracy of the model increases as the number of fibers discretization increases; thus, it was chosen to use 200 monitoring points per section to monitor nonlinear behavior.

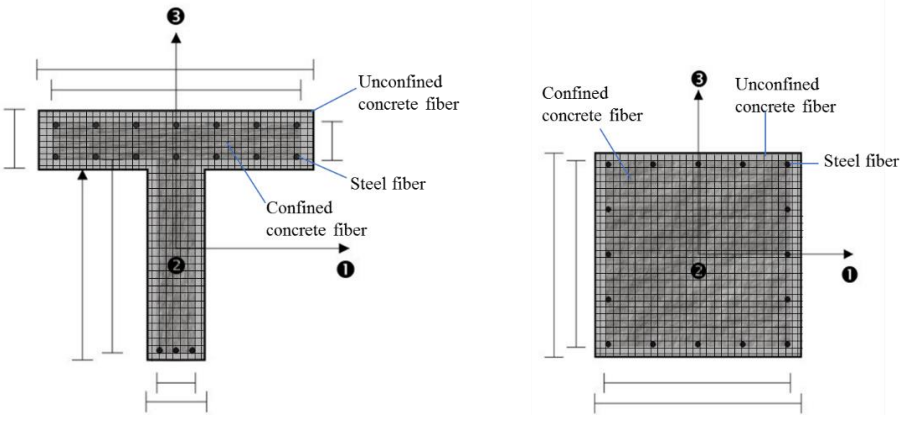

Figure 3: Cross sections used in modeling beams and columns

3.3.2. Elements

A 3-D cubic elasto-plastic element formulation was applied to model the spatial behavior of both column and beam elements accounting for inelasticity across element depth and length [37]. As the name implies, this elasto-plastic element utilizes a cubic shape function to provide the transverse displacement. For evaluation of the element forces and displacement, numerical integration of the cubic formulation equation is performed at two Gauss integration points whose location is depicted in Figure 4. The cross-section at each Gauss point is divided into a number of monitoring areas as discussed earlier, where the appropriate material constitutive model is applied, and strains and stresses are monitored and then integrated to model the response of the whole element cross-section and length employing the fiber approach. Geometrical nonlinearity due to second order effects is also accounted for. Since each element has a displacement-based formulation and just two integration points, several short length elements were used in order to ensure reasonable accuracy in inelastic modeling.

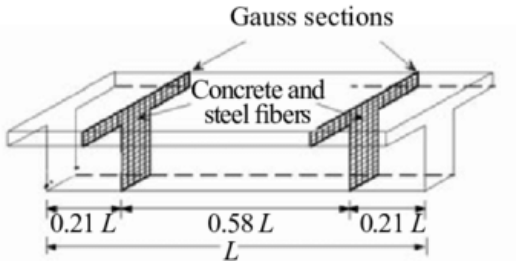

Figure 4: Location of the two Gaussian sections

Rayleigh damping elements were selected to model equivalent viscous damping in the structure, which can result from friction in concrete opened micro-cracks and interaction of nonstructural elements. Although, this damping part is very small compared to the more important hysteretic damping due to inelastic behavior and yielding (which is already implicitly accounted for within the nonlinear material models that allows energy dissipation though cyclic loading), it was chosen to still employ some viscous damping in order to provide numerical stability, where the damping matrix results in stabilizing the system of equations of motion. For this end, stiffness-proportional Rayleigh damping coefficient is calculated based on the periods of the structure in the first two modes of significant mass participation [38]. Although the Egyptian code ECP-201 [26] provides the design spectrum based on 5% first mode critical damping, this percentage also indirectly comprises the effect of inelastic behavior which is covered in the material models in nonlinear analysis. Therefore, 2% critical damping in the first mode was considered following the code provisions for wind load analysis in which structures are assumed to behave completely elastically. Also 5% of critical damping was assumed in the second mode.

Masses were represented by lumped 2D mass elements at beam-column intersections in dynamic analysis, in order to reduce computational demand, since the current work is focused on estimating structural global responses (like roof drift) rather than local stress state of members. Modeling infill walls was not included in the nonlinear dynamic analysis, except for their masses considered, because infill walls usually get damaged at low drift values and thus their contribution to stiffness stops at relatively low seismic action [39] and since the effect of infill walls is not as critical on the displacement behavior, which is the core of this study, as it is on the stress behavior.

4 IMPLEMENTATION OF NONLINEAR MODEL IN SEISMIC ANALYSIS

4.1 Seismic Input and Scaling

In this study, it was selected to use an ensemble of artificial accelerograms (acceleration time history ground motion records) for earthquake representation, with a single criterion which is compatibility of their 5% damped elastic spectra with the code spectrum used in the seismic design of the buildings over the period range of significance. Using artificial records provided the advantage of best fit to target spectrum as well as limiting the variability in results. It was opted to use a suite of seven ground motion records, and then to average the results pertinent to the provisions of ECP-201 [26] for THA. Accordingly, seven 20-seconds artificial accelerograms were generated using the program SIMQKE [40] such that their average matches the ECP-201 [26] "Type 1" elastic response spectrum for soft soil class "Type C" at PGA= 0.3g. The records were selected to have reasonable variability of frequency and energy content to reduce the bias in response. The software SEISMOSIGNAL [41] was used to evaluate some of the characteristics of the generated records, where maximum acceleration to maximum velocity (A/V) ratio serves as an energy content indicator, and the earthquake predominant period, T_p, as a frequency content indicator. Characteristics of the records that have been used with their reference notation are given in Table 2.

Earthquake reference	Predominant period (T_p)	A_{max}/V_{max}
EQ1	0.26	11.2
EQ2	0.12	8.6
EQ3	0.2	13.9
EQ4	0.28	9.4
EQ5	0.18	11.8
EQ6	0.16	14.1
EQ7	0.22	10.5

Table 2: Characteristics of selected artificial ground motion records

For the purpose of scaling the ground motion records, it was chosen to use the peak ground acceleration (PGA) as the intensity measure (IM) for scaling accelerograms later in the dynamic analysis rather than the most widely used IM, which is the 5%-damped spectral acceleration at the first-mode period of the structure. The latter has a major deficiency when used in analysis involving high excursion into the inelastic response range, where it does not consider the elongation of the first modal period of vibration as a result of nonlinear behavior. Additionally, PGA is considered the most important IM from a structural point of view because the resulting inertia forces in a structure are directly proportional to the acceleration, according to Newton's Second Law. And till present PGA is the key aspect of definition of seismic hazard in most seismic design standards including the ECP-201 [26], where it represents the first point on the elastic design response spectrum. Also, because relative spectral matching at all periods is closely achieved during the generation of the spectrum-compatible records, there is no need to provide separate scaling factors for each different height building depending on its fundamental period. PGA is measured as the maximum absolute amplitude on a recorded or synthetic accelerogram. In order to be used for scaling, at each incremental step a of analysis, each record is simply multiplied by a scale factor $Si_{ft} = a_i / a_1$, where a_i is the PGA

of ground motion record used in the analysis, and a_1 is the PGA of the original unscaled earthquake record (i.e. PGA =0.3g).

4.2 Performance Criteria

In order to identify the factors that affect the maximum displacement at various levels of seismic action, certain levels of performance were preselected and defined for studying their associated response. Three discrete structural performance levels corresponding to three major damage and functional states were investigated in the present work, following the definition of the guidelines of FEMA-356 [21]:

- Immediate Occupancy (IO) level, at which the structure is safe to be occupied immediately after the associated seismic event and repairs are minor, i.e. negligible damage.
- Life Safety (LS) level, at which the structure remains stable and has significant reserve capacity at the associated seismic event, and hazardous nonstructural damage is also controlled to ensure life safety.
- Collapse-Prevention (CP) level, at which the structure is barely standing after the associated seismic event, i.e. most severe damage before collapse.

Limiting values for the chosen response parameter, which is IDR, were assumed, following the acceptance criteria specified in the FEMA-356 document [21], and presented in Table 3. Therefore, the upper limits of IDR used to define the IO and LS performance levels were selected as 1% and 2%, respectively, while the limiting IDR for the CP level was chosen as 3% (less than the 4% specified by FEMA 356) for added conservatism in the global failure criteria as proved by several previous studies [42-42].

Structural Performance Levels and Damage – Vertical Elements				
		Structural Performance Levels		
Elements	**Type**	**Collapse Prevention**	**Life Safety**	**Immediate Occupancy**
Concrete Frames	Primary	Extensive cracking and hinge formation in ductile elements. Limited cracking and/or splice failure in some nonductile columns. Severe damage in short columns.	Extensive damage to beams. Spalling of cover and shear cracking (<1/8" width) for ductile columns. Minor spalling in nonductile columns. Joint cracks <1/8" wide.	Minor hairline cracking. Limited yielding possible at a few locations. No crushing (strains below 0.003).
	Secondary	Extensive spalling in columns (limited shortening) and beams. Severe joint damage. Some reinforcing buckled.	Extensive cracking and hinge formation in ductile elements. Limited cracking and/or splice failure in some nonductile columns. Severe damage in short columns.	Minor spalling in a few places in ductile columns and beams. Flexural cracking in beams and columns. Shear cracking in joints <1/16" width.
	Drift	4% transient or permanent	2% transient; 1% permanent	1% transient; Negligible permanent

Table 3: Definition of structural performance levels for RC frames (after FEMA 356 [21])

4.3 Incremental Dynamic Analysis

In order to derive maximum displacement expressions for RC frames corresponding to different levels of performance, it is required to study each prototype structure under various levels of seismic actions to investigate the factors that influence its maximum displacement pattern. This type of parametric analysis involving the extension of a single nonlinear THA into an incremental one by progressively scaling the seismic load is generally referred to as "Incremental Dynamic Analysis" (IDA). The scaling interval and limit is selected to adequately push the structure through the entire range of behavior under study, from elastic to inelastic and finally to collapse (or close to collapse). Appropriate postprocessing can present the structural response results as IDA curves, for each ground motion record, of the structural response parametrized by a seismic intensity level. For the purpose of IDAs performed herein, the following procedure is undertaken in order to develop IDA curves and create a response databank with the post-processed results at the study performance levels:

1. Multiply the accelerogram with the initial SF_1, which is taken as the reciprocal of the FRF used in design (FRF =5); therefore SF_1= 0.2.
2. Run nonlinear dynamic analysis with the ground motion record acceleration set as a_i = $SF_i \times PGA_{design}$ (0.3g), where i is the run number.
3. Extract all nodal displacements and calculate:
   - $(IDR_{max})_i$ = the maximum instantaneous inter-storey drift ratio at run i (the maximum difference between the lateral displacements of any two consecutive floors at any instance)
   - $(\mu r_{max})_i$ = maximum roof displacement at run i (the maximum difference between the lateral displacement of the roof and the base at any instance)
4. A reasonably small increment of 0.2 is chosen for progressively increasing the scale factors. Therefore, the new scale factor is computed as: SF_{i+1}= SF_i + 0.2. This is equivalent to having a PGA increment of 0.06g (0.2x 0.3g).
5. Repeat steps 2 to 3 until the (IDR_{max}) is greater than or equal 3%.
6. Plot the SF_i versus $(IDR_{max})_i$ and by linear interpolation, determine the scale factors SF_{IO}, SF_{LS}, SF_{CP} corresponding to the three following predefined performance levels (respectively):
   - IO when IDR_{max} equals to 1%
   - LS when IDR_{max} equals to 2%
   - CP when IDR_{max} equals to3%
7. Re-run the model using SF_{IO}, SF_{LS} and SF_{CP} and check that the IDR_{max} properly corresponds to the selected performance levels. If the target IDR_{max} is not achieved, interpolation is repeated, and scale factors are corrected until reaching the specified limits of IDR_{max} for the three study performance levels. In other words, for each pair of structure and accelerogram, three scale factors are identified for running the models.
8. For the same prototype structure, repeat steps 1 to 7, for the rest of the 7 artificially generated ground motion records.
9. Repeat steps 1 to 8 for the rest of the 9 prototype structures.

5 RESULTS AND DISCUSSION

This section discusses some of the results of IDA that are used to identify the factors and the form of the expression to be used for estimation of maximum roof displacement. The whole computational volume required to identify the selected performance levels was in the order of 1750 nonlinear THA runs, however for the presentation of the displacement profiles,

only the results at the study performance levels are included, after averaging the response of the seven ground motions for each prototype building.

5.1 Height-wise displacement profiles

The maximum displacement profiles for the study cases are presented based on the mean values of story displacement (average of the response for the seven ground motion records) that occurs at the seismic intensity identified for each performance level. Based on the results presented in Figures 5-7, it can be observed that the number of stories (n_F) is the main geometrical characteristics that affects the values of storey displacement and the shape of the displacement profile. Taller frames display higher displacement response, and their displacement profile shapes reflect higher modes of vibration than the fundamental translational mode. Shorter frames exhibit an almost linear displacement profile. Also, it can be inferred that an increase in the number of bays (n_B) produces a reduction in the maximum floor displacement due to the increased stiffness. This influence is more prominent in the nonlinear range for the LS and CP performance levels, with the reduction in displacement as related to the increased number of bays being more observed in the higher floors, especially for the roof displacement.

.

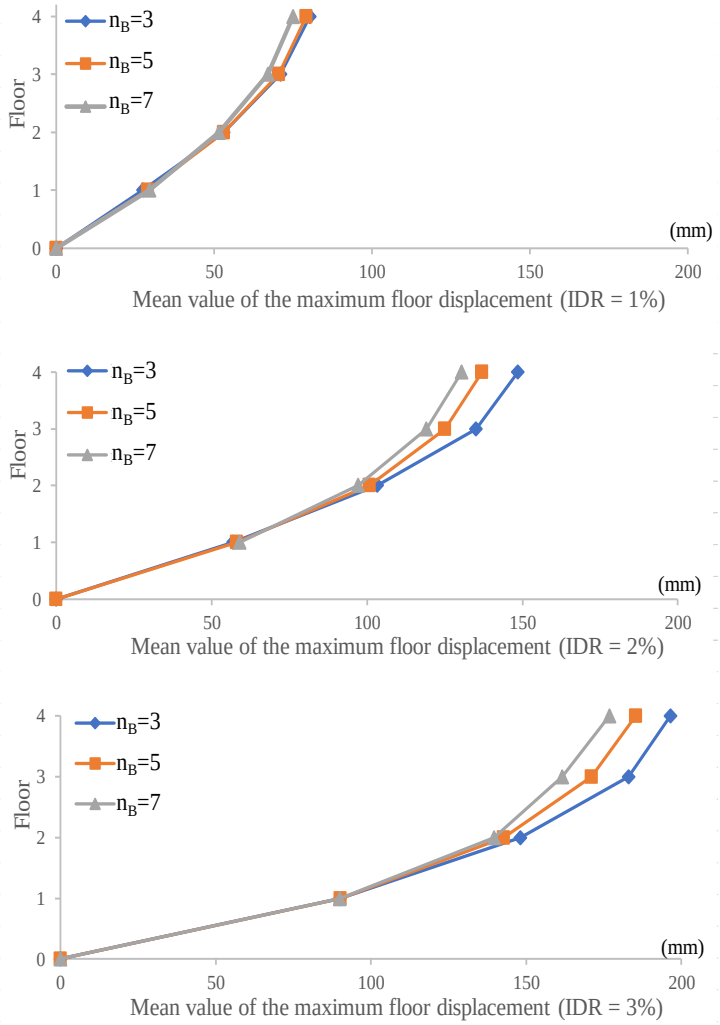

Figure 5: Mean values of the maximum floor displacements that represent the drift profile of the 4-story frames associated with the IO level (IDR =1%), LS level (IDR =2%), and CP level (IDR =3%).

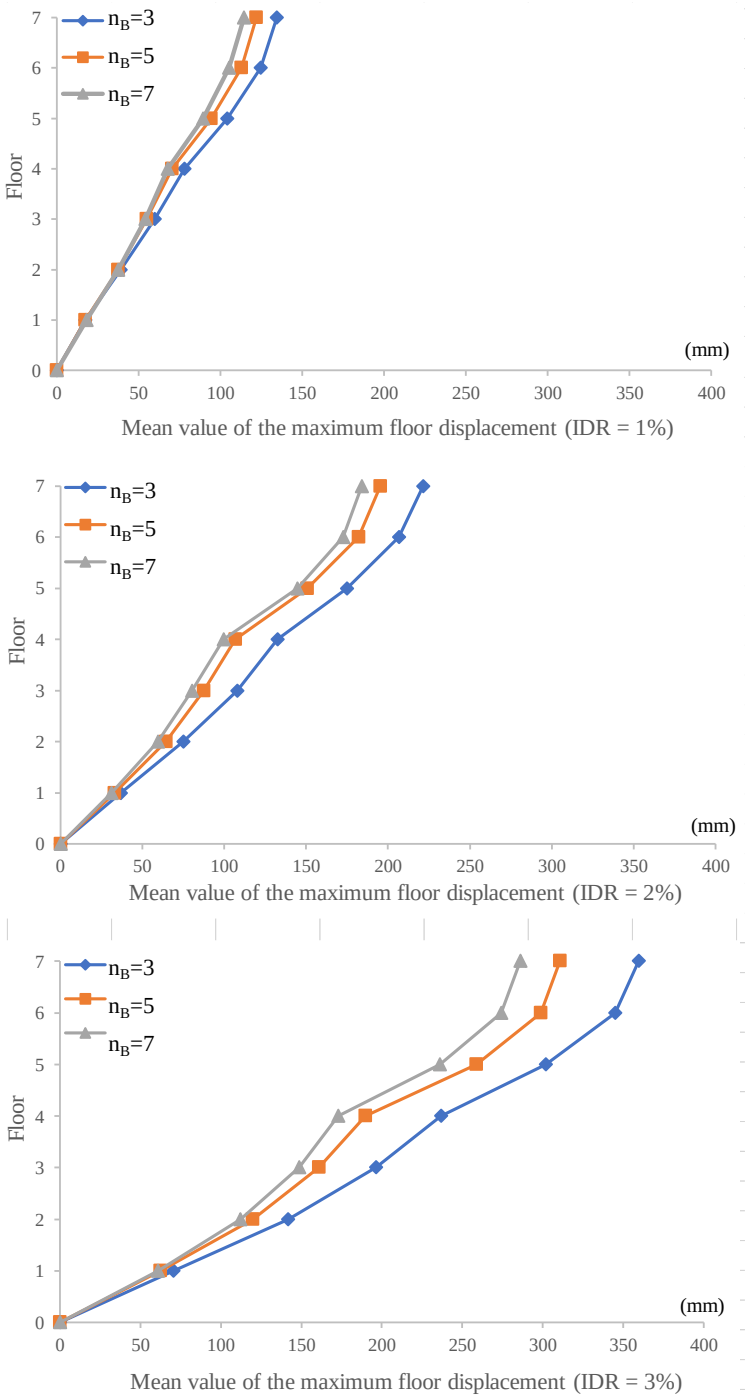

Figure 6: Mean values of the maximum floor displacements that represent the drift profile of the 7-storey frames associated with the IO level (IDR =1%), LS level (IDR =2%), and CP level (IDR =3%).

5.2 Parametric study

Three parameters are studied to understand their effects on the value of the maximum roof displacement, namely the number of floors (n_F), the number of bays (n_B) and the $IDR_{r,max}$ damage metric. Two of the parameters are alternatively fixed in order to be able to visualize the effects of the third parameter. The results of the parametric including all the results of the nonlinear THA are shown in Figures 8 and 9. By comparing the roof displacement versus IDR

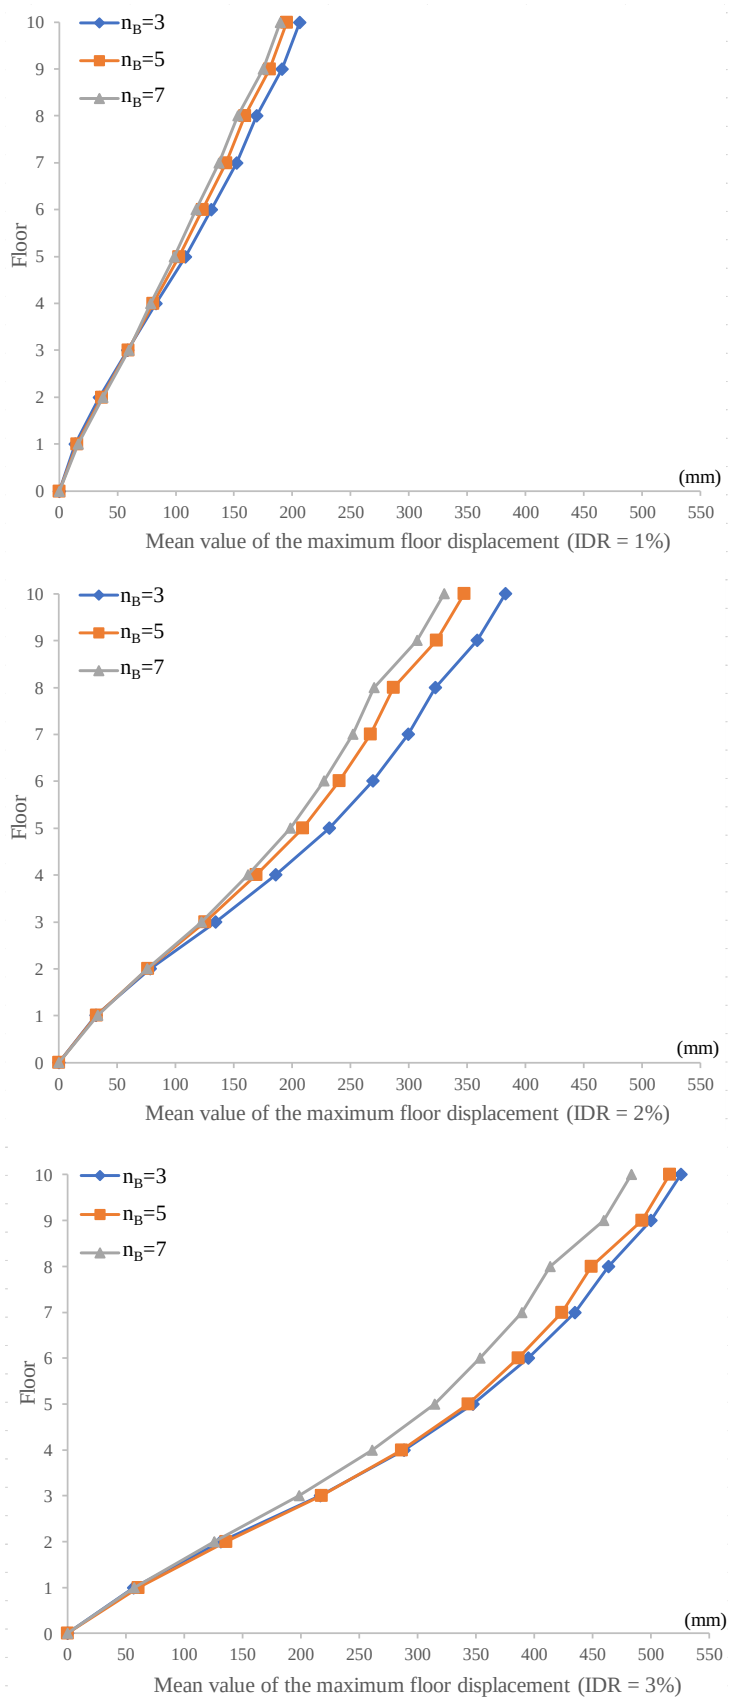

Figure 7: Mean values of the maximum floor displacements that represent the drift profile of the 10-storey frames associated with the IO level (IDR =1%), LS level (IDR =2%), and CP level (IDR =3%)

for the different height and width frames, a general increasing trend is observed with increasing building n_F and decreasing n_B. The effect of the number of stories is much more substantial, as clear in the plots. Also, there is higher sensitivity to the ground motion characteristics with increasing number of floors as proven by the higher dispersion of results in Figure 8, especially with higher excursion into inelastic action (higher IDR values). It can be observed that there is a change in slope with increasing IDR for the different height frames, which proves the interaction of these two factors in contributing to the estimate of maximum roof displacement. Figure 9 reiterates the same relationships and displays the range of sensitivity of the maximum roof displacement to the change in number of bays. The increase in roof displacement with decreasing number of bays is quite negligible for the 4 stories buildings, and the effect of number of bays becomes more prominent with increasing number of floors and especially at higher IDR values associated with more damage.

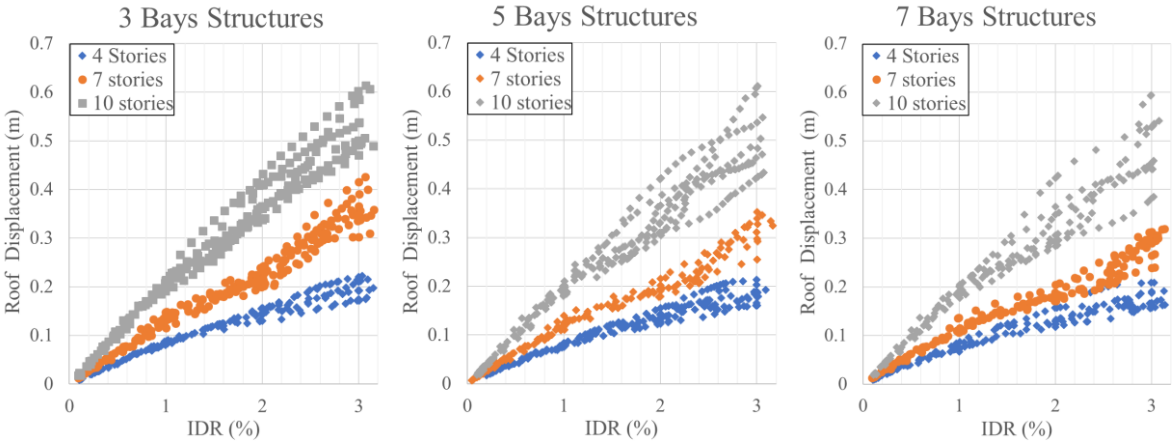

Figure 8: Dependency of the maximum roof displacement on IDR and n_F (for a given number of bays)

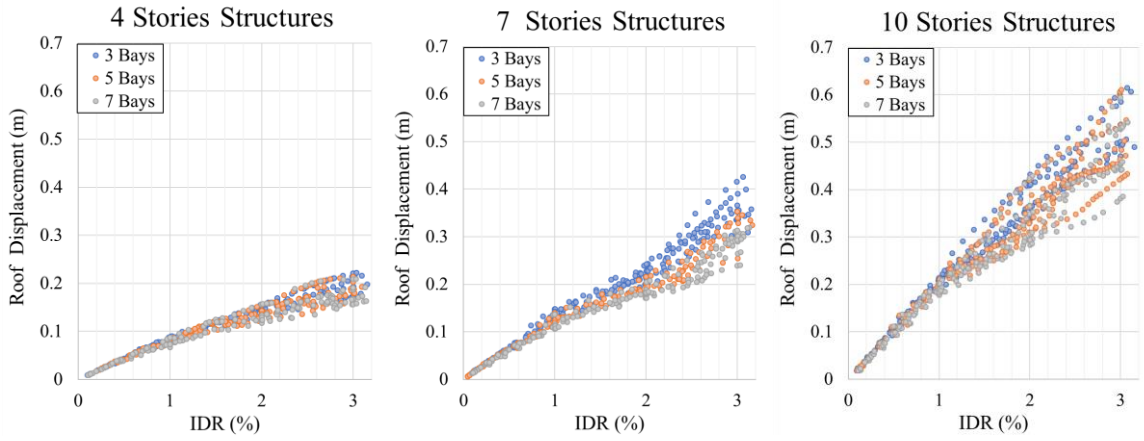

Figure 9: Dependency of the maximum roof displacement on IDR and n_B (for a given number of stories)

6 CONCLUSIONS

In order to incorporate damage in the initial stages of seismic design, a method is proposed for design of RC frame structures that involves modification of the familiar FBD method, where the design starts with a displacement variable that is converted into a force parameter,

and then design can proceed in the conventional way. The use of the proposed modification can yield designs with higher accuracy and more reliability in achieving the preselected performance targets, where the damage is controlled at every performance level. Additionally, due to minimizing the amount of iterations, this method can be considered a valid contribution to the stage of "Preliminary Building Design" of the framework of "next-generation performance-based seismic design" nominated by FEMA-445 [3].

This paper presents the modification envisaged which requires development of a mathematical that can estimate maximum roof displacement based on required performance objectives, and independent of the members cross sections, such that it can be used at the start of design. The computational methodology for development of such expressions are presented which requires developing rigorous nonlinear models of the RC structures and performing extensive parametric studies using nonlinear time-history analysis in order to identify the parameters that will be included in the displacement prediction relation. The effect of changing the number of floors and number of bays together with changing the performance level, on the displacement behavior is observed, so that they can be later incorporated by the authors in nonlinear regression to develop the required expressions. It should be noted that the conclusions herein are only valid for the range of structures under study and for areas with similar seismicity. In the long run, the recommended design scheme can present a promising design tool that can be implemented in design codes and textbooks, pending verification and validation on a wider range of structural systems and materials.

Abstract

The 2019-2021 RINTC project is the extension of the 2015-2017 RINTC project that assessed, explicitly, the seismic risk of code-conforming Italian structures (i.e., designed according to the seismic code currently enforced). The aim of the new RINTC project is to extend the methodological framework developed in RINTC to the existing structures (designed and built before 2008), which constitute the vast majority of Italian building stock. In 2018 some analyses, preliminary with respect to the 2019-2021 project, were carried out; i.e., the 2018 RINCT-e project. In particular, five structural typologies were considered: masonry, reinforced concrete, pre-cast reinforced concrete, steel, and seismically isolated buildings. In the framework of the 2018 project, several archetype structures for each typology have been designed and/or retrofitted according to standard practices consistent with outdated codes, enforced since the eighties, for five sites across Italy spanning a wide range of seismic hazard levels (evaluated according to current standards). The seismic vulnerability of the designed structures was assessed by subjecting three-dimensional nonlinear computer models to multi-stripe non-linear dynamic analysis. Integration of the probabilistic hazard and probabilistic vulnerability (i.e., fragility) yields the annual failure rate for each of the designed and modeled structure. In the paper, the 2019-2021 RINTC project is introduced and the preliminary failure rates of the existing structures are presented.

Keywords: Reliability, Structures, Earthquake Engineering, Failure, Damage.

1 INTRODUCTION

The 2015-2017 RINTC (*Rischio Implicito delle strutture progettate secondo le NTC*) project was a large research effort aimed at assessing the seismic structural reliability, expressed in terms of annual failure rate, of code-conforming structures in Italy [1][3]. For the purposes of the project three sites exposed to comparatively low- mid- and high-seismic hazard were considered; i.e., Milan (MI), Naples (NA) and L'Aquila (AQ). At these sites, residential/industrial buildings belonging to five structural typologies were designed according to the recent Italian seismic code; i.e., un-reinforced masonry (URM), reinforced concrete (RC), pre-cast reinforced concrete (PRC), steel (S), and base-isolated (BI) structures. All typologies were designed at all sites with reference to two limit states considered by the code; *damage control* and *life-safety*. Three-dimensional non-linear models were developed for the buildings, with the aim of running dynamic analysis for performance assessment with respect to two ad-hoc defined failure conditions*: usability-preventing damage* (UPD) and *global collapse* (GC). Earthquake records for the non-linear dynamic analysis were selected according to the *conditional-spectrum* (CS) [4] approach. The results mainly indicate that the seismic structural reliability changes by orders of magnitude as the seismic hazard changes from site-to-site, despite homogeneity of the exceedance return period of the design ground motion and of the other design and modelling choices. The contribution of uncertainty in modelling assumptions and soil-structure interaction was also quantified and found of relatively minor importance.

Herein the 2019-2021 RINTC project is introduced. It targets the seismic structural reliability of *low-* and *pre-code* structures in Italy. This is because these structures constitute the vast majority of the Italian building stock. To compare the reliability results to those already obtained for the code-conforming structures, the modelling and analysis framework is retained from the previous project. Three code levels, previous to the contemporary era, are broadly identified for the existing structures in Italy: (1) the 80-90s; (2) the 70s; (3) the pre-70s era. While (1) and (2) represent ages of evolution of the codes toward modern earthquake-resistant design, (3) is when most of the buildings in Italy were designed basically for gravity loads.

In this short paper, the workplan, in terms of analyzed structures, is presented together with the preliminary results from the preparatory activity developed in 2018. In particular the 2018 RINTC-e project is discussed. To this aim, the following is organized such that the case studies of the 2019-2021 RINTC project are illustrated. Subsequently, the structures analyzed in 2018, mostly referring to design or seismic upgrade of structures according to the codes enforced in the 80-90s (some also from the 70s) in Italy, are described along with the representation of the ground motion for reliability assessment via non-linear dynamic analysis. Then, the failure criteria considered, analogous to the 2015-2017 RINTC project are recalled. Finally, the, very preliminary, results in terms of failure rates are discussed. Final remarks close the paper.

2 RINTC-E SITES, STRUCTURES AND BUILDING CODES

The RINTC 2019-2021 project deals with existing buildings built, essentially, in the XX century, in which the design in Italy evolved from only gravity-load-design all-over the country to earthquake-resistant design in most of the country [5]. All the considered codes precede the contemporary era in which seismic actions are based on probabilistic seismic hazard analysis and the principle of seismic design (e.g., *capacity design*) are fully acknowledged by the code.

Table 1 provides a matrix where the buildings considered in the 2019-2021 project are associated to the design/construction age and the sites where they are supposed[1] to be located. It is to note that two sites, Rome (RM) and Catania (CT), have been specifically-considered for the purposes of the RINTC-e project. In particular, Catania has been considered as a site with relatively high seismic hazard according to the current code, yet characterized by gravity-load design only since a few decades ago. The addition of Rome downtown allowed to consider large URM buildings typical of historical downtowns in Italy, similar to Naples, yet exposed to different seismic hazard. Figure 1 (left), shows the considered sites overlaid on the map of the *peak ground acceleration* (PGA) with 475 years exceedance return period on rock, which is adopted by the current code as a basis to determine the current design actions [6],[7]. Figure 1 (right) shows the PGA on rock hazard curves for the five sites, ad-hoc computed, yet consistent with the probabilistic seismic hazard study at the basis of the current code [8]. The relative seismic design hazard levels can be observed from the figure. MI is the less hazardous and AQ is the most hazardous.

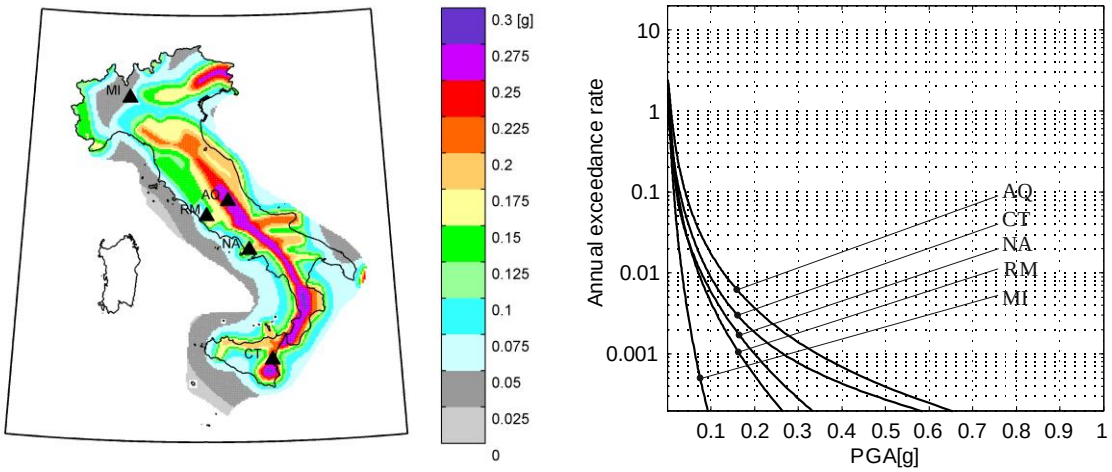

Figure 1: Left – considered sites on the map of peak ground acceleration (PGA) with 475 years exceedance return period on rock, adopted by the current code; right – PGA hazard curves on rock for the five sites.

Table 1: Building/sites matrix for the existing buildings to be studied in the 2019-2021 RINTC project and those analyzed in the 2018 RINTC-e project (in bold).[2]

The failure rates of buildings in bold in Table 1 are preliminarily addressed in this paper. The considered codes, although modern, are not at the contemporary level of seismic design, at least in terms of definition of design action and resistant mechanism rules such as capacity design. In most of cases, buildings were designed according to these codes; however, in the case of unreinforced masonry, older buildings were upgraded according to the considered code or, in some cases according to the current code, indicated as NTC [6]. In the following, few details for each typology are given; however, the interested reader should refer to the specific papers cited for a more comprehensive discussion about design, modelling and analysis.

2.1 URM buildings

For what concerns URM buildings, the 2018 RINTC-e plan was to retrofit older buildings. Retrofit interventions on URM buildings were designed according to the code, issued 1981, for repair and strengthening of buildings damaged by earthquakes [14], and the associated guidelines [15]. These documents incorporate the so-called POR method, originally proposed by Tomazevic [16], for the seismic analysis of retrofitted URM buildings. The relevance of this code is that it was published after the magnitude (M) 6.5 1976 (Friuli, northern Italy), M5.8 1979 (Norcia, southern Italy) and M6.9 1980 (Irpinia, southern Italy) earthquakes, and then extensively used in the reconstruction phases. Interventions were also alternatively designed according to the current code (NTC). Eventually, retrofit interventions were assessed according to the code update published in 2018 [7]. As an example, Figure 2 reports the upgraded buildings in Naples, about which further details can be found in [11].

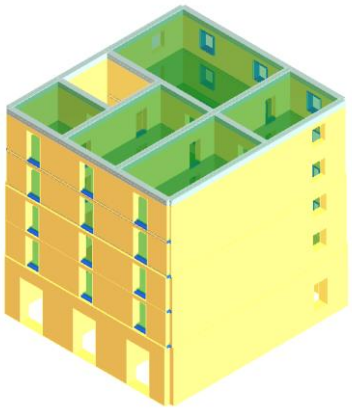

Figure 2: the URM building analyzed in Naples.

2.2 RC buildings

In 2018, case-study structures representative of the existing residential RC building stock in Italy were defined through a simulated design process. These structures were three-storey

buildings, designed for gravity loads only during the 70s (gravity-load-design, G) or for seismic loads during 80s-90s (seismic-load-design, S). G-buildings were designed according to [17]. S-buildings were designed according to [18], as technical code, and to [19], for seismic load provisions. S-buildings were assumed to be located in L'Aquila (*second seismic category* at the time of design; i.e., mid seismic loads in a set of three), and thereby they were designed with a base shear equal to 0.07 times the building weight, adopting a linear static analysis method. Both for G- and S-buildings, the allowable stress design method was used. In all cases modelling considered infilled structures. Details are given in [9], while Figure 3 provides an example of a three-storey RC building.

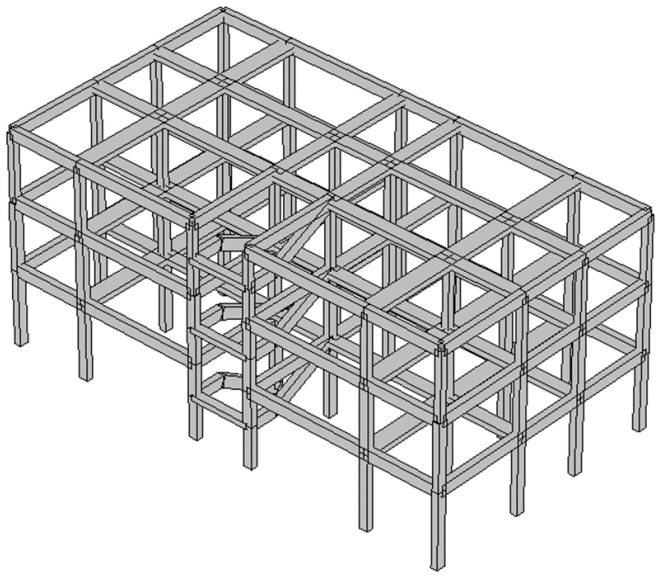

Figure 3: Three-dimensional view of a three-storey S building.

2.3 PRC buildings

Six different single-story PRC buildings were designed according to [17] and [20], enforced in Italy in the 70s, for three different sites (MI, NA, CT) and for two different heights of the columns (6 and 9 m).. The considered codes do not take into account seismic loads and the design follows a deterministic approach according to the allowable stress design. Roof elements and beams are designed only for vertical loads (dead and live loads), whereas the design of columns takes into account the wind load and temperature variations, which are the only horizontal forces acting on the buildings in the design phase. In fact, single-story PRC buildings are also designed according to the seismic codes enforced in Italy in 80s and 90s. Details are given in [10], while Figure 4 provides the front and plan views of the typical PRC buildings designed and modelled in the project.

2.4 S buildings

The building structures were obtained by simulating a design carried out according to the code and standards for steel buildings enforced in the years 1980s-1990s [19],[21][22]. In more detail, [21] contained information regarding variable load values (i.e., wind and snow loads and variable gravity loads). Instead, [19] contained information about the site seismic

classification and the consequent calculation of the equivalent static forces, for both horizontal and vertical components. In addition, [22] was a well know guideline for specific design of steel structures, in terms of resistance, stability and deformability checks. Steel structures design contemplated only hinged-portal (HP) in 2018, while corresponding fully-constrained portals (FP) will be examined in 2019-2021. Concerning the cladding, both sandwich panels (SP) and trapezoidal sheeting (TS), were considered. Details are given in [12], while Figure 3 provides a three-dimensional view of the typical steel building designed and modelled in the project.

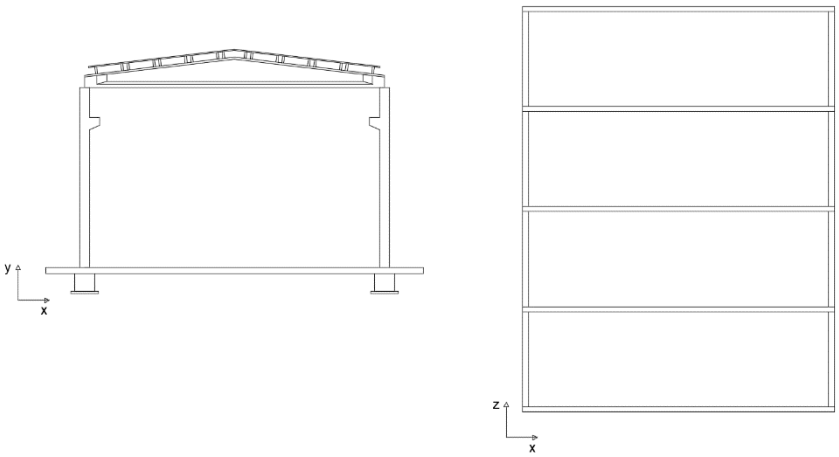

Figure 4: Front (left) and plan (right) views of the typical PRC buildings designed and modelled in the project.

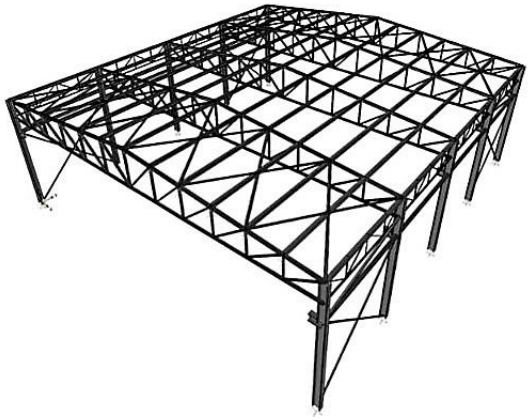

Figure 5: Three-dimensional view of the topical steel building designed herein.

2.5 BI buildings

For the case of BI, the objective was not to design the isolation system according to old codes, yet to protect the existing buildings according to the current code [6],[7]. In particular, for the existing fixed-base RC building (see Table 2), the base shear associated with the onset of plastic deformations was first identified by pushover analysis, assuming a uniform distribution of lateral forces. After that, the lowest value of the fundamental period of the base isolated building was derived entering the design spectrum with the spectral acceleration associated to the occurrence of the first plastic hinge. Next, the maximum displacement of the isolation system was evaluated using the displacement (code) spectrum at the *collapse* limit-state.

Based on the target period and required displacement capacity, suitable devices were selected from the manufacturers' catalogues. The verification of the base-isolated building was carried out through response spectrum analysis of a three-dimensional model of the structure, considering the performance requirements and compliance criteria specified in the current code. See [13] for details.

3 FAILURE CRITERIA

The failure rates were computed with respect to two performance levels, global collapse and usability-preventing damage. In general, the GC criterion is based on the deformation capacity corresponding to a certain level of strength deterioration, measured on the nonlinear static capacity curves of the structural models (Figure 6, left).[3] For all the structural models in any dynamic analysis, the occurrence of GC was checked using the maximum demand-over-capacity ratio in the two directions.

The criteria for UPD are based on a multi-criteria approach (Figure 6, right) that considers the onset of any of the following three conditions: (a) light damage in 50% of the main non-structural elements (e.g., infills); (b) at least one of the non-structural elements reached a severe damage level leading to significant interruption of use; (c) attainment of 95% of the maximum base-shear of the structure. Although these are the general criteria, several existing buildings belonging to the case studies analyzed required ad-hoc adjustments and further considerations about failure. The details on these issues are given in the companion articles for these specific typologies.

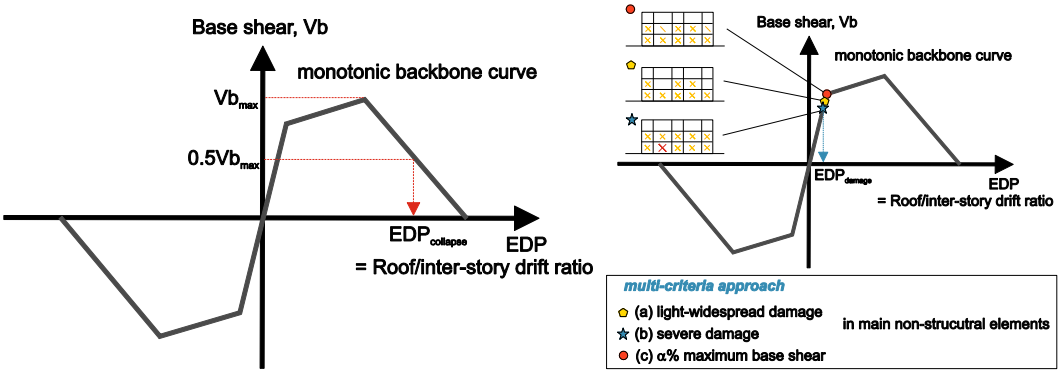

Figure 6: left – general definition for the GC e failure criterion; right – general definition of the UPD failure criterion. (Figure adapted from [3])

4 SEISMIC HAZARD AND RECORDS FOR DYNAMIC ANALYSIS

To compute the failure rates, hazard curves are required (see section 8). The ground motion intensity measures (IMs) considered are pseudo-spectral acceleration Sa at periods (T) close to the first-mode periods of the developed structural models. Table 2 reports the ground motion intensity measures the pseudo-spectral accelerations considered at the sites. The table acknowledges that the soil class for the analysis (and for the design, where applicable), was C according to the site classification of Eurocode 8 [23].

The hazard curves, expressed in terms of annual exceedance rate, $\lambda_{Sa(T)}(x)$, versus ground motion intensity, needed for the calculations, were computed as described in [3], that

[3] The GC condition for BI buildings was assumed to occur either if the superstructure fails or if the base isolation system fails.

is using the seismic zone source model of [8], with the magnitude distribution and rates described in [24], and the ground motion prediction equation of [25] (or that of [26] for the longer spectral periods not covered by [25]). Hazard calculations have been carried out via the OPENQUAKE platform [27].

Table 2: periods at which pseudo-spectral acceleration hazard has been computed at each site for record selection and failure rate computation.

Site	Soil C
MI	$T=\{0.5s,1.0s,2.0s\}$
NA	$T=\{0.25s,0.5s,1.0s,2.0s,3.0s\}$
RM	$T=\{0.15s,\ 0.5s\}$
CT	$T=\{0.5s,1.0s,2.0s\}$
AQ	$T=\{0.5s,1.0s,\ 2.0s,3.0s\}$

Hazard curves were discretized in ten IM values corresponding to the following return periods (T_R) in years: $T_R=\{10,50,100,250,500,1000,2500,5000,10000,100000\}$. No IM-values with exceedance return period longer than $T_R=100000\,yr$ were calculated, to avoid large extrapolations.

To select the ground motion records to be used as input for dynamic analysis, the CS approach has been considered, in analogy to what done in [3]. It accounts for seismic hazard disaggregation, to fit the scopes of non-linear dynamic multi-stripe analysis (MSA), which was used to assess seismic structural vulnerability.

The record selection procedure was that available at http://web.stanford.edu/~bakerjw/research/conditional_spectrum.html. The selected records were extracted mainly from the Italian accelerometric archive (http://itaca.mi.ingv.it/; [28]) and only if no records with similar spectra were available there, suitable records in the NGAwest2 (http://peer.berkeley.edu/ngawest2/) database [29] were selected instead.

The record selection delivered two-hundreds pairs of records for each IM; twenty records for each one of the ten stripes. Hence, two-hundred records have been employed in the analysis of each individual structural model. To reduce the computational demand from non-linear dynamic analysis, the selected records have been post processed to remove the parts of the signal outside $\{t_{0.05\%},t_{99.95\%}\}$ range, where $D_{99.90\%}=t_{99.95\%}-t_{0.05\%}$ is the 99.90% significant duration of the record [30], yet keeping synchronization of horizontal components.

5 STRUCTURAL ANALYSIS AND FAILURE RATES

The failure rates (λ_f) shown in the following, were evaluated via equation (1):

$$\lambda_f=\int_0^{x_{10^{-5}}} P\left[\,failure\middle|Sa(T)=x\right]\cdot\left|d\lambda_{Sa(T)}(x)\right|+10^{-5}. \qquad (1)$$

In the equation, $d\lambda_{Sa(T)}(x)$ is the derivative of the hazard curve of interests, and $P\left[\, failure \middle| Sa(T)=x \right]$ is the failure probability of the structure for which the failure rate is being evaluated; i.e., the structural fragility. The integral stops at the last IM value $\left(x_{10^{-5}}\right)$ for which hazard is computed; i.e., that with 10^{-5} annual exceedance rate. Thus, to account for this truncation 10^{-5} is added to the integral. This is an approximation that assumes structural failure, with certainty, for IMs larger than $x_{10^{-5}}$.

It has been briefly recounted in the previous section how $\lambda_{Sa(T)}$ (i.e., the seismic hazard) has been computed. For what concerns $P\left[\, failure \middle| Sa(T)=x \right]$, it has been evaluated for each structure via MSA (see [3]). In particular, each (three-dimensional) structural model has been subjected to 20 records (two horizontal pairs), ad-hoc selected (see section 4) for each of ten IM values corresponding to the return periods at which probabilistic seismic hazard was computed. The sample of 20 response values collected in this way forms a so-called *stripe*, because, in a hypothetical plot of response vs IM, they are all aligned. For each stripe, the fragility was computed via equation (2):

$$P\left[\, failure \middle| Sa(T)=x_i \right] = \left\{ 1-\Phi\left[\frac{log\left(edp_f\right)-\mu_{log(EDP)|Sa(T)=x_i}}{\sigma_{log(EDP)|Sa(T)=x_i}} \right] \right\} \left(1-\frac{N_{col,Sa(T)=x_i}}{N_{tot,Sa(T)=x_i}} \right) + \frac{N_{col,Sa(T)=x_i}}{N_{tot,Sa(T)=x_i}} \quad (2)$$

where EDP is the *engineering demand parameter*), representing a structural response measure (e.g., maximum inter-storey drift ratio) and edp_f is the structural capacity for the performance of interest. The quantities $\left\{ \mu_{log(EDP)|Sa(T)=x_i}, \sigma_{log(EDP)|Sa(T)=x_i} \right\}$ are the mean and standard deviation of the logarithms of EDP when $Sa(T)=x_i$, $i=\{1,\ldots,10\}$, while $\Phi(\bullet)$ is the cumulative Gaussian distribution function and $N_{col,Sa(T)=x_i}$ is the number of collapse cases (i.e., those reaching global instability according to the terminology in [31]). Finally, $N_{tot,Sa(T)=x_i}$ is the number of ground-motion records, here 20, with $Sa(T)=x_i$, $i=\{1,\ldots,10\}$.

Although equation (2) is the general framework, in selected cases $P\left[\, failure \middle| Sa(T)=x \right]$ has been empirically evaluated by counting the number of records for which failure has been observed, $N_{f,Sa(T)=x_i}$, as shown in equation (3).

$$P\left[\, failure \middle| Sa(T)=x_i \right] = \frac{N_{f,Sa(T)=x_i}}{N_{tot,Sa(T)=x_i}} \quad (3)$$

5.1 Preliminary results

Figure 7 provides the preliminary failure rates for the buildings analyzed in 2018. The figure contemplates both the UPD as well as the GC rates for soil C. Data are arranged per increasing design hazard of the sites according to the current code. It can be seen that the trend observed in [1][3] for current-code-conforming structures, which implied decreasing reliability for increasing design hazard, is less clear for existing buildings, likely due to the large heterogeneity of the buildings analyzed. Moreover, as expected these rates are generally larger than those of new constructions. Nevertheless, these are very preliminary and are far to be

considered consolidated yet. For example, rates for UPD and GC for BI structures, needs further deepening.[4]

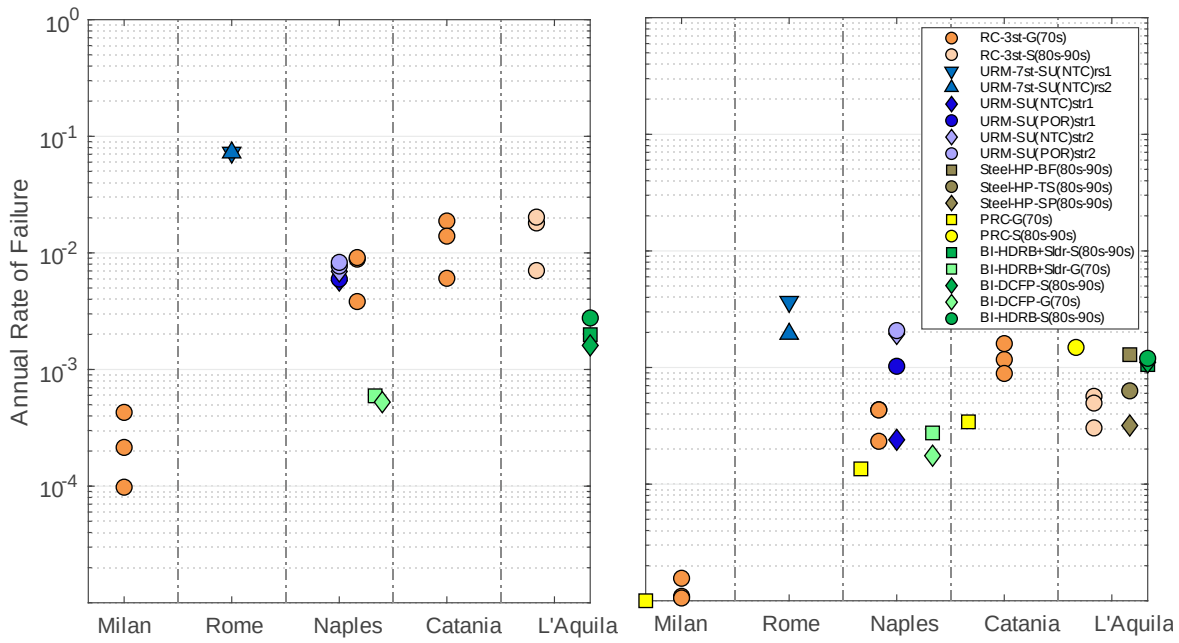

Figure 7: preliminary failure rates from the 2018 RINTC-e project for soil C; left is UPD, right is GC.

6 FINAL REMARKS

In this paper the 2019-2021 RINTC project was introduced. The project deals with the seismic reliability assessment of the existing building designed for earthquake resistance via obsolete codes or for gravity loads only. The project has the ambition to consider a wide range of Italian codes, following the evolution of construction practice in the XX century. As a preliminary work, some cases were investigated in 2018, in the framework of the RINTC-e project propaedeutic to the 2019-2021. These are mostly buildings designed according to 70s or 80s-90s codes as well as older buildings seismically upgraded according to codes from 80s-90s. Finally, base-isolated buildings are existing buildings of the mentioned type seismically upgraded according to the current code. Failure rates computed for these cases show a less clear trend with respect to what observed for current-code-conforming structures and generally higher values, as expected. Nevertheless, these results are not yet consolidated and will be likely revisited during the course of the 2019-2021 RINTC project.

7 ACKNOWLEDGEMENTS

The study was developed between 2017 and 2018 in the framework the ReLUIS-DPC and EUCENTRE-DPC projects, funded by the *Presidenza del Consiglio dei Ministri, Dipartimento della Protezione Civile* (DPC).

Abstract

The present work is devoted to estimate the resistance model uncertainty within plane stress non-linear finite element analyses (NLFEAs) of reinforced concrete structures subjected to cyclic loads. Specifically, various shear walls experimentally tested are considered for the investigation. The comparison between the plane stress NLFE structural model results and the experimental outcomes is carried out considering the possible modelling hypotheses available to describe the mechanical behaviour of reinforced concrete members subjected to cyclic loads. Several NLFE structural models are defined for each experimental test in order to investigate the resistance model uncertainty.

Keywords: model uncertainties, NLFEAs, reinforced concrete structures, modeling hypotheses, cyclic loads.

1 INTRODUCTION

In the last decades, non-linear finite element analyses (NLFEAs) have increasingly become the most common and practical instruments able to model the actual mechanical behaviour of structural systems, such as reinforced concrete elements, in any loading condition (i.e., service limit state (SLS) and ultimate limit state (ULS)). In this context, although several guidelines for NLFEAs have been recommended by [1]-[4] in order to assure an accurate calibration and definition of the structural FE model, the results from such complex modelling need to be properly processed in order to satisfy safety and reliability requirements for engineering purposes [5]-[6]. To this aim, Bayesian finite elements have been proposed by [7] to take into account the model uncertainties for structural analysis. Contextually, different safety formats for NLFEAs have been proposed and commented in literature by several authors [8]-[13] and international codes [14]-[15] as well as their applications have been discussed by [16]-[18]. In these safety formats, uncertainties regarding the material (i.e., aleatory uncertainties) and the definition of the structural model (i.e., epistemic uncertainties) should be properly addressed in order to derive reliability-consistent design values of the global structural resistances. With regard to the material uncertainty, the corresponding randomness is usually well known and assessed, whereas the model uncertainty (i.e., uncertainty mainly related to the definition of the resistance model) associated with NLFEAs is not typically simple to be evaluated due to the different modelling hypotheses for the definition of a non-linear FE structural model. In fact, the prediction of the actual structural response through NLFEAs is characterized by a certain level of uncertainty because any numerical model aims to describe the essential characteristics of the overall behaviour neglecting other aspects.

All the research studies evidence the need to assess the model uncertainties by means of a comparison between simulations and experimental outcomes with the consequence that an in-depth characterization of the model uncertainties for NLFEAs of reinforced concrete structures is necessary to incorporate their effects on the global structural resistance assessment within the safety formats for cyclic loads. However, the assessment of the model uncertainties for calibration of a partial safety factor should also considers the different modelling hypotheses to run NLFEAs due to the different assumptions regarding the parameters that govern the equilibrium, kinematic compatibility and constitutive equations in dynamic conditions. In fact, different choices related to the described above parameters may lead to discordant results (i.e., epistemic uncertainty [19]).

With this aim, this work compares different experimental tests known from the literature [20]-[22], concerning different walls having different behaviours and failure modes in terms of global structural resistance with the numerical outcomes achieved by means of appropriate two-dimensional non-linear FE structural models (i.e., plane stress configuration). Several non-linear FE structural models are defined for each experimental test in order to investigate the influence of the model uncertainties on 2D NLFEAs of reinforced concrete members. Precisely, the assessment of the resistance modelling uncertainties in 2D NLFEAs, that belong to the group of the epistemic uncertainties, is herein based on the definition of eighteen (18) plausible structural models using different types of software and different mechanical behaviours for the reinforced concrete elements (i.e., modelling hypotheses [19]) in dynamic conditions.

2 RESISTANCE MODEL UNCERTAINTIES FOR NLFEAS

In general, the uncertainties in structural engineering can be classified in two families: aleatory and epistemic [19]. The aleatory uncertainties concern the intrinsic randomness of the variables that governs a specific structural problem, whereas the epistemic uncertainties are

mainly related to the lack of knowledge in the definition of the structural model [19],[23]-[25] and sometimes represented also by auxiliary non-physical variables/choices [19]. The safety assessment of a structural system by means of NLFEAs should account for explicitly both these sources of uncertainty.

Within the semi-probabilistic limit state method [26]-[28], the safety assessment of a structural system requires a reliable definition and characterization of the structural resistances, which increasingly often derive from NLFEAs. For this purpose, different safety formats have been proposed in the literature [8]-[15]. In particular, EN 1992 [14] defines a safety format based on the definition of the partial safety factors descending from representative values and design values of the material strengths (i.e., concrete compressive strength and reinforcement steel yielding strength). While, *fib* Model Code 2010 [15] provides three different methodologies for the assessment of the structural reliability: the probabilistic method, the global resistance method and the partial factor method. These different safety formats (with the exception for the partial factor method) allow the estimation of the design structural resistance R_d, that represents the global structural resistance of a structure with its behaviour and failure mode, as expressed by Eq.(1):

$$R_d = \frac{R_{rep}}{\gamma_R \gamma_{Rd}} \tag{1}$$

where R_{rep} denotes the value representative of the global structural resistance estimated by means of NLFEAs and in compliance with the selected safety format, γ_R is the partial safety factor accounting for the randomness of material properties (i.e., aleatory uncertainties) and γ_{Rd} represents the partial safety factor related to the modelling uncertainties (i.e., epistemic uncertainties). Therefore, the aleatory uncertainties are separated from the epistemic uncertainties within *fib* Model Code 2010 safety formats for NLFEAs [8],[15]. The procedure for the estimation of the partial factor γ_R is suggested by the corresponding safety format. Conversely, the value of the partial safety factor for the resistance model uncertainties γ_{Rd} remains an object of investigation. More recently, *fib* Model Code 2010 [15] has suggested to assume different values of γ_{Rd} depending on the level of validation of the structural model. The γ_{Rd} factor equal to 1 may be adopted for models with no epistemic uncertainties (i.e., presence of evidences of model validation in the actual design conditions [15]).

However, when NLFEAs have to be performed for dynamic simulations on structures having more complex geometry (that may differ from the simple case of the beam in the failure mode), the epistemic uncertainties related to the definition of the resistance model may be larger than expected. Therefore, an in-depth characterization of the partial safety factor γ_{Rd} needs to be addressed.

3 EVALUATION OF THE RESISTANCE MODEL UNCERTAINTIES

This section describes the methodology adopted in the present work for the assessment of the partial safety factor related to the resistance model uncertainties in the definition of 2D NLFEAs under cyclic loads. As discussed by [10],[29]-[30], the following aspects have to be considered in order to identify the resistance model uncertainties for NLFEAs:

- the database of the experimental data should contain, if possible, all the parameters necessary for the reproduction of the tests and for the definition of non-linear FE structural models; note that some information, related to the material properties, is so often missing and, in the practice, usually is derived from the available data under appropriate assumptions according to the scientific literature with an increase of the model uncertainty;

- the experimental results should be related to different typologies of structures with different failure modes;
- a probabilistic analysis of the observed model uncertainties needs to be carried out in order to define the most likely probabilistic distribution with the corresponding parameters.

In compliance with [8],[15], the resistance model uncertainty, separated from the aleatory one (Eq. (1)) and denoted as ϑ_i, can be expressed by a multiplicative law. This latter relates the i-th actual global resistance (response) estimated from an experimental test $R_i(X,Y)$ to the i-th global resistance (or response) estimated by a NLFEA $R_{NLFEA,i}(X)$ and, may be expressed as follows:

$$R_i(X,Y) \approx \vartheta_i R_{\mathrm{NLFEA},i}(X) \tag{2}$$

where X is a vector of basic variables included into the resistance model, Y is a vector of variables that may affect the resisting mechanism but are neglected in the model. Note that the unknown effects of Y variables, if present, are indirectly incorporated and covered by ϑ_i. As widely explained in the next section, different modelling hypotheses are possible to model a specific reinforced concrete structure by means of NLFEAs. A comprehensive calibration of the resistance model uncertainties for 2D NLFEAs requires to account for the different modelling hypotheses which may be selected by engineers for seismic analyses.

4 NON-LINEAR SIMULATIONS: PARAMETRIC ANALYSIS RESULTS

In this section, different experimental tests corresponding to different structural systems are considered and reproduced by means of NLFEAs. These simulations are performed considering a set of modelling hypotheses in order to estimate the resistance model uncertainties with the aim to calibrate the corresponding values of the partial safety factor within the safety formats proposed by [15]. Note that all the numerical simulations have been performed by the authors after a sensitivity/calibration analysis and this is an important requirement for the proposal of this study because leads to a reduction of the epistemic uncertainties, in other words, the designers, involved in NLFEAs for the structural verification process, should be confident with this approach. As known, the structural analysis is based on the fundamental principles of mechanics such as equilibrium, of displacement compatibility and of constitutive laws [31]. In the field of NLFEAs, these principles are attended by iterative calculation procedures which inevitably lead to a certain degree of error in the final solution. Moreover, the definition of a specific structural model [31] requires different assumptions about the parameters describing the equilibrium, kinematic compatibility, constitutive equations leading to different numerical outcomes, which may be more or less realistic. Therefore, the multiplicity of choices (i.e., epistemic uncertainties) which can be assumed during the definition of a non-linear FE model leads to have a certain degree of uncertainty in the final solution. It follows that, consistently with the framework of the safety formats for NLFEAs [14]-[15], the estimation of the partial safety factor γ_{Rd} for the resistance modelling uncertainties is necessary. Considering different experimental tests known from the literature [20]-[22], Subsection 4.1 describes the different modelling hypotheses that any engineer may assume during the computational phase. The numerical results in terms of global structural resistance from the NLFEAs are described in Subsection 4.2 and also compared to the experimental outcomes.

4.1 Different modelling hypotheses within NLFEAs

A multitude of modelling hypotheses is available to carry out 2D (plane stress) NLFEAs of reinforced concrete structures. In this work, two software [32]-[33], identified anonymously by Software A, and Software B in order to avoid advertising for the different codes, are adopted in order to reproduce the outcomes of a set of experimental tests. For each software, several choices about the hypotheses and mechanical parameters related to equilibrium, compatibility and constitutive laws can be performed. Specifically, in each software four-node quadrilateral iso-parametric plane stress finite elements, based on linear polynomial interpolation and 2x2 Gauss point's integration scheme, are used for the numerical simulations as well as the FE meshes are properly defined after a calibration procedure. The non-linear system of equations is solved by means of the standard Newton-Raphson iterative procedure based on the hypothesis of linear approximation [1]. Moreover, for each software the following main characteristics for the FE models are also assumed:

- non-linear behaviour of concrete in compression including softening with a reduction of the compression strength and shear stiffness (shear retention factor variable from a minimum value of 0.1 to a maximum value of 0.3) after cracking [34]. In detail, the mono-axial constitutive model for concrete proposed by EN 1992-1-1 [14], the constitutive model described by Model Code 1990 [15] and the constitutive model described by Thorenfeldt et al. [35] have been selected in order to fit as much as possible the experimental results with each software [32]-[33];
- smeared cracking with fixed crack direction model [36]-[38];
- tri-linear σ–ε curve for the reinforcement steel [34];
- discrete and smeared models of the reinforcement, assuming a perfect bond between the reinforcement and the surrounding concrete [34];
- Young's modulus and tensile concrete strength, as also explained previously, are the material properties derived as a function of the experimental compressive strength, according to [27].

The summary of the main hypotheses assumed in the definition of the simulations for 2D NLFEAs, adopting Software A and B [32]-[33], is listed in Table 1.

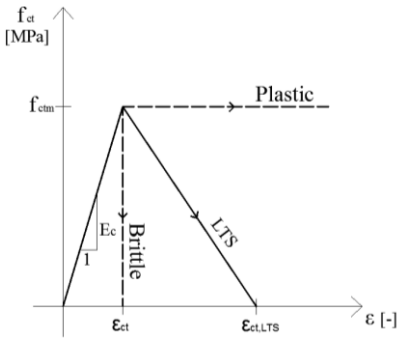

Figure 1: Different constitutive laws for concrete tensile behaviour.

In addition to the described above differences inherent to the use of two software, another important differentiation in the definition of non-linear FE models has been considered with respect to the concrete tensile mechanical behavior and the shear stiffness in cracked concrete. As known, concrete is considered as quasi-brittle material in compression and purely brittle in tension. However, the local interaction between reinforcing bars and concrete between cracks gives rise to the "tension stiffening effect" [38]. In numerical simulations, this effect may be taken into account through a modification of the constitutive tensile behavior of the concrete matrix. In general, this modification refers to the definition of a tension softening law in the

post peak concrete tensile behavior. In the present paper, three different constitutive laws for concrete in tension are considered in order to cover different hypotheses accounting for the tension stiffening effect [34]: elastic-brittle, elastic-plastic and a linear tension softening as shown in Figure 1. The first two constitutive laws are conceived as upper and lower limit (non-physical) approaches. While, the constitutive law having a linear tension softening for the concrete tensile behavior represents the physical modelling hypothesis and has been calibrated by means of an iterative specific process in each software with the aim to best fit each experimental result. In this iterative process, the ultimate deformation in tensile of concrete (i.e., $\varepsilon_{ct,LTS}$ in Figure 1) is assumed as a function of the corresponding elastic one (i.e., ε_{ct} in Figure 1) varying in a range from $2\varepsilon_{ct}$ to $10\varepsilon_{ct}$ without highlighting any dependence on the software and on the compressive strength.

	Software A	Software B
Equilibrium	*- Standard Newton-Raphson based on the hypothesis of linear approximation [1]* *- Convergence criteria based on strain energy* *- Load step sizes defined in compliance with the experimental procedure*	
Compatibility	*Finite Elements* - Isoparametric plane stress 4 nodes (2x2 Gauss points integration scheme with linear interpolation) - Discrete reinforcements - Element size defined by means of an iterative process of numerical accuracy	*Finite Elements* - Isoparametric plane stress 4 nodes (2x2 Gauss points integration scheme with linear interpolation) - Smeared reinforcements/discrete reinforcements - Element size defined following an iterative process of numerical accuracy
Constitutive laws	*CONCRETE* - Fixed crack model, smeared cracking, constant shear retention factor equal to: 1) 0.1 2) Variable 3) 0.3 - Mono-dimensional model extended to biaxial stress state - Compression: Non-linear with post peak linear softening branch - Tension (differentiating between 3 modelling hypotheses): 1) Elastic - Brittle (BRITTLE) 2) Elastic with post peak linear tension softening (LTS) 3) Elastic - perfectly plastic (PLASTIC) *REINFORCEMENTS STEEL* - Tri-linear elastic – plastic	

Table 1: Summary of the basic hypotheses assumed in the definition of non-linear FE numerical models.

Once the tensile behavior has been established, for each of the three tensile behaviours the same investigation procedure was used to calibrate the shear retention factor (β) with a value between 0.1 and 0.3. Specifically, for each software and experimental test, three different models for the different tensile behaviour are defined and for each one 0.1 and 0.3 are imposed as limits for β, and, in addition, an iterative process is used to define the most appropriate value of β to best fit the experimental tests.

Altogether, 18 different structural models (i.e., modelling hypotheses which belong to the group of the epistemic uncertainties because a specific choice can lead to a reduction of the

uncertainty [19]) can be defined combining the three different concrete tensile behaviours with the three different values of shear retention factor and the two software codes. A scheme of the modelling hypotheses adopted in this study is summarized in Figure 2. By this way, the resistance model uncertainties can be identified and computed for the different experimental tests of the 9 specimens as described in the following subsection, leading to a total number of NLFEAs equal to 162, as shown in Fig. 2.

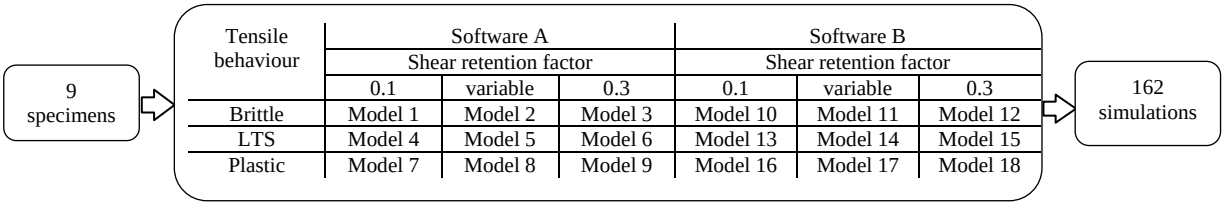

Figure 2: Distinction between the 9 structural models (Mo.1-9 for each software) for the resistance model uncertainty investigation and summary of the benchmark NLFEAs.

4.2 NLFEAs of different experimental tests: results and comparison

In this section, the experimental results presented in the scientific literature [20]-[22] and related to 9 different r.c. walls are considered and assumed as benchmark test set. All these experimental tests, have been performed through a cyclic loading process up to failure as discussed by [20]-[22]. The specimens have been realized in laboratory and supported by statically determined configurations. The experimental results, in terms of load vs displacement, are compared to the outcomes from the different 162 2D NLFEAs carried out taking into account the resistance model uncertainties as previously discussed. It is worthy to specify that some experimental systematic errors (e.g., modifications in the geometry or in the constraints) can affect the experimental results and represent another source of uncertainties, as commented below for the comparison with some experimental results [29],[39].

In the following, the experimental and numerical tests are described in details and illustrated in Figures 3-11.

The experimental tests described by Pilakoutas and Elnashai [20], analyzed six reinforced concrete walls designed in pairs so as to have the same percentage of bending reinforcement and differing in the percentage of shear reinforcement. For this work, only 3 of the all walls have been taken into consideration denoted respectively as SW4, SW6, SW8, with the following geometrical properties: 1.20 m high, 0.6 m wide, 0.06 m thick and stiffened by a 0.2 m thick and 0.25 m high lower beam, and by a 0.2 m thick and 0.15 m high upper beam where the load is applied. All walls are subjected to the same load history. The test was carried out in displacement control from 2 mm up to failure, performing two complete cycles with a 2 mm increment. The concrete compressive strength ranges from 36.9 to 45.8 MPa in the different tests, while the flexural reinforcement remains constant in the web and the shear reinforcement and the vertical reinforcement vary in the boundary elements. The numerical results in terms of global structural resistance of the simulations are listed in Table 2 and 3. The results from NLFEAs, in Figures 3-5 (a)-(f), are plotted for the same shear hypothesis, for the different tensile behaviors and for the two software codes. The lowest results in terms of maximum load are achieved when the brittle constitutive law is adopted for concrete tensile behavior, while the plastic constitutive law always leads to an overestimation of the maximum load and of stiffness. It can also be noted that the best results are obtained for a shear retention factor of 0.1 or in any case close to this value. In general, all the simulations overestimate the maximum load and then the structural resistance, but underestimate the ductility because a lot of simulations failure before then experimental tests. Figure 3-5 (a-c) and (d-f) show the in-

trinsic dependence of the results on the software choice (software A and B, respectively), in which the simulations (a-c) fail the simulation before the end of the load history, while the simulations (d-f) reach the end of the analysis but they overestimate the resistance, especially in the case of the models 12, 15, 18. The failure mode occurs with the progressive yielding of the tensile reinforcements and concrete crushing in the boundary element compressed on the opposite side. This failure is in compliance with the experimental results. When the ultimate deformation for the concrete in compression is reached, all the simulations have been stopped due to the convergence loss of the numerical procedure.

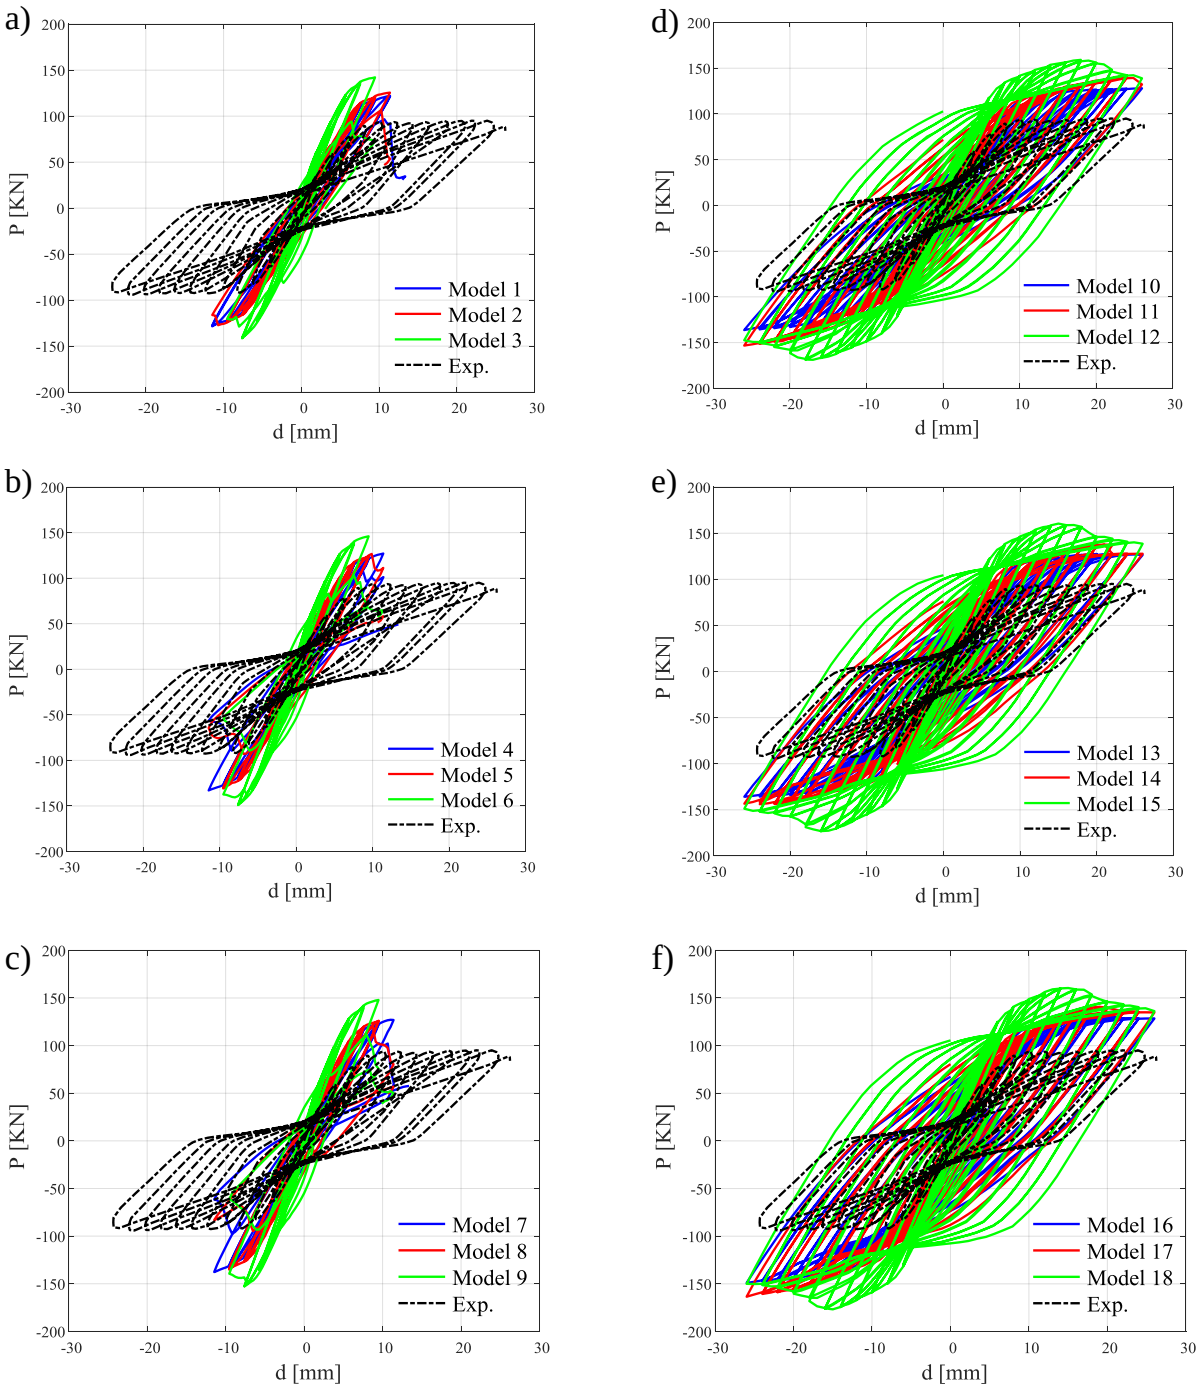

Figure 5: Load vs displacement diagrams from experimental tests SW8 of Pilakoutas [20] and NLFEA results; (a-c) Software A, (d-f) Software B.

The experimental results of Lefas and Kotsovos [21] are related to four identical walls of dimensions 1300x650x65mm, that are constrained inferiorly by a beam of section 200x300mm which simulates a rigid foundation. At the top there is a rigid beam to uniformly transmit the imposed displacement on the top of the wall. The flexural reinforcement is made up of ϕ8/100mm in the web, while the distance is reduced to 70mm in the boundary elements. Similarly, the shear reinforcement is composed of ϕ6.25/260mm over the entire width of the wall and additional stirrups in the boundary elements with ϕ4/130mm. The imposed displacement tests present a load history composed of four or five cycles with displacements of a few millimeters and then an increase of monotonic displacement up to failure. The concrete compressive strength varies in the range 35-53 MPa in the different tests. The numerical results in terms of global structural resistance of the simulations are listed in Tables 4-5. Figures 6-8 (a)-(f) show that models (3, 6, 9, 12, 15, 18) related to elastic-plastic constitutive law for the concrete tensile behavior, always lead to an overestimation of the resistance and stiffness, while models elastic-brittle and with a linear tension softening in tension have more or less the same behavior, with a stiffness similar to the real one in the cyclic phase, but, in general, an underestimation of the resistance. It can be also noted that as the shear retention factor increases, the dissipated energy also increases. The failure mode occurs with the progressive yielding of the tensile flexural reinforcements on the side where the displacement is imposed and concrete crushing at the bottom of the boundary element in the other side. Some simulations don't reach the ultimate experimental displacement but fail upon reaching the maximum load or for a slightly greater displacement than that achieved in the cyclic phase.

The experimental results discussed by Zhang and Wang [22], focused on four reinforced concrete walls, denoted as SW7, SW8 and SW9 being 1.75 m high, 0.7 m wide, 0.1 m thick. The structural member is fully restrained at the base with a 0.5 m high and 0.4 m wide beam and loaded by an axial force at the top, that is considered evenly distributed at 25 cm from the top surface of the wall, while the horizontal imposed displacement is applied at 1.5 m from the base of the wall. Hence, the effective height of the wall is 1.5 m. The walls SW7 and SW8 have the same reinforcement that consist of ϕ8/150mm as flexural reinforcement in the web,

while for shear ϕ8/100mm over the total width of the wall and hoops ϕ6/50mm in the boundary elements. The difference is in flexural reinforcement in the boundary elements of the wall which consists respectively of 4ϕ14 and 4ϕ12 on each side of the wall. The SW9 is more reinforced, and presents 4ϕ20 on each boundary element, and a greater amount of shear reinforcement than the previous ones with ϕ8/75mm+ ϕ6/150mm over the total width of the wall and hoops ϕ6/75mm in the boundary elements. The walls also differ in the axial load: SW7 and SW9 have an axial-load ratio of 0.24 while SW8 has a greater axial-load ratio equal to 0.35. The loading histories are quite similar and follow the same procedure: at the first time the axial load is applied in small incremental steps, after that the wall is subjected to the cyclic phase with horizontal load divided in two parts. The first consists in 10 cycles until the yielding of flexural reinforcement; in the second phase at each cycle it is proceeded with a displacement increase equal to half that recorded for yielding. The numerical results in terms of global structural resistance of the simulations are listed in Table 6-7. The NLFEA results, plotted in Figure 9-11 (a)-(f), show that models related to elastic-plastic constitutive law for the concrete tensile behavior, always lead to an overestimation of the stiffness. Models elastic-brittle in tension do not always represent the lower bound. Figure 9-11 (a-c) and (d-f) show the dependence of the results on the software choice (software A and B, respectively), in which (a-c) reflect the real behavior for small displacement and reach the experimental maximum load, while for bigger displacement there is a progressive reduction of stiffness and resistance and in many cases the simulation fails (especially for models with elastic-plastic tensile behavior). For Software B instead, in general, all the models overestimate the structural resistance, but reach the end of the loading history by following the real behavior quite well.

The results deriving from the abovementioned 162 non-linear FE simulations are useful to assess the resistance model uncertainties in 2D NLFEAs of reinforced concrete structures characterised by different failure modes under cyclic loads. These results have also demonstrated the several difficulties, which commonly occur considering different types of software and constitutive laws, in reproducing the actual failure behaviour of structural members.

5 CONCLUSIONS

This work evaluates the values of the model uncertainties (i.e., epistemic uncertainties) regarding the global structural resistance for 2D non-linear finite element method analyses of reinforced concrete systems under cyclic loads. Various experimental tests concerning different walls subject of cyclic shear action, have been numerically simulated by means of appropriate 162 NLFEAs considering two different software codes, three different constitutive laws for the behaviour of concrete in tension and three different shear behaviour after cracking. From the comparison with the experimental outcomes, the FE results have demonstrated the several difficulties, which commonly occur employing different types of software and constitutive laws, in reproducing the actual failure behaviour and the actual failure load of the all structural members considered. In general, it can be observed that a tensile behavior of the concrete perfectly plastic always gives a greater overestimation of the structural resistance, and that the variation of the shear retention factor varies the amplitude of the cycle, and therefore the dissipated energy. However, in terms of resistance, a shear retention factor close to 0.1 is the one that best fits the experimental test.

ACNOWLEDGEMENTS

Abstract

The knowledge of in-situ material properties is the first step in the assessment process of existing structures and, where needed, in the design of the consequent strengthening interventions. In order to achieve this goal, destructive (DT; e.g., cores) and non-destructive (NDT; e.g., ultrasonic, rebound) test methods are generally adopted, either alone or combined. Although many literature papers and guidelines propose to minimize the number of cores in the estimation of the concrete strength in reinforced concrete structures, the European and Italian codes prescribe that the estimation of in-situ strength has to be mainly based on cores drilled from the structure (DT). In this framework, the paper reports results of an experimental program aimed at evaluating the effects of core tests on RC columns, as well as the effectiveness of the structural restoration of drilling holes. Specifically, three sets of column specimens have been considered: (i) drilled columns, (ii) drilled and subsequently restored columns, and (iii) reference not drilled (as-built) columns. Compression tests have been carried out on each column and the results have been compared with the prediction based on codes or other literature approaches. This helped to recognize the main phenomena affecting the column members behavior under axial loads.
At the same time, the authors calibrated detailed finite element models based on the experimental results of the tests carried out on column specimens. An advanced Fem tool was used to set-up 3D models. Numerical simulations aimed at better understanding the failure mechanism, especially in the presence of the hole related to the core extraction. The role of longitudinal and transverse reinforcement has been evaluated, highlighting that concrete crushing in the areas around the hole causes the early buckling of rebars, leading to premature failure of drilled column specimens.

Keywords: Destructive tests, concrete strength, core drilling, finite element model, nonlinear numerical simulation.

1 INTRODUCTION

The investigation of structural characteristics (geometry, structural details, materials quality, etc.) is a crucial step in the assessment of existing reinforced concrete (RC) structures [1, 2] and, where needed, in the design of consequent strengthening interventions [3]. Specifically, the knowledge of in-situ material properties is the first step in the assessment process of existing structures. In order to achieve this goal, destructive (DT; e.g., cores) and non-destructive (NDT; e.g., ultrasonic, rebound) test methods are generally adopted, either alone or combined. Although many literature papers and guidelines propose to minimize the number of cores in the estimation of the concrete strength in reinforced concrete structures, the European and Italian codes prescribe that the estimation of in-situ strength has to be mainly based on cores drilled from the structure (destructive test, DT). Non-destructive tests (NDTs) can only supplement coring, thus permitting a more economical and representative determination of concrete properties throughout the whole structure under examination. In this framework, the paper reports results of an experimental program aimed at evaluating the effects of core tests on RC columns, as well as the effectiveness of the structural restoration of drilling holes. Twenty RC column specimens (dimension 30cm x 30cm x 80cm) have been purposely built and tested by both non-destructive and destructive tests. Specifically, after the preliminary campaign of ultrasonic tests performed on all structural members, three sets of column specimens have been considered: (i) drilled columns (3 specimens), (ii) drilled and subsequently restored columns (4 specimens), and (iii) reference not drilled (as-built) columns (3 specimens). Compression tests have been carried out on extracted cores and, finally, on each column.

After the experimental campaign was concluded, the authors calibrated detailed finite element models based on the experimental results of the tests carried out on specimens. A software package able to fully account for the main nonlinear properties of concrete like, for instance, cracking and crushing, as well as the reduction of shear and compressive strength after cracking, has been used in setting up the finite element models made up of 3D tetrahedral elements [4]. The numerical models have been used to carefully evaluate the failure mode, especially for drilled specimens. This latter, indeed, are characterized by failure mechanisms different from as-built and restored specimens that causes their premature failure.

2 EXPERIMENTAL PROGRAM

In the framework of the experimental program carried out at the Laboratory of Structures of the University of Basilicata, totally 10 columns (out of 20 specimens available) have been subjected to compression test until failure. The program was intended to explore the effects of core drilling in RC members and the effectiveness of the holes' restoration. This latter, in comparison to the capacity of as-built specimens, not subjected to drilling nor restoration. For this reason, the specimens' range comprised as-built, drilled and drilled-restored columns, according to table 1. Restoration grout is an anti-shrinkage thixotropic mortar having compressive strength after one day equal to 30 MPa, and 50 MPa after 28 days.

Columns are 80 cm high with a cross-section of 30x30 cm with different longitudinal reinforcement. They were extracted from other specimens, namely full-scale beam-column joints tested in the same laboratory [7] during a previous experimental campaign. As can be seen in table 1, specimens are named "NS" or "S", depending on the beam-column joint they are extracted from, where S specimens are extracted from seismically designed joints and are provided of 8 mm diameter hoops (spaced 20 cm) and six 14mm diameter longitudinal bars. The only difference for NS specimens is that the number of longitudinal rebars is four instead of six.

This has no influence when computing confining effect according to confining models reported in the following, since the additional bars of S specimens are not restrained. Specimens show typical defects of real constructions, such as the variability of concrete cover thickness due to movements of the reinforcement during the casting operations.

Type	Column ID	f_c	Mean concrete cover
		MPa	mm
As-built	NS4	-	35.7
	NS7	-	37.5
	S4	-	45.0
Drilled	NS1	39.56	36.6
	S2	34.60	35.0
	S9	39.80	40.3
Drilled-restored	NS6	39.06	39.1
	S6	34.64	40.3
	S11	38.85	40.0
	S12	37.92	44.4

Table 1: List of 10 columns under investigation with concrete strength of extracted cores f_c, and detected concrete cover thickness.

In fact, table 1 reports also the concrete cover measured by means of the pacometer survey before testing. Only for drilled and drilled-restored columns, a concrete cylinder strength is shown. These values derive from the compression tests carried out on the extracted cores corrected through the method reported in [8]. This method allows taking into account drilling damage, shape factor of the core and possible presence of reinforcement inside the core specimen. Mean value of concrete strength reported in table 1 is f_{med}=37.88 MPa while the standard deviation is σ=2.09 MPa. Being the low value of the coefficient of variation CV=0.055, the mean value can be properly assumed as the concrete strength of as-built specimens.

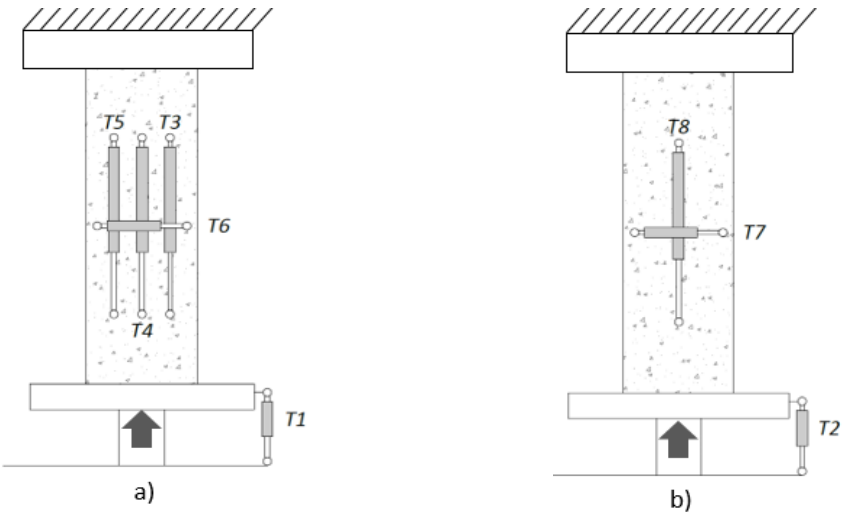

Figure 1: Loading schema and main instrumentation: a) on the front face and b) on the rear face.

The compression test machine applies the load moving his bottom plate and contrasting the top face of the specimen. The machine capacity is 3000 kN and the testing procedure is load controlled by applying increments of 30 kN/s until the peak load is found. When the load decreasing (after the peak is achieved) reaches 20% of the peak load, the machine unloads the specimen to start a new loading cycle. Figure 1 describes the loading scheme along with the instrumentation which consists of four Linear Variable Displacement Transducers (LVDT) placed on the front face of the specimens, one LVDT to measure the displacement of the bottom plate of the testing machine and additional 3 LVDT on the rear face. Out of these, two are placed on the concrete surface and one to measure the plate displacement on its opposite corner. Sometimes, an additional horizontal LVDT has been placed on the front face of the specimen like for example in fig. 2a). As examples, figure 2 shows the three types of tested columns placed on the Universal testing machine used throughout the experimental campaign. The front face is that where the core, if any, is drilled and possibly restored.

a) b) c)

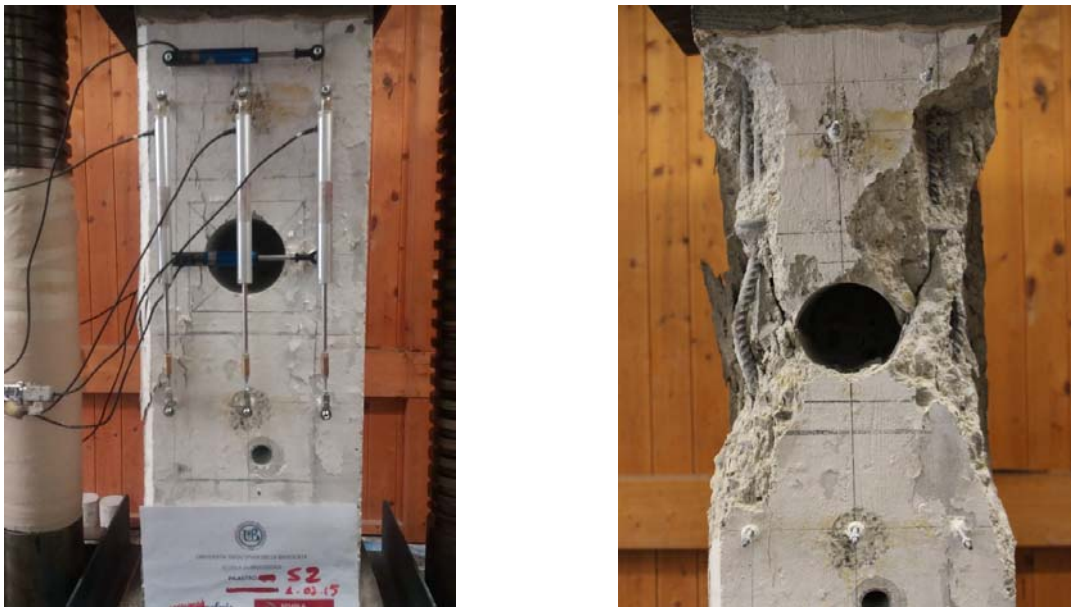
Figure 2: a) as-built b) drilled and c) drilled-restored specimens before testing.

3 TEST RESULTS AND DISCUSSION

Different collapse mechanisms have been observed during the compression tests carried out on the three typologies of columns. Similar mechanisms have been found in as-built and drilled-restored in which a progressive deterioration of concrete cover is observed generally before reaching the peak load. The ultimate condition is, however, represented by the rebars' buckling which is poorly restrained due to the low amount of hoops. The drilled columns, as could be expected, are characterized by quite different behaviour especially in the first phases of compression tests. The first damage appears on the side of the hole in the front face, usually where the rebar is nearest to the hole. Figure 3 shows two stages of the compression test on S2 specimen. The first vertical crack appears on the left side of the hole (figure 3a) when the load is approaching the peak. In the following load cycles damage further concentrates in that region causing the buckling of the left bar (figure 3b). Uneven damage distribution causes eccentricity between load and resisting cross-section, which is an additional source of damage.

Results in terms of ultimate load measured on tested specimens are displayed in figure 4. The experimental ultimate load is averagely equal to 2293 kN for as-built specimens, 2260 kN for restored specimens and 1981 kN for drilled ones, respectively. So, drilled columns show a mean capacity reduction compared to as-built columns equal to about 14%. Restored columns show a reduction of only 1.4%, meaning that current procedures for restoring interventions

are effective. This conclusion has been drawn neglecting differences in terms of longitudinal reinforcement which can be considered small.



a) b)

Figure 3: S2 column: a) before peak load and b) at the end of the test.

Along with experimental results, also the analytical predictions of ultimate load for each column is reported. It is related to the gross concrete area times the compressive strength of each specimen added to the reinforcement contribution, as in expression (1):

$$F_{ug} = A_c \cdot f_c + A_s \cdot f_{ys} \tag{1}$$

where: A_c is the gross concrete area, A_s is the total steel area, f_{ys} is the steel yielding strength. For drilled specimens, A_c is obtained subtracting the horizontal projection of the hole which has 104 mm diameter and 220 mm depth.

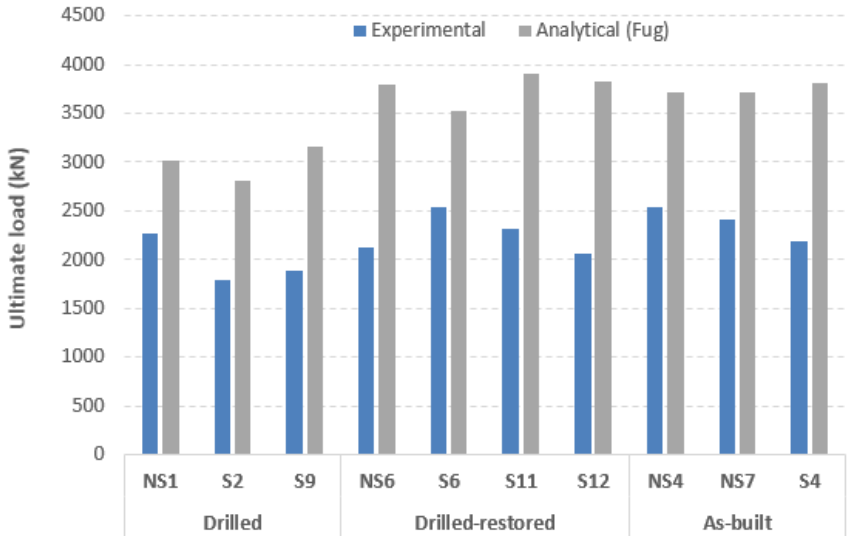


Figure 4: Comparison between experimental and analytical ultimate load values (gross section).

As can be seen, the analytical prediction of the ultimate load F_{ug} provides far higher values than the experimental ones. The observed scatter between experimental and analytical values is 52%, 67% and 58% for drilled, drilled-restored and as-built specimens, respectively. This difference strongly suggests that a much smaller value of the effective resisting cross section needs to be considered. This is also suggested by observing that in all tests concrete cover was spalled before reaching the peak load.

As a result, the effective section is assumed equal to the area confined by the steel cage, i.e. the gross section minus the concrete cover area (dashed area in figure 5). Moreover, in order to comply with international standards and codes for the design of concrete structures, the role of confining effect on concrete strength has been considered.

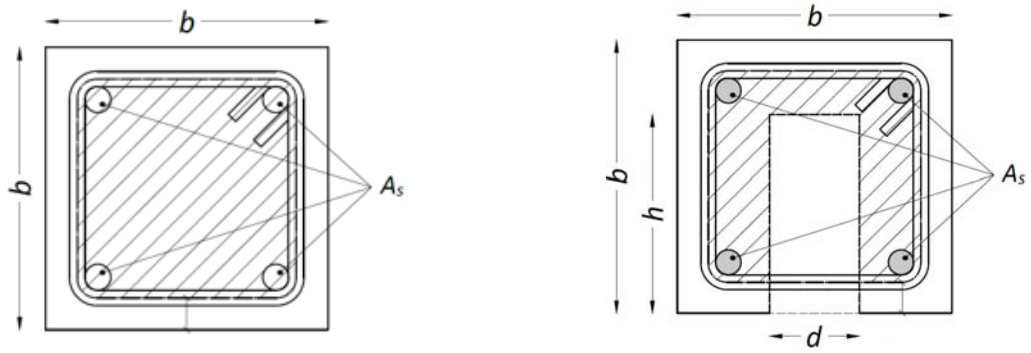

Figure 5: Effective cross section of a) as-built and drilled-restored and b) drilled specimens.

Some confinement models available in the literature [9,10] as well as the model reported in the Italian seismic code [1] have been considered. In the following, reference only to the model reported in [9] is made, because it provided the best matching with experimental results, while, for the sake of brevity, results obtained with the application of the other models are not discussed in the paper. By applying the confinement model in [9], a 5% increment of concrete strength is averagely obtained. Taking into account this concrete strength increase and the modified effective section displayed in figure 5, updated analytical values are computed and the comparison with the related experimental values is reported in figure 6.

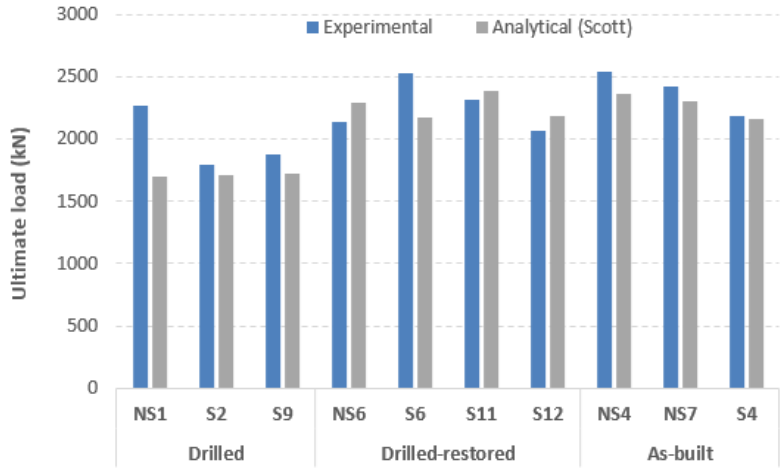

Figure 6: Comparison between experimental and analytical ultimate load values (confining model [9]).

As can be seen, the difference exp-num values remarkably decreases being averagely equal to 13%, 11% and 4% for drilled, drilled-restored and as-built specimens, respectively. Larger difference for drilled and drilled-restored specimens is somehow expected, due to the additional influence of the presence of the hole or the restoration unit on the collapse mechanism. Further, it is worth noting that, analytical results are always on the safe side for both as-built and drilled specimens, while, for drilled-restored specimens, they are generally higher thus unconservative.

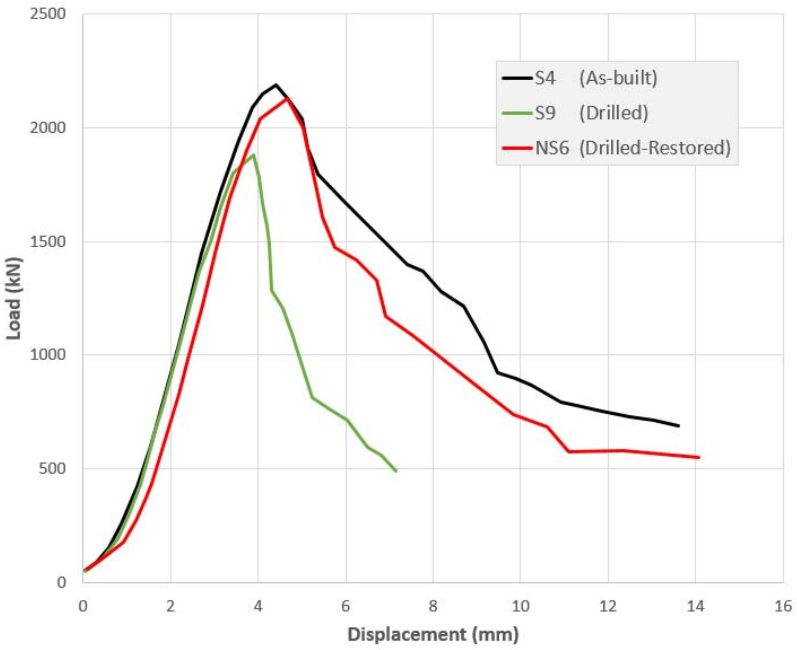

Figure 7: Envelope of skeleton curves of NS6, S4 and S9 specimens.

Although it seems inappropriate speaking of ductility for specimens whose failure is characterized by fragile mechanisms (concrete crushing and rebars' buckling), some differences have been found among the columns' typologies. In order to highlight this issue, the skeleton curves of the load-displacement envelopes have been plotted in figure 7 for three specimens: S4 (as-built), S9 (drilled) and NS6 (drilled-restored).

Beyond the expected lower failure load of the drilled column, degrading phenomena affecting as-built and drilled restored elements are more gradual. In fact, a 50% load reduction is found at displacements of 8 and 9 mm for drilled-restored and as-built specimens, respectively, while the drilled one shows the same reduction at around 5 mm. It is important to underline that restoration is able to provide the columns with almost the same ductile capacity compared with the as-built ones. Instead, more brittle failure is expected in drilled columns.

In addition to the previous discussion, it is worth remembering that specimens subject of this study belonged to seismically tested beam-column joints, whose concrete cover was mostly cracked at the moment of compression tests. Therefore, the reported results are particularly meaningful for seismically damaged structures for which residual capacity to carry vertical loads must be carefully evaluated, neglecting the contribution of the concrete cover.

4 FINITE ELEMENT ANALYSES

Nonlinear finite element models using ATENA 3D software package [4] were developed in order to more deeply investigate the failure mode found in drilled columns. The software is

based on the nonlinear fracture mechanics [11] and is capable to take into account compression softening as well as crushing and cracking of concrete.

For concrete, the robust smeared crack model "CC3DNonLinCementitious2" was used. The modelled column is NS1, that is a drilled one. The main properties of concrete are derived from the results of the compression test on the core extracted from the same column, that is f_c = 39.5MPa, f_t = 2.89 MPa, ν = 0.2, and E_c = 32.5 GPa, being respectively the compressive strength, tensile strength, Poisson ratio, and elastic modulus. Actually, with the exception of the compressive strength f_c, all other mechanical properties are derived from literature expressions based on f_c. As previously discussed, in accordance with the confinement model in [9], the concrete strength has been increased by 5%, assuming f_c=41.5 MPa in the numerical simulations.

A fictitious uniaxial stress-strain law (figure 8-a) with displacement based softening has been adopted [12].

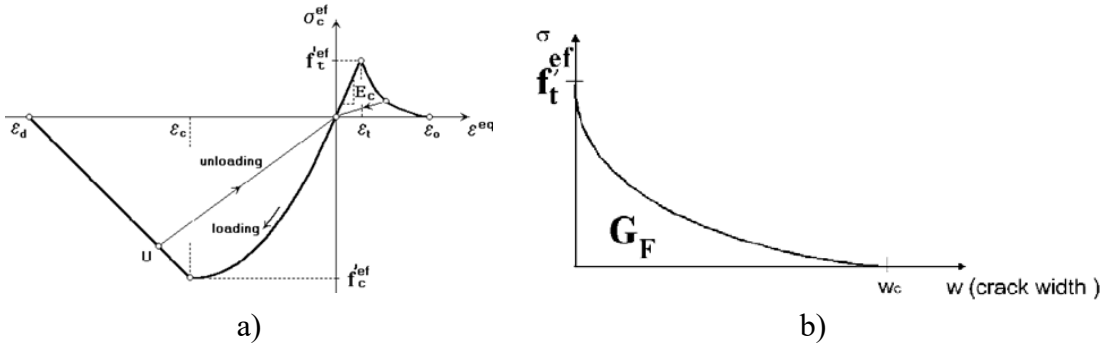

Figure 8: a) Uniaxial compressive stress-strain law and b) crack opening law for tensile stresses for concrete.

Under tensile stress, concrete behavior is governed by a crack opening law, as in figure 8-b defining the fracture energy (G_F). The tensile strength presents an exponential degrading law. The fracture energy was computed by means of Remmel's law [13].

An elastoplastic law with hardening was chosen for the reinforcing steel stress-strain relationship, with yielding strength f_y=480 MPa and failure strength f_t=590 MPa. These values were based on experimental tests carried out on rebars belonging to the same steel supply used for the specimens' construction. No bond slip between concrete and steel has been considered since the column is provided of ribbed bars and slip phenomena are not significant to global behavior under compression loads.

The global finite element model is referred to column NS1 without the concrete cover, based on the previous considerations, after having verified that the concrete cover is ineffective to increase the maximum load carrying capacity of the members under study. This means that only the concrete core inside the steel cage has been modeled giving a cross section 260mm x 260 mm.

Due to the presence of the core's hole, having diameter 104 mm and depth 220 mm, the mesh could not be structured (i.e. made of an ordinate repetition of elements having the same size). The mesh, in fact, is made of tetrahedral elements whose mean size near the hole is 10 mm while far from it, is set equal to 25 mm. The final mesh size has been determined by a sensitivity analysis gradually decreasing the element size. Despite only a short column is under study a huge model has been generated (figure 9-a). As a whole, the model is made up of 264 straight truss elements (i.e. carrying only axial loads) to simulate the steel reinforcement

(figure 9-b), 40347 tetrahedral elements to simulate concrete and the upper steel plate, and 9009 nodes. Analyzing such a model under cyclic loads is time expensive even using a powerful workstation, thus only monotonic analyses have been made to save time. Loading history was displacement controlled, applying to the top plate 5 mm displacement subdivided into 100 steps which the program can divide into further sub-steps based on numerical solution needs.

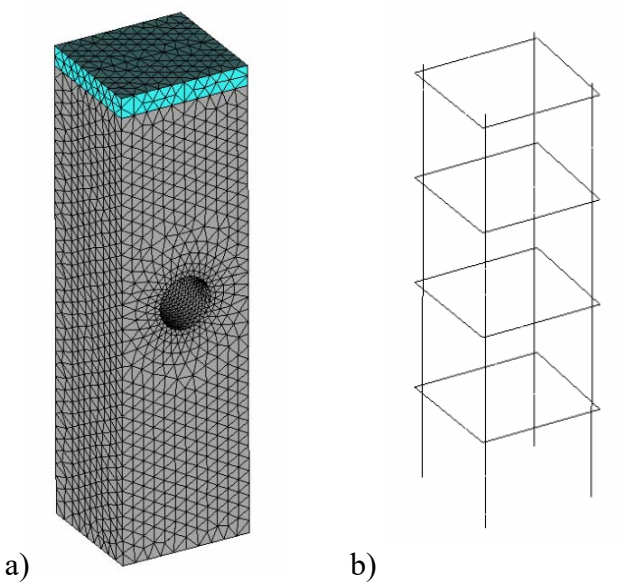

Figure 9: a) Mesh of NS1 FE model, b) steel reinforcement.

Firstly, to evaluate the effectiveness of the FEM model, experimental and numerical load-displacement curves are compared. As can be seen from figure 10, the peak load is well predicted by the numerical simulation, while differencence are found in the ascending branch, mainly ascribable due to the presence of a neoprene layer placed between the top face of column and the machine plate, having the role of uniformly applying the compression load during the test. Descending branches are not coincident due to the fact that numerical analysis is not cyclic and, then, generates less damage accompanied by a lower strength degradation.

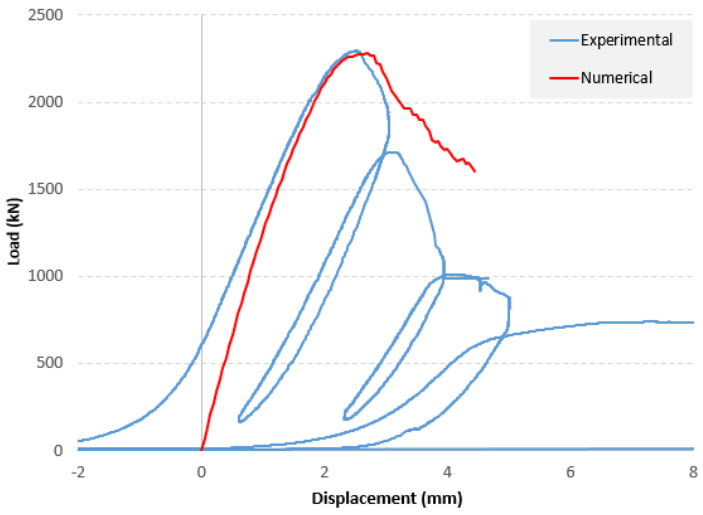

Figure 10: Experimental and numerical load-displacement curves for NS1 specimen.

4.1 Analysis of the failure mechanism

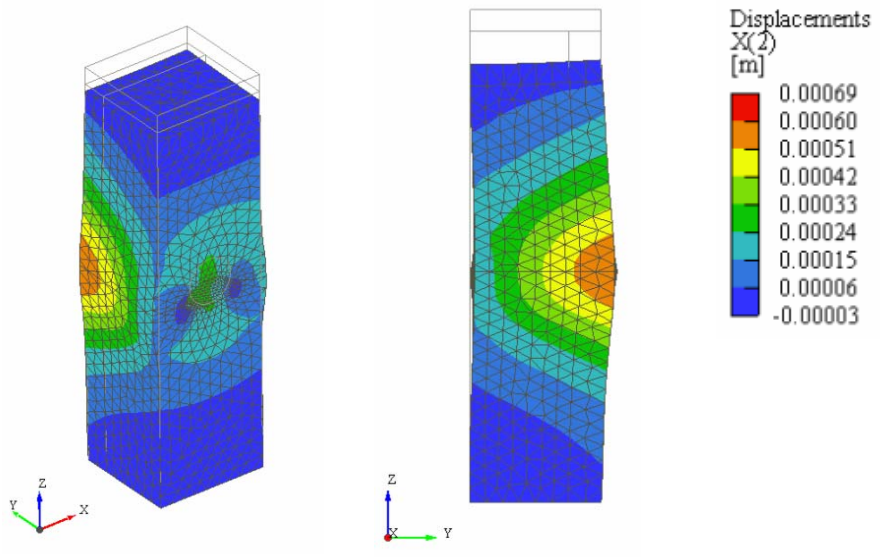
By studying the model of the drilled column NS1, the failure mode of the specimen due to presence of the extraction hole can be better understood. Specifically, figure 11a shows the deformed shape of the specimen by means of an isometric view and a side view. The presence of the hole determines an eccentricity between the applied load, directed along the column axis, and the center of the resisting section, not coincident with the column axis. This eccentricity introduces a bending moment around the X-axis with consequent displacements in the Y direction, especially for the column region around the hole.

Figure 11 shows the deformed shape at the peak load. Although horizontal displacements in the Y direction are low (below 1.0 mm), this involves an asymmetry of vertical (Z) displacements too.

This latter can be seen in figure 12a, where the relation between vertical displacements measured during the experimental tests by LVDT no. 4 (on the front face) and no. 8 (on the rear face) is displayed. As can be seen, there is a remarkable difference, matching the deformed shape obtained by the FEM model (figure 11).

Figures 12b and c display the colormap of Z displacements on the same faces of the specimen. From this colormap, similar differential displacements can be found between the points where the aforementioned LVDT are anchored.

This latter demonstrates the good calibration of the FEM model and its ability to predict the column's behavior.



a) b)

Figure 11: Colormap of Y displacements as a) isometric view and b) side view.

In order to complete the description of the collapse mechanism, figure 13 shows the rebars' stresses at peak load. Longitudinal reinforcement (figure 13a) overcomes the yielding stress in compression (f_y=480 MPa), being the minimum value equal to 484 MPa. They are yielded for most of their length as can be seen by the evolution plotted along the bars' development. Going beyond the peak load of the specimen, the stress increases to about a maximum value of 500 MPa. This means that the bars do not fail being their tensile strength equal to 590 MPa.

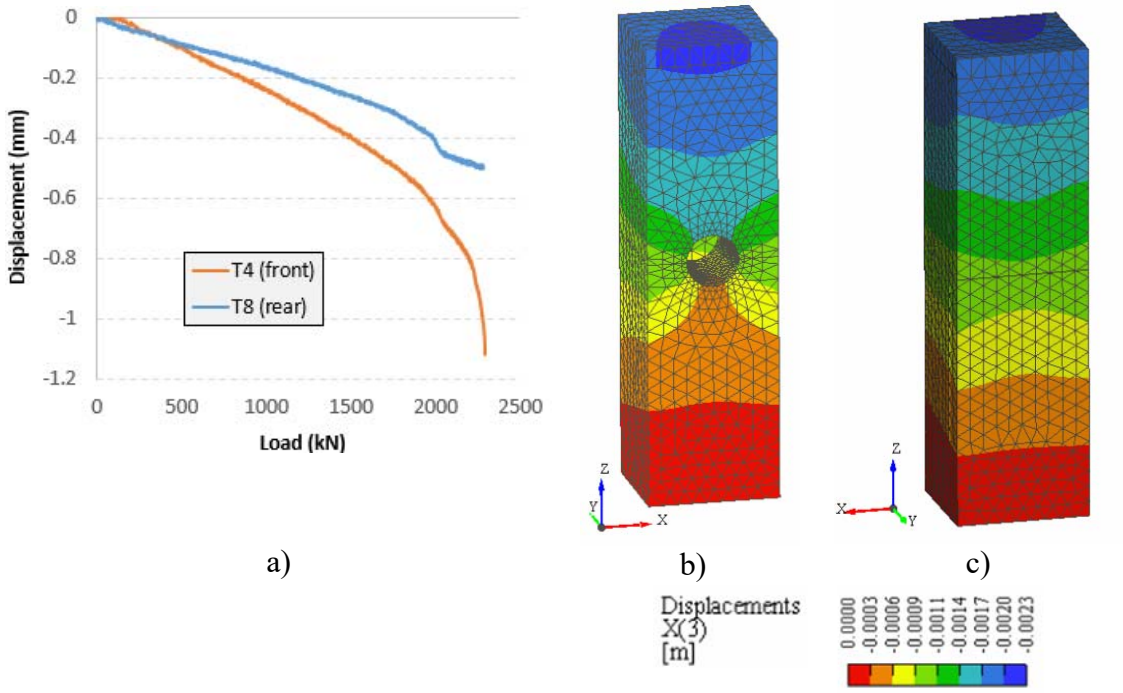


Figure 12: a) Experimental displacements and numerically evaluated on the front face (b) and on the rear face (c)

Hoops' stress is equal to 480 MPa corresponding to the yielding strength of steel. After the peak load, the hoops reach tensile stress values lower than 485 MPa. The most stressed branches of hoops are those normal to the core axis according to the deformed shape shown in figure 11a.

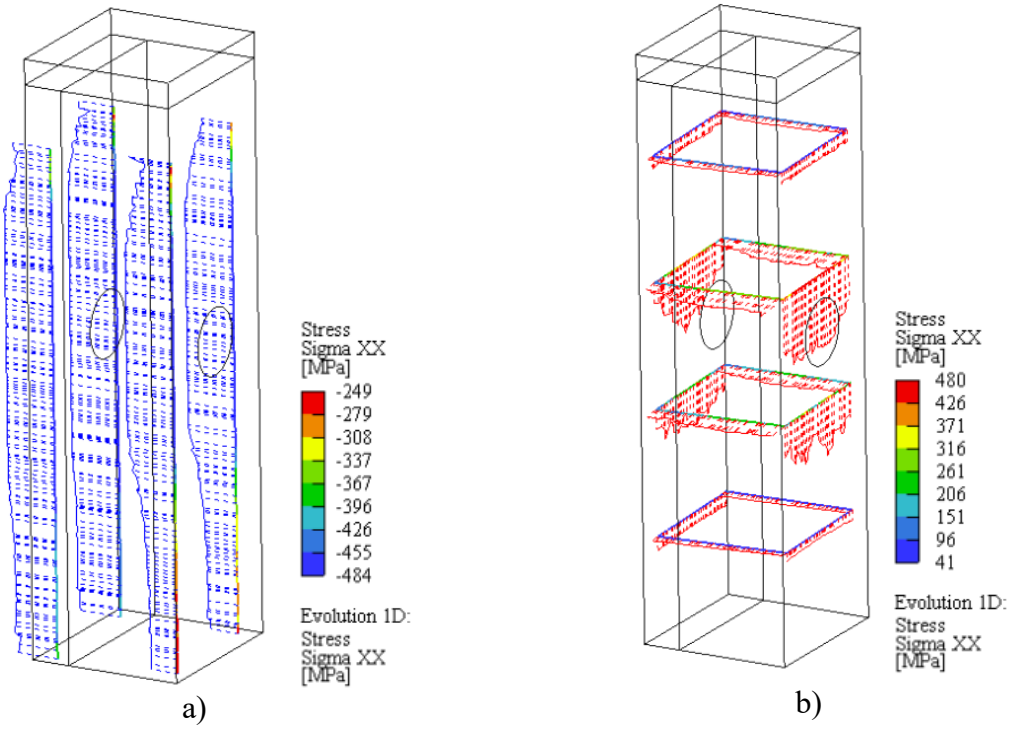

Figure 13: a) Longitudinal reinforcement and b) transverse reinforcement stresses distributions.

Summarizing, steel strength and ductility is not fully exploited as shown by the stress values achieved by longitudinal and transverse reinforcement. This happens because crushing of concrete on the core sides leads to the early buckling of reinforcement and consequent failure.

5 CONCLUSIONS

This paper reports a study on the behavior of reinforced concrete columns under axial compression load previously subjected to a seismic loading history as part of beam-column joints. By means of compression tests, the behavior of as-built, drilled and drilled-restored columns is investigated in order to evaluate the effect of core drilling and the effectiveness of the holes' restoration according to a standard procedure in the in-situ destructive testing campaign on RC buildings. Further, nonlinear finite element models were developed in order to better investigate the failure mode found in drilled columns.

The main findings from the experimental and numerical study are:

- Experimental results show that the failure of columns is characterized by early concrete cover spalling and consequent bar buckling. In particular, concrete cover spalling happens before reaching the peak load. Analytical ultimate load evaluated accounting for the gross concrete section is far higher than the correspondent experimental value.
- Based on the previous result, analytical prediction of the columns' strength can be done by considering only the confined concrete section, accounting also the confining effect. The most accurate capacity prediction is related to the confinement model reported in [9].
- Drilled specimens show a mean compression load capacity reduction equal to about 14% compared to as-built specimens. Restored specimens, instead, exhibit a negligible reduction (about 1.4%).
- Also, drilled specimens show a significant ductility reduction which has not been observed in restored specimens. This means that restoration is able to provide the columns with almost the same capacity of the as-built condition.
- The nonlinear FEM model of a drilled specimen showed a satisfying predictive capacity proved by the good agreement between experimental and numerical load-displacement curves.
- The failure behavior of columns is characterized by the eccentricity between the axial load and the resisting cross-section at the hole's location. This is clearly shown by the deformed shape of the numerical model that matches the experimental measurements of the LVDT placed on the front and rear face of the column.
- Finally, the failure of the studied column is characterized by the concrete crushing of regions around the hole. This causes the early spalling of concrete cover and consequent buckling of longitudinal bars that reach the compression yielding stress but are unable to exploit their full strength.

The experimental and numerical investigation on column specimens here reported suggests that the compression load carrying capacity of previously seismically loaded column members is far lower than that obtained from code-based analytical predictions accounting for the full cross-section. This is particularly true for weakly reinforced concrete columns as those of the present study, for which bar buckling can be not effectively restrained by hoops and ties.

DISPLACEMENT-BASED DESIGN OF DAMPED BRACES FOR EXISTING R.C. BUILDINGS WITH DEGRADING SEISMIC RESPONSE

Fabio Mazza[1]

Abstract

The widespread use of damped braces is closely related to the availability of simplified yet reliable design procedures along with the new generation of seismic codes based on the performance-based design. On the other hand, the seismic retrofitting of a reinforced concrete (r.c.) framed building goes through a proper evaluation of the structural behaviour before failure and sensitivity to damage. In fact, lack of knowledge on strength and stiffness degradation may not be compensated for in the following calculation of a passive control system. A Displacement-Based Design (DBD) procedure to proportion hysteretic damped braces (HYDBs) is proposed in order to take into account the effects of the seismic degradation of a structure that needs to be retrofitted. To this end, a hysteretic model based on plastic and damage mechanisms is adopted to describe the inelastic response of r.c. frame members. Then, nonlinear seismic analysis of a single-degree-of-freedom system, equivalent to a multi-degree-of-freedom model of the structure, is used to generate the capacity boundary curve by means of the hysteretic model defined starting from the initial backbone curve. Two-, four- and eight-storey r.c. framed structures, representative of low-, mid- and high-rise r.c. framed buildings, are designed for a medium-risk seismic zone of a former Italian code. These structures are then to be retrofitted by inserting HYDBs to attain performance levels imposed by current Italian code in a high-risk seismic zone. Different retrofitting solutions are compared, considering for each retrofitted structure: i) variable damper ductility coupled with constant frame ductility; ii) variable frame ductility coupled with constant damper ductility. The effects of different damage levels and different damage evolution laws are also investigated.

1 INTRODUCTION

Thanks to the displacement and velocity dependent mechanisms (e.g. hysteretic and viscous) with in-built amplification (e.g. toggle and scissor jack brace configurations), the effectiveness of supplementary energy dissipation devices inserted on steel braces (i.e. damped braces) has been widely recognised as reducing the level of seismic energy to building structures [1, 2]. The widespread use of this technology is closely related to the availability of simplified yet reliable design procedures along with the new generation of seismic codes based on the performance-based design that combines seismic limit levels with hazard levels [3]. The most promising ideas are those in which the estimation of seismic demand and capacity of the structure is based on Displacement-Based-Design (DBD) and Energy-Based-Design (EBD) procedures. In particular, in the DBD approaches the design starts from a target deformation, combining the nonlinear static analysis of the multi-degree-of-freedom (MDOF) model of the actual structure with the response spectrum analysis of an equivalent single-degree-of-freedom (SDOF) system [4-6]. The EBD approaches, on the other hand, explicitly address cumulative and localized structural damage, assessing the energy absorption and the dissipation mechanisms that can be made to balance the total seismic energy input, through use of nonlinear dynamic analysis or optimization procedures [7-9].

Structural behaviour in past earthquakes confirms that reinforced concrete (r.c.) framed buildings, poorly reinforced with regard to the requirements of the seismic damage control, may suffer permanent damage from a combination of highly inelastic excursions and severe cyclic loading [10]. This observation opens up the search for a more realistic estimation of the deformation capacity through a displacement based approach in which strength and stiffness degradation of the MDOF system are evaluated starting from the initial backbone curve of the corresponding SDOF system [11]. Various types of hysteretic models can be used to study the effects of the deterioration modes of structural components on their hysteretic behaviour under sizeable inelastic deformations [12]. In the present work, to account for the cyclic behaviour, the initial backbone curve is replaced by a sequence of N linear segments defined by a combination of as many elastic-perfectly plastic (EPP) mechanisms as necessary. Then, cyclic deterioration is reproduced by introducing N elastic-softening damage (ESD) mechanisms acting in-parallel with the EPP ones, controlled by a damage variable (ψ) and corresponding damage index (Ψ).

To evaluate the effectiveness of the proposed Displacement-Based Design (DBD) procedure of hysteretic damped braces (HYDBs), accounting for the cyclic behaviour of r.c. frame members, two-, four- and eight-storey r.c. framed structures are adopted as test structures. These are first designed in line with a former Italian code for a medium-risk seismic zone [13] and then retrofitted to attain performance levels imposed by the current Italian code in a high-risk seismic zone [14]. Six solutions are compared, considering for each retrofitted structure: three design values of the damper ductility (i.e. μ_D=10, 15 and 20), coupled with a constant design value of the frame ductility (i.e. μ_F=1.5); three design values of the frame ductility (i.e. μ_F=1.2, 1.5 and μ_{Fu}), coupled with a constant design value of the damper ductility (i.e. μ_D=15). Moreover, six hysteretic laws, corresponding to different levels of degradation, are assessed: i.e. low (i.e. Ψ=0.33), medium (i.e. Ψ=0.5) and high (i.e. Ψ=0.83) constant values of the damage index (Ψ); continuous damage evolution with linear (i.e. ε=1.0) and nonlinear (i.e. ε=0.5 and 0.2) laws related to the parameter (ε) governing the rate of degradation. Finally, pushover curves of the original (unbraced) and retrofitted (damped braced) structures are evaluated, with and without considering degradation of the hysteretic response of r.c. frame members on the DBD procedure of the HYDBs.

2 DISPLACEMENT-BASED DESIGN PROCEDURE OF DAMPED BRACES

A multistep iterative DBD procedure, for proportioning HYDBs in order to get a designated performance level of an existing r.c. regular framed structure for a specific level of seismic intensity [5], is proposed to take account of the main modes of cyclic deterioration of r.c. frame members during seismic loads. The main steps of the new procedure are briefly summarized below, with the main focus on the strength and stiffness degradation of the SDOF system equivalent to the original MDOF system.

2.1 Nonlinear static analysis of the original multi-degree-of-freedom system

Nonlinear static analysis of the original unbraced frame, under constant gravity loads and monotonically increasing horizontal loads (Figure 1a), is carried out to obtain the base shear versus (e.g. roof) displacement ($V^{(F)}$-d) curve (Figures 1b,c) of the MDOF system, where the modal participation factor (Γ) controls the transformation to the equivalent SDOF system (Figure 1d). The lowest capacity curve is selected from those corresponding to constant lateral-load patterns based on "modal" and "uniform" displacement shapes, in line with provisions of the European seismic code [15] for regular structures: i.e. a "first-mode" pattern, obtained by multiplying the first-mode components (ϕ_1, ϕ_2, ..., ϕ_n) by the corresponding floor masses (m_1, m_2, ..., m_n); a "uniform" pattern, only proportional to the floor masses.

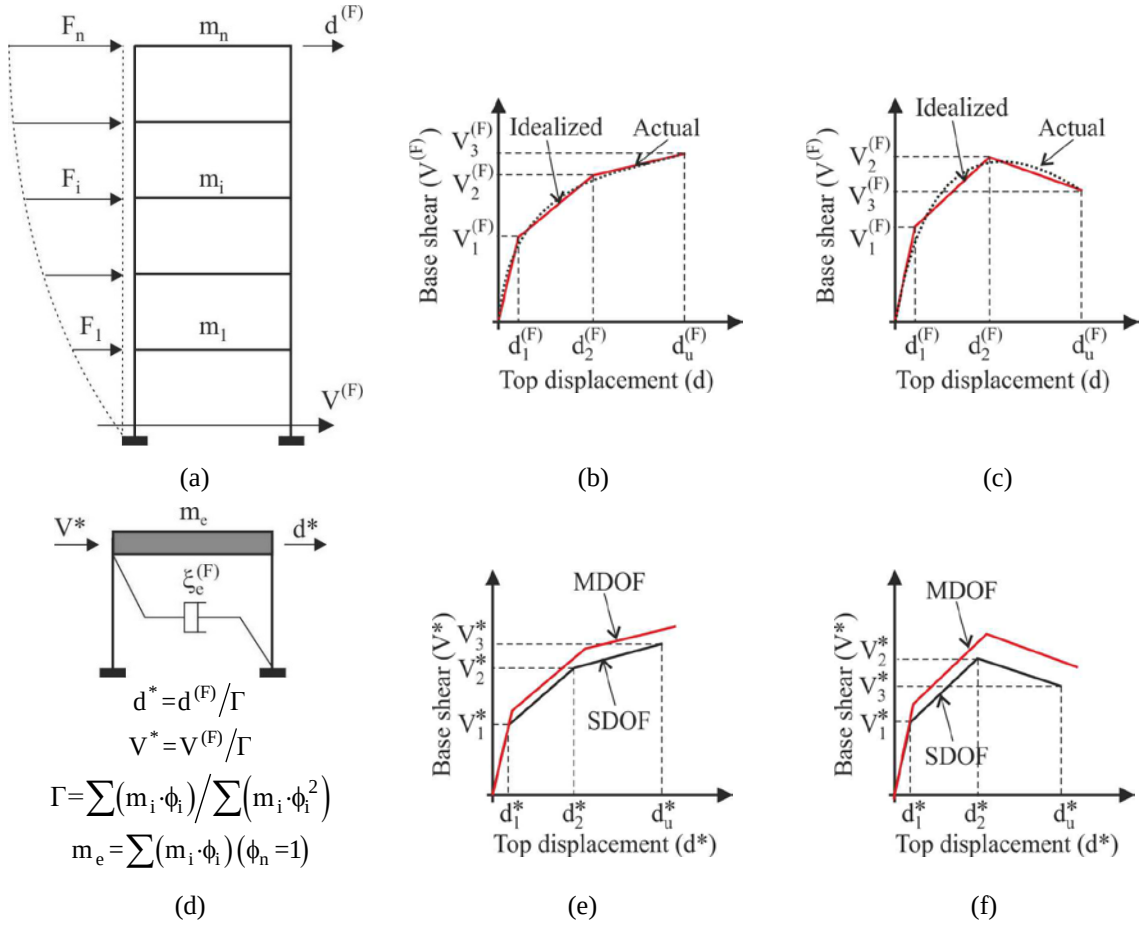

Figure 1: Pushover curves of the original (MDOF) and equivalent (SDOF) systems.

Then, the initial backbone curve of the SDOF system, incorporating yielding and positive (e.g. hardening in Figures 1b and 1e) and negative (e.g. hardening and softening in Figures 1c

and 1f) stiffness, is fitted by means of a piecewise linear function. By using this piecewise linear fit and leaving aside damage (i.e. a damage index Ψ=0), it is possible to account for the cyclic behaviour considering the hysteretic model obtained as a combination of N elastic-perfectly plastic (EPP) mechanisms corresponding to a sequence of N linear segments. Moreover, the i-th linear segment is coupled with the corresponding i-th plastic mechanism described by an EPP law expressed as (Figure 2):

$$V_{P,i}^{*\pm}=K_{P,i}^{\pm}\cdot\left(d^{*\pm}-d_{y,i-1}^{*\pm}\right),\ \left|d_{y,i-1}^{*\pm}\right|<\left|d^{*\pm}\right|\leq\left|d_{y,i}^{*\pm}\right| \tag{1}$$

$$V_{P,i}^{*\pm}=V_{yP,i}^{*\pm}=K_{P,i}^{\pm}\cdot\left(d_{y,i}^{*\pm}-d_{y,i-1}^{*\pm}\right),\ \left|d^{*\pm}\right|>\left|d_{y,i}^{*\pm}\right| \tag{2}$$

$V^*_{yP,i}$ and $d^*_{y,i}$ being the force and displacement at the i-th yielding point and $K_{P,i}$ the elastic stiffness. It should be noted that the initial backbone curve can exhibit multi-linear elastic hardening with a final positive (Figure 2a) or negative (Figure 2b) stiffness segment. In this case, the last (i.e. N-th) plastic mechanism of the hysteretic model will be represented by an elastic-linear law. Moreover, the unloading stiffness of the i-th plastic mechanism is assumed to be the same as the elastic one.

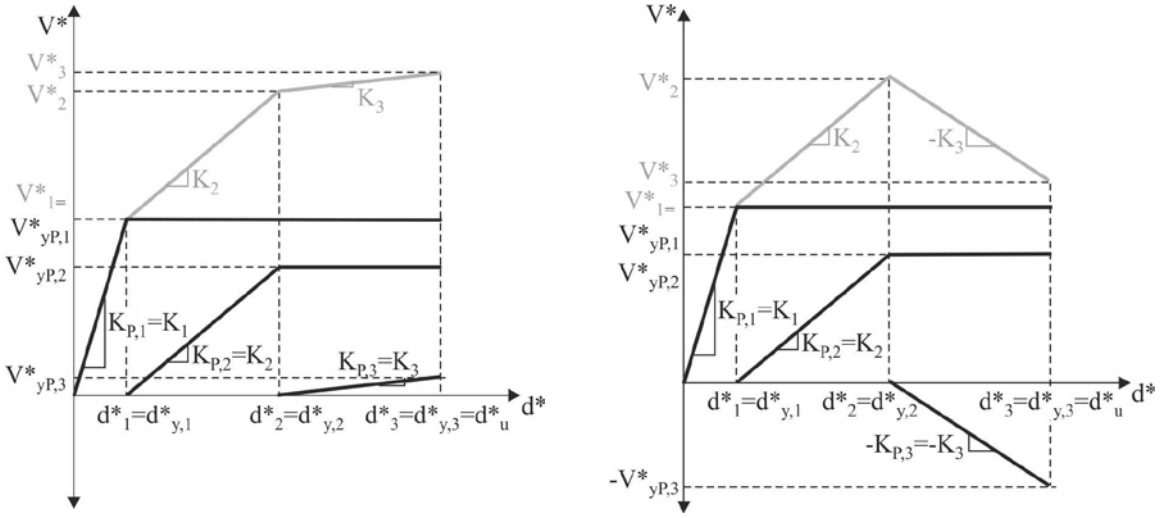

Figure 2: Illustration of the plastic mechanisms (Ψ=0).

2.2 Nonlinear dynamic analysis of the equivalent single-degree-of-freedom system

Nonlinear dynamic analysis of the equivalent SDOF system includes the cyclic deterioration by modifying the initial backbone curve, representative of the response for monotonically increasing loading, as function of the seismic loading history. One way of achieving this is to overlap N damage mechanisms onto the previously defined N plastic mechanism. In particular, the i-th damage mechanism presents an elastic-softening law characterized by a first linear upward branch until the attainment of yield displacement of the corresponding i-th plastic mechanism (Figure 3)

$$V_{D,i}^{*\pm}=K_{D,i}^{\pm}\cdot\left(d^{*\pm}-d_{y,i-1}^{*\pm}\right),\ \left|d_{y,i-1}^{*\pm}\right|<\left|d^{*\pm}\right|\leq\left|d_{y,i}^{*\pm}\right| \tag{3}$$

with an elastic stiffness of

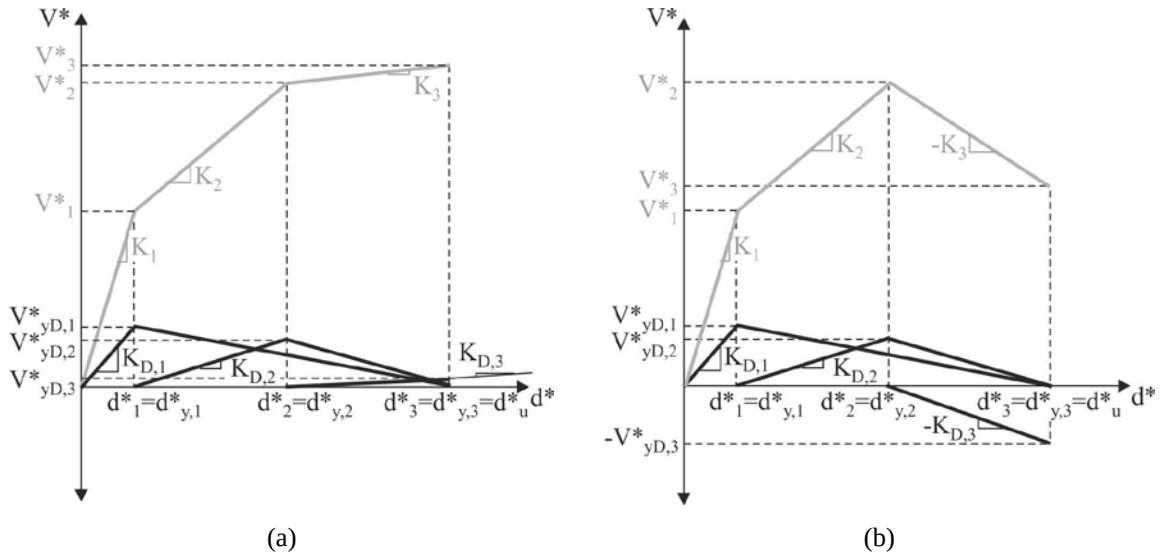
$$K_{D,i}^{\pm}=\Psi^{\pm}\cdot K_i^{\pm} \tag{4}$$

Ψ being a damage index. Since the stiffness of the i-th segment of the backbone curve results from an in parallel combination of plastic (Figure 2) and damage (Figure 3) mechanisms

$$K_i^{\pm}=K_{P,i}^{\pm}+K_{D,i}^{\pm} \tag{5}$$

the initial plastic stiffnesses can be written as

$$K_{P,i}^{\pm}=\left(1-\Psi^{\pm}\right)\cdot K_i^{\pm} \tag{6}$$



(a) (b)

Figure 3: Illustration of the damage mechanisms (0<Ψ<1).

With regard to the second linear downward branch of the i-th monotonic elastic-softening damage (ESD) mechanism the following expression can be used (Figure 3)

$$V_{D,i}^{*\pm}=V_{yD,i}^{*\pm}-K_{sD,i}^{\pm}\cdot\left(d^{*\pm}-d_{y,i}^{*\pm}\right),\ \left|d_{y,i}^{*\pm}\right|<\left|d^{*\pm}\right|\leq\left|d_u^{*\pm}\right| \tag{7}$$

where the stiffness of the softening branch is equal to

$$K_{sD,i}^{\pm}=\alpha_i^{\pm}\cdot K_{D,i}^{\pm}=\alpha_i^{\pm}\cdot\Psi^{\pm}\cdot K_i^{\pm} \tag{8}$$

by placing

$$\alpha_i^{\pm}=\frac{d_{y,i}^{*\pm}-d_{y,i-1}^{*\pm}}{d_u^{*\pm}-d_{y,i}^{*\pm}} \tag{9}$$

The unloading stiffness of the i-th cyclic elastic-softening damage (ESD) mechanism is assumed equal to:

$$K_{uD,i}^{\pm}=\beta_i^{\pm}\cdot K_{D,i}=\beta_i^{\pm}\cdot\Psi^{\pm}\cdot K_i^{\pm} \tag{10}$$

given

$$\beta_i^{\pm}=\alpha_i^{\pm}\frac{d_u^{*\pm}-d_i'^{*\pm}}{d_i'^{*\pm}} \tag{11}$$

where d' is the displacement of the softening branch corresponding to the initial point of the

unloading phase. In so doing, the unloading branch of the i-th ESD mechanism is oriented towards the origin.

The cyclic deterioration of the plastic and damage mechanisms described above is controlled by damage index Ψ, which involves one or more damage variables ψ (e.g. inelastic deformation and hysteretic energy) and represents a dimensionless parameter varying between Ψ=0, when there is no damage, and Ψ=1, when failure occurs [16]. Furthermore, a lower bound threshold of the damage variable ψ (i.e. ψ_e) corresponds to a substantially linear elastic response, while $\psi=\psi_u$ is the upper bound threshold corresponding to part or all of the ultimate capacity of the system under a monotonically increasing load (i.e. ψ_{mon}). An additional degradation parameter ε needs to be introduced in order to characterize the shape of the ever-increasing Ψ-ψ law:

$$\Psi^{\pm}=0, \text{ for } \psi^{\pm}\leq\psi_e^{\pm} \tag{12}$$

$$\Psi^{\pm}=\left(\frac{\psi^{\pm}-\psi_e^{\pm}}{\psi_u^{\pm}-\psi_e^{\pm}}\right)^{\varepsilon} \quad \text{for } \psi^{\pm}>\psi_e^{\pm},\ \varepsilon\geq 0 \tag{13}$$

ψ being the current value of the damage variable from nonlinear seismic analysis [17-21]. Moreover, the displacement of the SDOF system is considered as damage variable (ψ=d*) where ψ_e=d*$_{y1}$ and ψ_u=d*$_u$ are assumed as elastic and ultimate thresholds, respectively.

Finally, the force deformation curve that envelopes the hysteretic behaviour of the equivalent SDOF system subjected to seismic loads (i.e. the cyclic envelope V*-d*) can be evaluated (Figure 4a) and idealized as bilinear (Figure 4b), where $d_y^{(F)}$ and $V_y^{(F)}$ represent yielding values of displacement and base shear, respectively. Once the displacement corresponding to a selected performance level (d_p) is fixed, base shear at the performance displacement ($V_p^{(F)}$), stiffness hardening ratio (r_F) and ductility μ_F(=$d_p/d_y^{(F)}$) can be also evaluated for the frame.

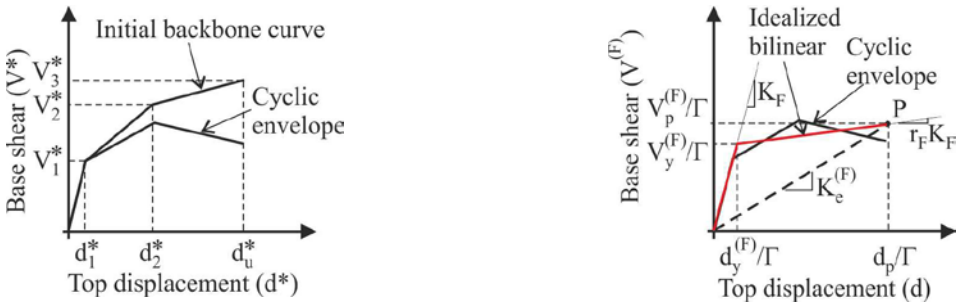


Figure 4: Idealization of the cyclic envelope for the equivalent SDOF system.

2.3 Equivalent viscous damping of the frame with damped braces

The equivalent viscous damping of the in-parallel system of framed structure (F) and damped brace (DB) can be evaluated iteratively by using the following expression, where a suitable value of the elastic viscous damping for the framed structure is assumed (e.g. ξ_V= 5%)

$$\xi_e(\%)=\xi_V+\frac{\xi_F^{(h)}\cdot V_p^{(F)}+\xi_{DB}\cdot V_p^{(DB)}}{V_p^{(F)}+V_p^{(DB)}} \tag{14}$$

being

$$\xi_F^{(h)}(\%)=\frac{1}{3}\left(63.7\frac{\left(\mu_F-1\right)\cdot\left(1-r_F\right)}{\mu_F\cdot\left[1+r_F\cdot\left(\mu_F-1\right)\right]}\right) \tag{15}$$

and

$$\xi_{DB}(\%)=63.7\frac{\left(\mu_{DB}-1\right)\cdot\left(1-r_{DB}\right)}{\mu_{DB}\left[1+r_{DB}\cdot\left(\mu_{DB}-1\right)\right]} \tag{16}$$

A bilinear base shear-displacement curve represents the response of the equivalent hysteretic damped braces (HYDBs) of the actual structure ($V^{(DB)}$-d), where $\mu_{DB}(=d_p/d_y^{(DB)}$, with $d_y^{(DB)}$ displacement corresponding to yielding of the HYDBs) and r_{DB} are ductility demand and stiffness hardening ratio, respectively.

2.4 Design of the equivalent damped brace

Once the effective period (T_e) of the damped braced frame (DBF) is evaluated as the vibration period of the design spectrum corresponding to the equivalent viscous damping (ξ_e) and performance displacement (d_p), it is possible to calculate the effective stiffness of the equivalent damped brace

$$K_e^{(DB)}=K_e-K_e^{(F)}=\frac{4\cdot\pi^2\cdot m_e}{T_e^2}-K_e^{(F)} \tag{17}$$

and shear contributions at the performance and yielding points ($V_p^{(DB)}$ and $V_y^{(DB)}$, respectively)

$$V_p^{(DB)}=K_e^{(DB)}\cdot d_p,\ V_y^{(DB)}=\frac{V_p^{(DB)}}{1+r_{DB}\cdot\left(\mu_{DB}-1\right)} \tag{18a,b}$$

2.5 Design of the hysteretic damped braces for the framed structure

If the structure is assumed to be regular, a proportional stiffness criterion can be used to assess the vertical distribution of the HYDBs, although more refined criteria are available in the literature [22]. In particular, the same value of stiffness ratio $K^*_{DB}(=K_{DB}/K_F$, K_{DB} being the elastic lateral stiffness of the damped braces and K_F that of the unbraced frame) is assumed at each storey. At a given storey, for a diagonal brace with hysteretic damper inclined at angle α with respect to the horizontal direction, the elastic stiffness of the damped brace ($K_i^{(DB)}$) and the yield-load (N_{yi}) can be expressed as

$$K_i^{(DB)}=\frac{V_{yi}^{(DB)}}{\left(\phi_i-\phi_{i-1}\right)\cdot d_y^{(DB)}}\frac{1}{cos^2\alpha_i},\ N_{yi}=\frac{V_{yi}^{(DB)}}{cos\alpha_i} \tag{19a,b}$$

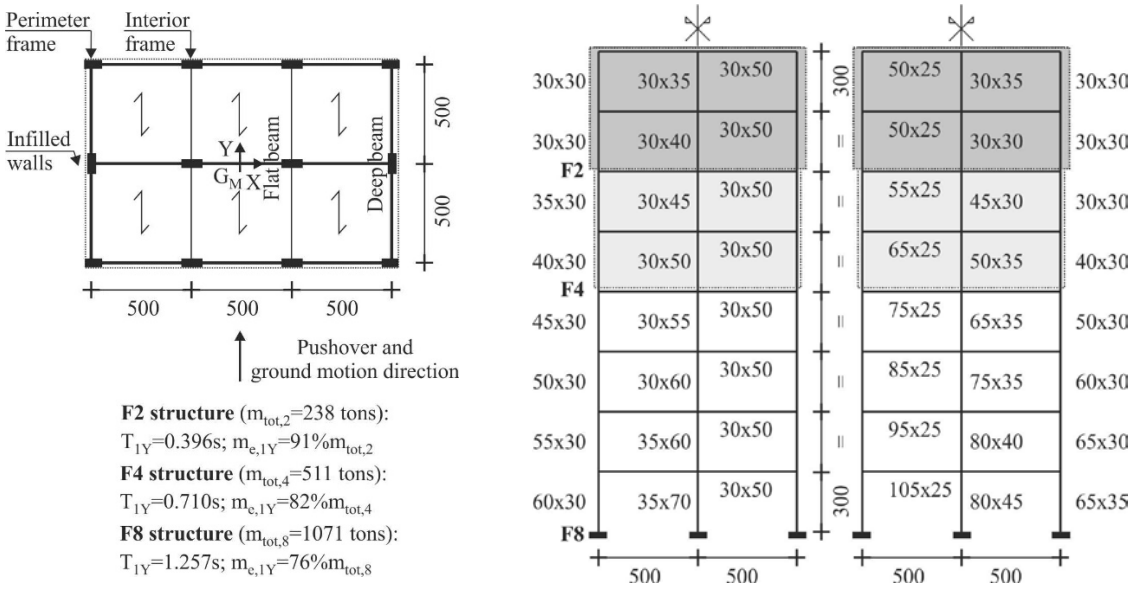
as function of the shear at that storey

$$V_{yi}^{(DB)}=\sum_{j=i}^{n}F_{yj}^{(DB)}=\sum_{j=i}^{n}\frac{m_i\cdot\phi_i}{\sum_{j=1}^{n}m_j\cdot\phi_j}V_y^{(DB)} \tag{20}$$

3 ORIGINAL AND RETROFITTED TEST STRUCTURES

Two- (F2), four- (F4) and eight-storey (F8) r.c. framed structures, with a symmetric plan with 5m long bays (Figure 5a) and a constant interstorey height of 3 m (Figures 5b,c), are

considered as test structures. Note that cross sections of the r.c. frame members at the upper two and four levels of the F8 structure correspond to those of the F2 and F4 structures, respectively. A simulated design of the original (unbraced) buildings is carried out in accordance with a former Italian code [13], for a medium-risk seismic region (seismic coefficient: C=0.07) and a medium subsoil class (subsoil parameter: ε =1). The gravity loads are represented by a dead load of 5.0 kN/m^2 on all the floors, and a live load of 1.5 kN/m^2 on the top floor and 2.0 kN/m^2 on the other floors. A dead load of 1.9 kN/m^2 is also considered for the masonry infill walls. The cross sections of columns (i.e. corner, perimeter and central) and beams (i.e. deep and flat) are reported in Figures 5b,c, where for clarity the dimensions of the r.c. frame members are indicated with reference to Y direction, which will be considered to be the same as the one for the nonlinear static and dynamic analyses. Concrete cylindrical compressive strength of 25 MPa and steel yield strength of 375 MPa are assumed. Finally, the fundamental vibration period (T_{1Y}) and effective mass ($m_{e,1Y}$) of the test structures along Y, expressed as percentage of the total mass (m_{tot}), are reported in Figure 5a. Further details regarding the design can be found in previous work [23].



(a) Plan. (b) Perimeter frame. (c) Interior frame.

Figure 5: Original r.c. test structures (units in cm).

First, the nonlinear static analysis of the framed structures along the Y direction is carried out, considering horizontal loads applied at the centre of mass (G_M) of each storey [23]. A lumped plasticity model constituted of two parallel elements, one linearly elastic and the other elastic-perfectly plastic, describes the inelastic behaviour of a r.c. frame member [24]. For a more accurate estimation of the seismic capacity that takes into account the degradation of the Fi under cyclic loading, a piecewise linear fit of the initial backbone curve is used when applying the hysteretic model described in Section 2.1 to the equivalent SDOF system. Then, the nonlinear dynamic analysis of the SDOF systems, equivalent to the corresponding MDOF ones, is carried out along the Y direction, coupling the elastic perfectly-plastic (EPP) and elastic-softening damage (ESD) mechanisms. To this end, seven recorded accelerograms, reflecting the provisions of the current Italian seismic code [14] for the geographical coordinates (longitude 16.17° and latitude 39.31°) at the site in question (i.e. subsoil class C), are selected from the European Strong Motion database [25] and scaled to match, on average, the design spectrum [26]. Cyclic curves resulting from the proposed hysteretic model are evaluated, with

reference to constant and variable values of the damage index (Ψ), in terms of base shear (V_{base}) versus top (roof) displacement (d_{top}). Moreover, monotonic curves that envelope the hysteretic response of the equivalent SDOF systems (i.e. the capacity boundary curves) are plotted in Figure 6, together with the monotonic backbone curve resulting from the nonlinear static analysis (i.e. Ψ=0). In detail, the capacity boundary curves correspond to constant (i.e. Ψ=0.33, 0.5 and 0.83) and variable (i.e. assuming rate degradation of damage governed by ε=1.0, 0.5 and 0.2) values of Ψ.

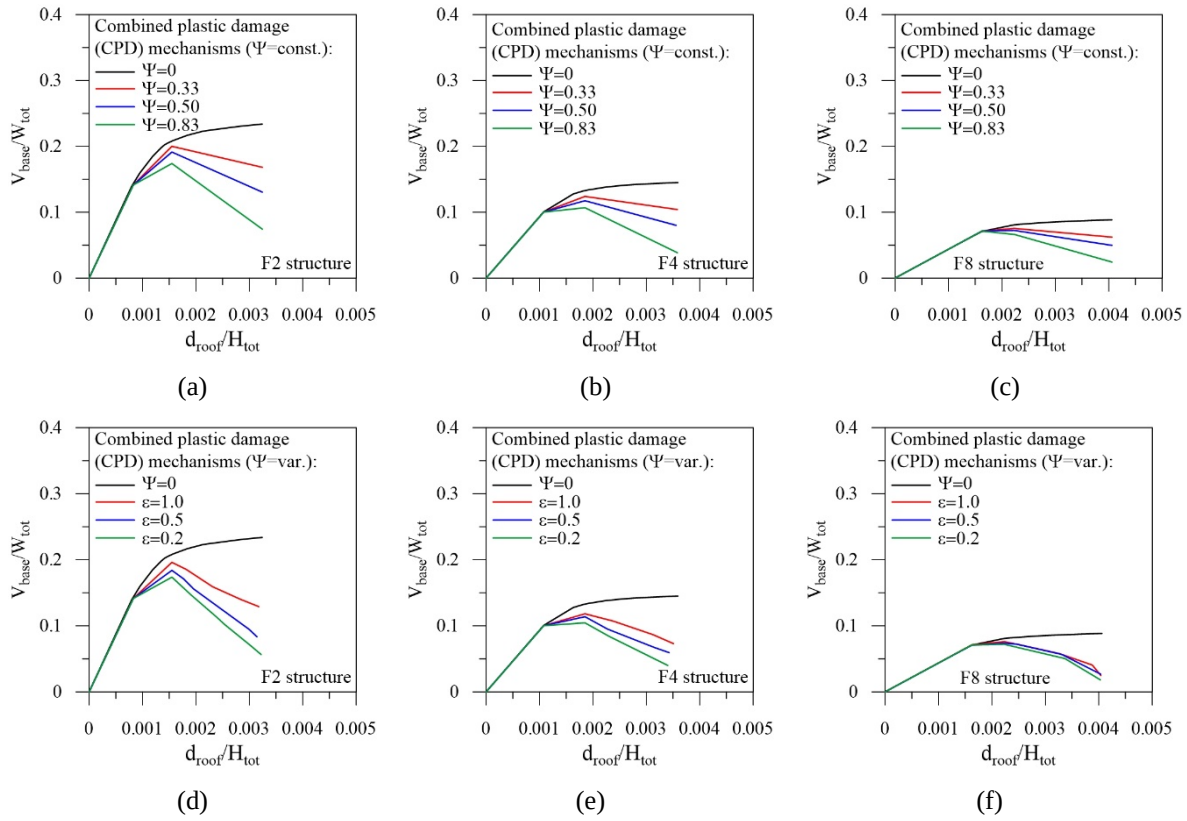


Figure 6: Monotonic and cyclic envelopes for the equivalent SDOF system: constant (a, b, c) and variable (d, e, f) values of damage index Ψ.

For the purpose of retrofitting the original r.c. framed structures (i.e. Fi, i=2, 4 and 8) to the performance levels imposed by NTC18 provisions, in a high-risk seismic zone (peak ground acceleration on rock, a_g=0.26g at the life-safety limit state) and medium subsoil class (type B, site amplification factor S=1.14), diagonal steel braces equipped with hysteretic dampers (HYDs) are inserted in the perimeter frames. Specifically, the damped braced (retrofitted) structures (i.e. DBFi, i=2, 4 and 8) are characterized by HYDBs placed in the central bay, in the X direction, and in both bays, in the Y direction, of the perimeter frames (Figure 7). The Displacement-Based design (DBD) procedure of HYDBs presented in Section 2 is used to proportion the HYDBs. In detail, six retrofitting solutions are considered for each structure, assuming: three design values of the damper ductility (i.e. μ_D=10, 15 and 20) with a constant design value of the frame ductility (i.e. μ_F=1.5); three design values of the frame ductility (i.e. μ_F=1.2, 1.5 and μ_{Fu}) with a constant design value of the damper ductility (i.e. μ_D=15). Moreover, six design solutions are evaluated for each selection of the design parameters, considering the capacity boundary curves corresponding to constant (i.e. Ψ=0.33, 0.5 and 0.83) and variable (i.e. ε=1.0, 0.5 and 0.2) values of the damage index. Finally, the monotonic backbone

curve (i.e. Ψ=0) corresponding to a simplified Displacement-Based Design (DBD) procedure is also examined to provide a comparison. The design results, omitted for the sake of brevity, highlight that the effective stiffness $K_e^{(DB)}$ is underestimated in all examined cases when the force-displacement curve that envelopes the hysteretic behaviour is not considered. As expected, increasing values of effective stiffness of the equivalent HYDB are obtained when stiffness and strength degradation rules depend on increasing (constant) values of the damage index. Assuming different rates of degradation, a similar trend is observed when the variability of Ψ with the current value of inelastic deformation is also taken into account. On the other hand, note that the yield-load is less sensitive than effective stiffness to degrading assumptions. Negligible effects of the μ_D variability are observed throughout, while significant variations of $V_y^{(DB)}$ are highlighted when μ_{Fu} is assumed as the design value of frame ductility.

4 NUMERICAL RESULTS

To evaluate how different nonlinear modelling assumptions of the degrading hysteretic behaviour affect the seismic retrofitting with hysteretic damped braces (HYDBs), a new displacement-based-design (DBD) procedure is developed. Different damage levels on the DBD procedure of HYDBs are investigated based on a damage index (Ψ) on which the capacity boundary curve depends. Specifically, constant values of Ψ, from no damage up to light and moderate repairable damage ($0 \leq \Psi \leq 0.5$) and irreparable damage up to partial or total collapse ($0.5 < \Psi < 1$), are compared with different evolution laws of Ψ, referring to linear ($\varepsilon = 1$) and nonlinear ($\varepsilon < 1$) degradation rules. Stiffness and strength properties of the HYDBs are evaluated on the assumption that the deformability of the steel brace is negligible given its rigidity (i.e. $K_{DB} \cong K_D$, where K_{DB} and K_D are the lateral stiffnesses of the damped brace and hysteretic damper, respectively). An analogous assumption is made for the stiffness hardening ratio of the HYDBs (i.e. $r_{DB} \cong r_D$).

To evaluate the effectiveness of the proposed DBD procedure of HYDBs for the seismic retrofitting of the original two- (F2), four- (F4) and eight-storey (F8) r.c. framed structures, capacity curves of the DBFi structures are plotted in Figure 8, where dashed lines represent

results obtained for the corresponding Fi ones. In view of the low impact of the damper ductility on design properties of the HYDBs, only the value μ_D=15 is assumed in combination with the hardening ratio r_D=3%. Moreover, a frame ductility μ_F=1.5, limiting the inelastic demand to the original structures, is selected together with hardening ratio r_F=1%. The nonlinear static analysis of the DBFi is terminated once the ultimate value of damper ductility is attained (i.e. μ_{Du}=30). An ultimate ductility check has also been carried out for the r.c. frame members for both Fi and DBFi. In detail, HYDBs are designed with reference to constant (Figures 8a,c,e) and variable (Figures 8b,d,f) values of the damage index Ψ.

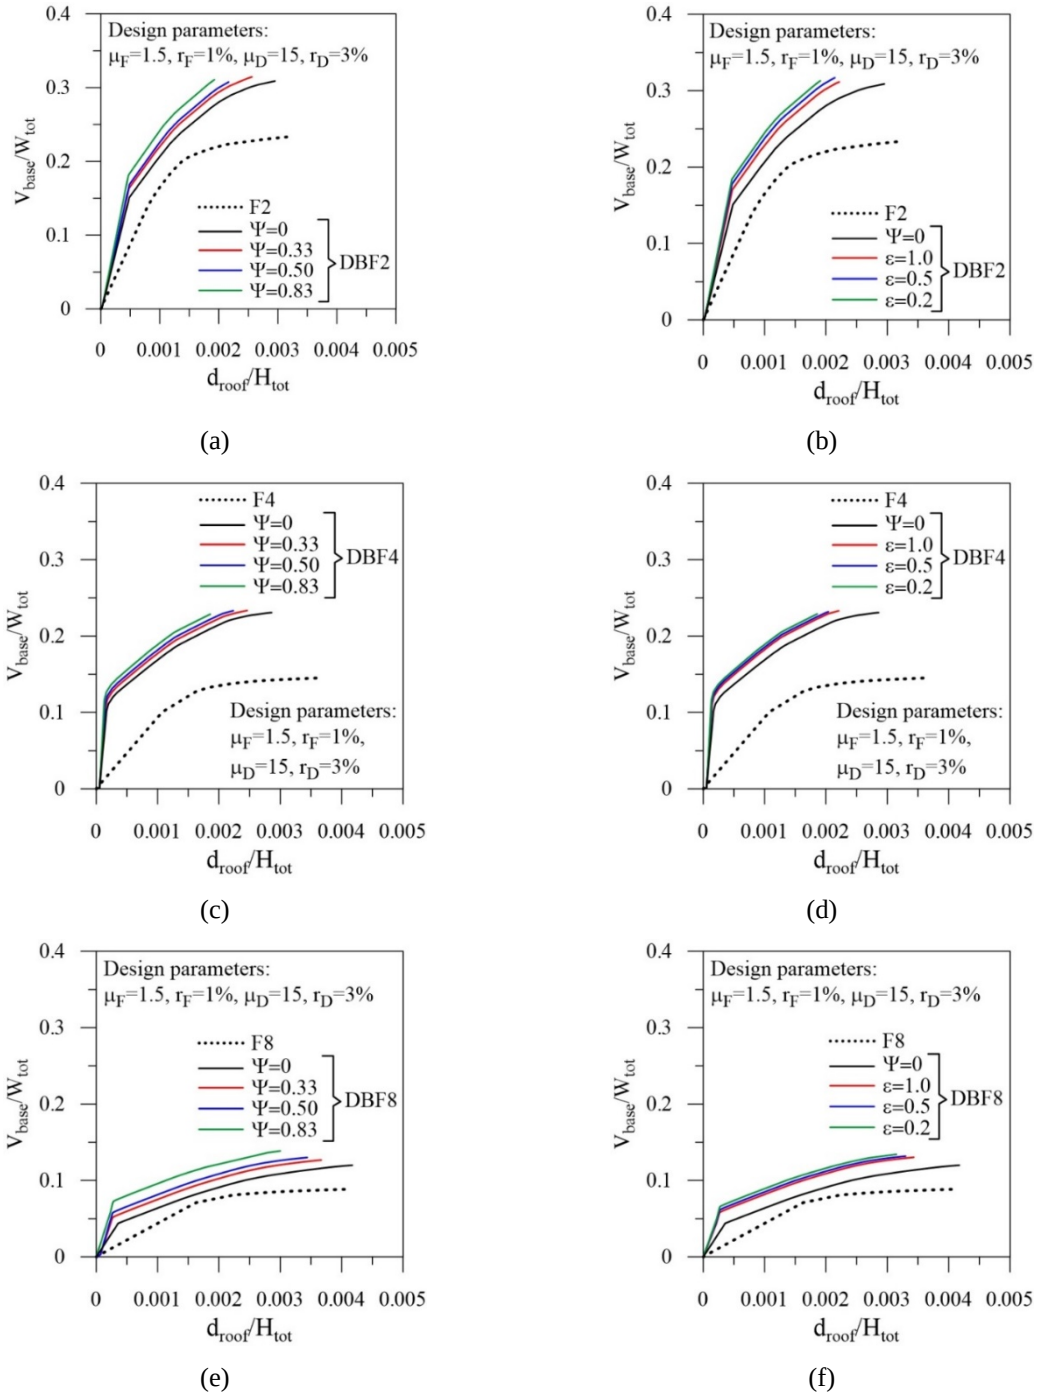

Figure 8: Pushover curves of retrofitted structures designed with and without considering degrading response of original r.c. framed structures, assuming constant (a, c, e) and variable (b, d, f) values of Ψ.

The DBD procedure is shown to be more effective for the low- (i.e. F2) and medium-rise (i.e. F4) structures than for the high-rise (i.e. F8) ones, where the lowest level of seismic protection is obtained. Capacity curves where the HYDBs are designed with the simplified DBD procedure, without considering the degrading response (Ψ=0), are also plotted. Significant variation in the results occurs when constant or variable values of the damage index Ψ are assumed. Moreover, the shear strength capacity of the DBFi structures increases for increasing values of damage index Ψ (Figures 8a,c,e) and decreasing values of rate parameter ε (Figures 8b,d,f). The opposite is observed for the lateral displacement capacity, for which there is a significant overestimation when the simplified DBD procedure is applied (i.e. Ψ=0). This behaviour highlights the need for special attention to the degrading cyclic response of r.c. frame members to ensure a successful retrofit.

Next, local structural damage along the building height of the Fi and DBFi structures is shown in Figures 9 and 10, in terms of maximum curvature ductility demand at the end sections of beams and columns.

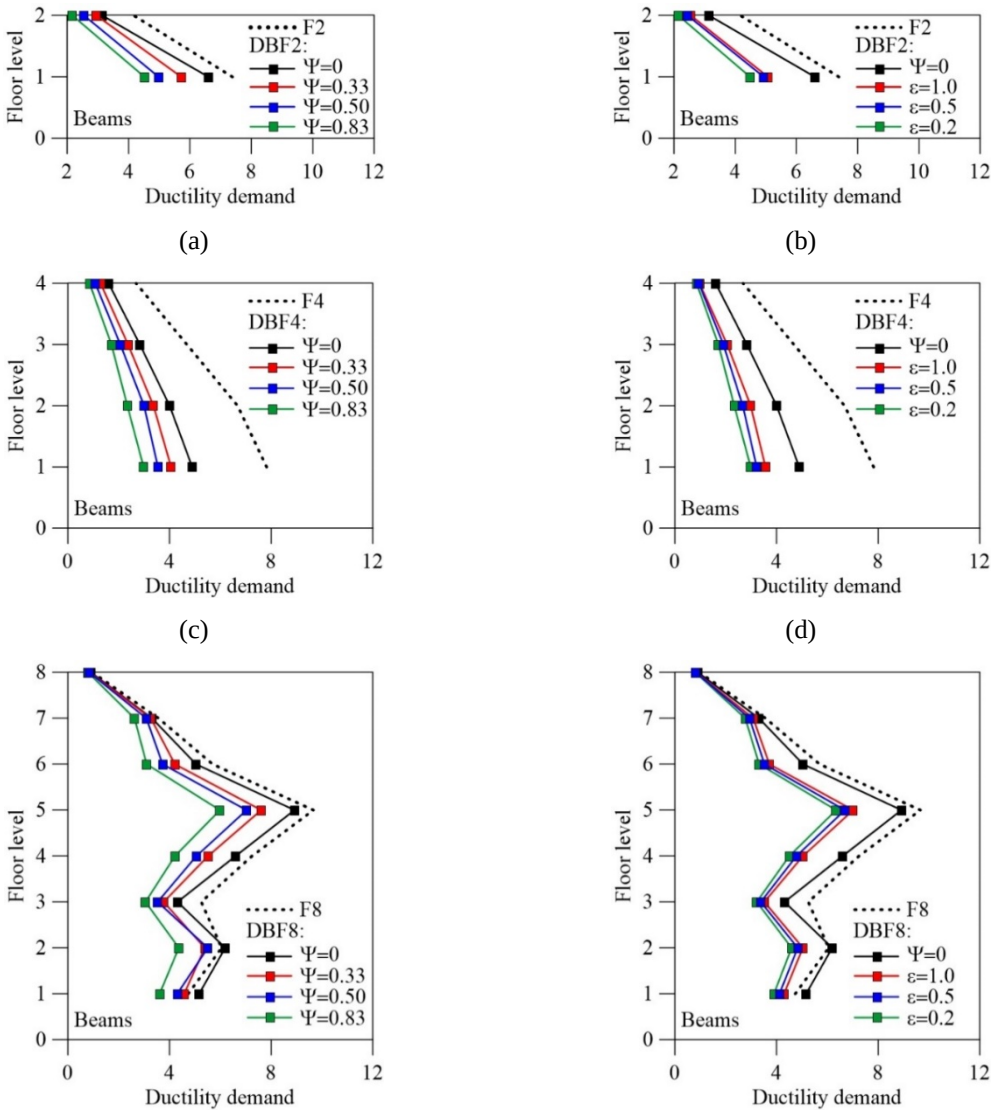

Figure 9: Local response of beams of retrofitted structures designed with and without degrading seismic response of original r.c. framed structures.

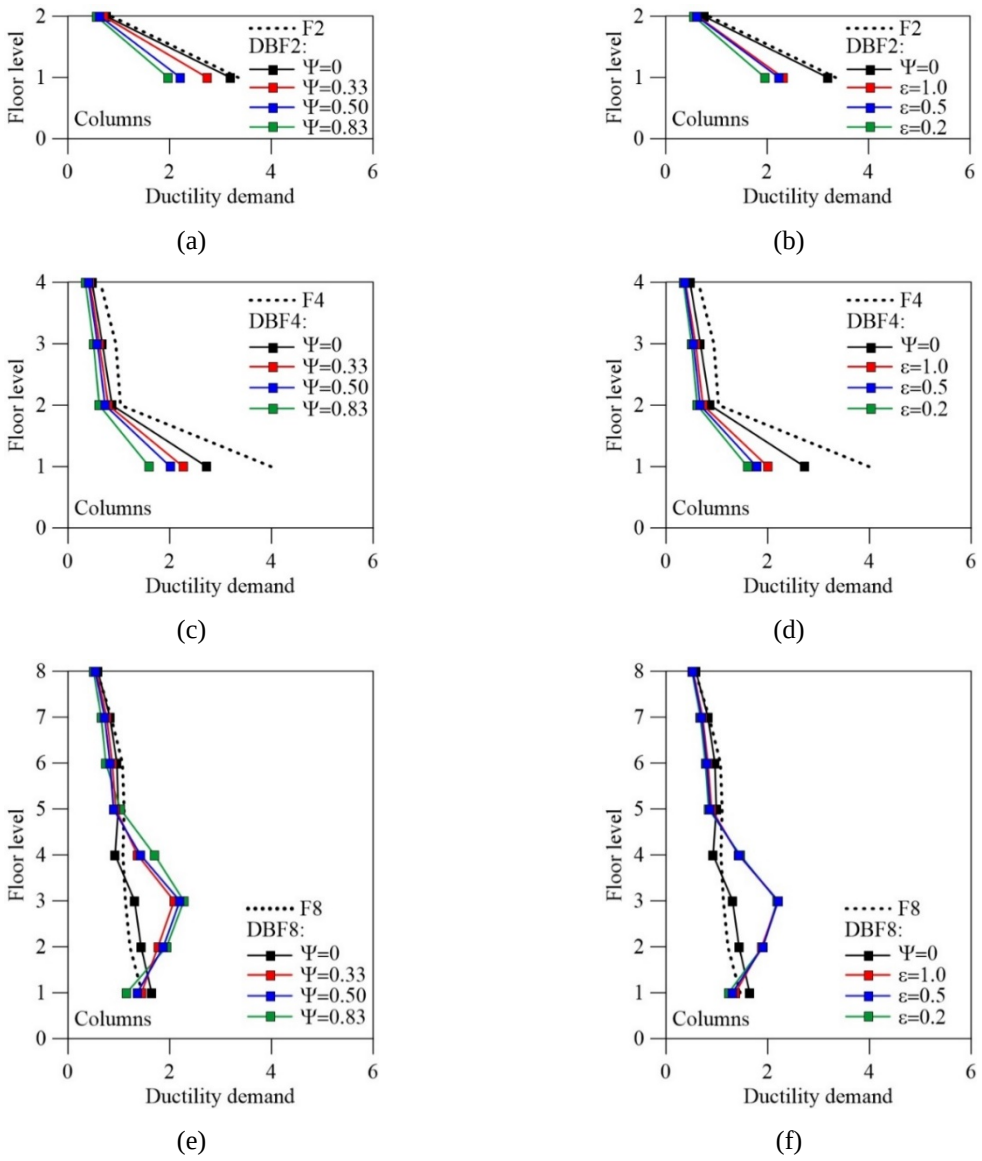

Figure 10: Local response of columns of the retrofitted structures designed with and without considering a degrading seismic response of original r.c. framed structures.

In particular, perimeter and interior frames in the Y direction are examined, assuming μ_F=1.5 combined with μ_D=15. The DBFi suffer collapse due to the attainment of the ultimate value on the ductility demand of HYDBs, before reaching inelastic capacity of r.c. frame members, while the Fi are characterized by a "strong-column weak-beam mechanism". The DBD procedure ensures notable reductions in the ductility demand of beams, for both increasing values of Ψ (Figures 9a,c,e) and decreasing values of ε (Figures 9b,d,f). Moreover, brittle failure phenomena do not occur, with maximum ductility demand of columns (Figure 10) which is always lower than that of the beams (Figure 9). A slight increase in ductility demand is observed for increasing values of Ψ, only for columns at lower storeys of the DBF8 (Figures 10e,f). This effect can be explained by observing that the DBFi are characterized by higher values of the axial load in the columns than the Fi, but the balanced compressive load is exceeded only at the lower storeys where ductility demand is increased. Finally, all design parameters being equal, the simplified DBD procedure (Ψ=0) leads to an overestimation of the ductility demand of r.c. frame members compared to the new DBD (Ψ>0) procedure.

5 CONCLUSIONS

A Displacement-Based Design (DBD) procedure is developed for retrofitting with hysteretic damped braces (HYDBs) a given framed structure, also considering the effects of degrading cyclic response of the r.c. frame members. Specifically, a piecewise linear approximation of the capacity boundary curve instead of initial backbone is adopted to obtain seismic capacity of the entire structure with reference to an equivalent nonlinear SDOF system. A combined plastic-damage (CPD) hysteretic model, resulting from an in-parallel combination of elastic-perfectly plastic (EPP) and elastic-softening damage (ESD) mechanisms, is adopted to describe the degrading hysteretic response represented by the capacity boundary curve. To verify the reliability of the DBD procedure, two-, four- and eight-storey r.c. framed buildings are retrofitted by sizing HYDBs in a high-risk seismic zone of the current Italian code. Six structural solutions are compared for each structure, considering: i) variable damper ductility combined with constant frame ductility; ii) variable frame ductility combined with constant damper ductility. Moreover, six design solutions are compared for each assortment of the design parameters, considering the cyclic envelopes corresponding to constant (i.e. Ψ=0.33, 0.5 and 0.83) and variable (i.e. ε=1.0, 0.5 and 0.2) values of the damage index. As a comparison, the results for the monotonic backbone curve (i.e. Ψ=0) are also examined. The seismic response from the nonlinear static analysis of the retrofitted structures confirms the effectiveness of the DBD procedure, especially for the low- and medium-rise framed buildings. Specifically, the shear strength capacity of the DBFi structures increases for increasing values of damage index Ψ and decreasing values of parameter ε. The opposite is observed for the lateral displacement capacity, where a significant overestimation is obtained assuming Ψ=0. Moreover, the DBD procedure makes it possible to obtain notable reductions of local ductility demand, for both increasing values of Ψ and decreasing values of ε, unlike the simplified DBD procedure corresponding to Ψ=0, leading to an overestimation of the ductility demand of r.c. frame members. As a final remark, special attention to the degrading cyclic response of r.c. frame members is advisable for a successful retrofit with HYDBs.

Abstract

Bond related failures still pose a significant threat to the structural integrity of an increasing number of aging reinforced concrete structures. An accurate theory-based method for determining detailing parameters of a lap splice is not yet available. For this reason, modern codes are still relying on semi-empirical formulas for describing the bond behavior of bars in anchorages or splices. The most recent design recommendations are that of Model Code 2010 (MC 2010), which have already been used as the basis for the draft revision of EN 1992 to be published in 2023. Experience has shown that the application of MC 2010 provisions can lead to even longer laps compared to those required by EN 1992 (2004). In this paper, a comparison of the key available design models for determining the tension lap strength will be presented, focusing mainly on the influence of the internal transverse reinforcement (stirrups) present within the lap length. Conclusions regarding the shortcomings of the available design models will also be made.

Keywords: Reinforced Concrete, Bond Strength, Lap splices, Design Codes & Models, Transverse Reinforcement.

1 INTRODUCTION

Bond is one of the key interaction mechanisms between concrete and reinforcing bars that ensures proper structural performance of reinforced concrete structures. This has been widely known since the early stages of reinforced concrete design, as demonstrated by a very rich scientific research and some relevant design provisions included in the earliest available Design Standards (as early as 1966 by ACI and 1978 by CEB-FIP). The most recent codified design recommendations can be found in Model Code 2010, while the latest background data and design methods' development are presented and discussed in ACI 408R-03 and fib Bulletins N^o 10 (more detailed) and N^o 72 (more recent).

Two critical steps in the research history of bond were: a) the development of "local" bond stress–slip (τ-s) relationships (calibrated using experimental data), and b) the recognition and differentiation of the two possible failure modes, that of splitting (SP) and pull-out (PO), depending on whether or not the concrete cover splits. Bars in unconfined (or passively confined, by concrete cover and stirrups) concrete usually fail by splitting of the surrounding concrete, while bars in actively confined concrete fail by being pulled-out of the concrete (concrete is sheared on the surface defined by the ribbed profile of the bars). Passively confined bars may also fail with a pull-out failure mode depending on available cover and bar spacing. These two main assumptions, along with the following generic descriptive equation for bond strength, have been the subject of the most important scientific research in this field: $f_b=(\Delta\sigma_s A_b)/(\pi d_b l_b)$, where f_b: average bond stress over l_b, $\Delta\sigma_s$: change of bonded bar stress over l_b, A_b: cross section area of bonded bar, d_b: bar diameter, and l_b (or l_d later): bond (development) length.

Fiber reinforcement
Consolidation (vibration, construction related vibrations, revibration, etc.)

Table 1: Parameters affecting bond.

However, this last expression is a major simplification of the complex engineering problem of evaluating bond resistance. In reality, and contrary to earlier beliefs, bond strength is affected by many parameters and is not just a concrete material property (as it might be implied by the previous expression). ACI 408R-03 includes a detailed discussion on the major factors affecting bond and separates them in three main categories: structural characteristics, bar properties and concrete properties (see also Table 1). Although there is a general consensus regarding which parameters affect bond resistance, there have been significantly different scientific approaches and conclusions regarding the quantification of each parameter's influence.

Over the years, there have been many attempts to capture and explain all key aspects of the problem, with researchers relying on different type of models. Earliest attempts used simplified force equilibrium models on a plane perpendicular to the axes of the bonded reinforcement. In this way, bond-slip relations could not be applied. Alternatives have been also proposed based on kinematic relations between longitudinal bar displacements (slip) and radial displacement (dilatancy) of surrounding concrete. Both types of models were semi-empirical. Some purely analytical attempts have been made, but their accuracy and applicability is questionable since they are usually based on pull-out failure modes and tend to estimate bond behaviour only along the axis of the longitudinal reinforcement. More recently, numerical models offering full three-dimensional assessment of the bond mechanism have been developed. However, their calibration has been proved to be too complex and unreliable for routine design, limiting their applicability.

In most practical applications of lap-splices in columns or beams, splitting is the governing failure mode. The presence of transverse reinforcement within the lap-splice length can potentially increase the RC member's bearing capacity by increasing the bond strength and limiting the splitting crack width. Previous works by the authors (see Chronopoulos et al. 2012, Chronopoulos & Tassios 2013, Chronopoulos et al. 2016) have shown differences in that relevant design code provisions. In this paper, some key design models will be shortly presented and compared in terms of their estimation of the transverse reinforcement influence on bond strength and lap-splice performance in general.

2 INFLUENCE OF TRANSVERSE REINFORCEMENT

Tepfers (1973) and Orangun et al. (1977) has already established that legs of transverse reinforcement crossing the splitting crack can enhance bond behaviour by delaying crack progression and increasing the bar stress required to cause failure. In this sense, transverse reinforcement acts in a similar way with confining pressure (due to a different source), which if sufficiently high may lead to a pull-out type of failure (instead of a splitting one). It is rather obvious, that once pull-out failure is ensured, the effectiveness of additional transverse reinforcement is significantly reduced (or even becomes negligible).

Most of the available design models agree that the additional contribution of confining reinforcement to bond shall be represented in the relevant expressions as summative (except Esfahani & Kianoush 2005, who represent it as multiplicative). Considering this, a simplified expression of the total bond force can be written as: $T_b=T_c+T_s$, where T_c: bond force due to concrete (without transverse reinforcement) and T_s: bond force due to transverse reinforcement. It is important here to highlight that according to Zuo & Darwin (1998, 2000) T_c is affected by the presence of transverse reinforcement. This study has shown that in order to achieve better correlation with test data, an effective value of bar clear spacing c_{si} (actually internal "side cover", greater that the actual value, see Figure 1) shall be used in the relevant expression and taken equal to: $c_{si,eff}=1.6c_{si}$. However, for bars with transverse reinforcement, better match is achieved by using a reduced value for the effective bar spacing equal to: $c_{si,eff}=$

c_{si}+0.25in (c_{si}+6.4mm), still greater that the clear distance between bars (c_{si}). As a general conclusion, the influence on T_c is small, but measurable.

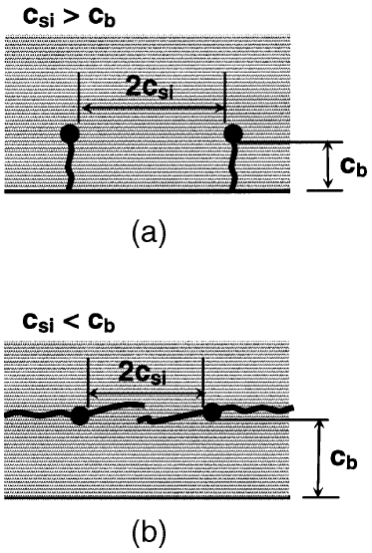

Figure 1: Bond cracks according to ACI408R-03: (a) $c_{si} > c_b$; and (b) $c_{si} < c_b$.

The two most important parameters that determine the transverse steel contribution to the total bond force T_s are the area of reinforcement crossing the potential crack planes A_{st} and the effective transverse reinforcement stress. Values of A_{st} can differ even for the same transverse reinforcement arrangement (same number of legs) depending on concrete cover and bar spacing (which affect splitting crack patterns, see also Chronopoulos et al. 2012). Different researchers have proposed various expressions that also consider other factors, which amongst others include concrete strength, bonded bar size and deformation properties (relative rib area), and yield strength of reinforcement (see also next paragraph). An increase in either bar size or relative rib area (rib size and spacing) leads to an increase in the wedging action exerted by the slipping bonded bars to the transverse reinforcement. This effect produces transverse dilatancy and mobilises tension stresses into the confining reinforcements, that causes an increase to the clamping force acting on the bonded bars.

It is worth noting that contrary to earlier beliefs, it has been observed during a lot of experimental studies that in such cases transverse reinforcements rarely yields. This observation is clearly stated in ACI408R-03 and is based on the studies of Maeda et al. (1991), Sakurada et al. (1993), and Azizinamini et al. (1995). The authors are also in support of and have already offered further justification for this opinion, even in zones with high shear forces. The relevant test results presented in Chronopoulos & Tassios (2013) and Chronopoulos et al. (2016), including monitoring of internal stirrups and external jacket strains, have shown maximum values of hoop strains of approx. 1‰ for stirrups. This observation raises some serious concerns about earlier works of e.g. Orangun et al. (1977) and Giuriani et al. (1991, see also Figure 2), which rely on transverse steel yield strength and both have influenced past design code provisions.

Fib Bulletin No 72 (2013) also highlights one other issue regarding the calibration of some key available semi-empirical models for estimating bond strength: “all have been calibrated based on test results of a data base where the majority of the tests were on specimens with no confining reinforcement (crossing potential splitting planes). The additional contribution from confining reinforcement was then estimated from the difference between strengths obtained

from otherwise identical specimens with confining reinforcement". This observation proves that at least a verification (if not a new calibration) of these expressions is required based on tests specifically designed for this purpose.

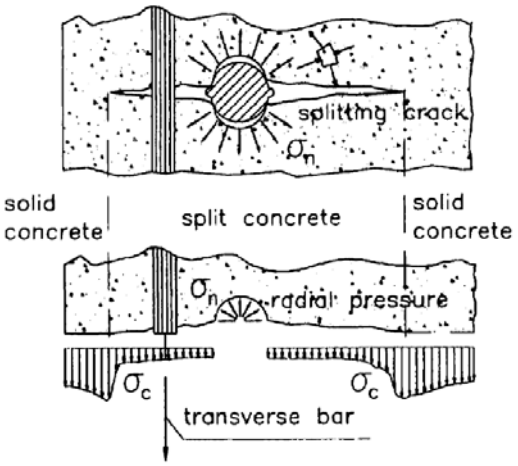

Figure 2: Splitting crack and confining actions around a ribbed bar according to ACI408R-03.

3 BOND MODELS CONSIDERING TRANSVERSE REINFORCEMENT

As already discussed in previous paragraphs, an accurate theory-based expression for calculating the additional bond resistance offered by the presence of transverse reinforcement is not yet available. In the following, a comparison of the key available semi-empirical design models is made, along with a short commentary of the major affecting parameters. This paragraph concludes with a short parametric study of the transverse reinforcement's influence to bond strength .

3.1 Orangun et al. (1977)

Orangun et al. developed their model for estimating the total bond force $T_b=T_c+T_s$ (expressed in relation to $\sqrt{f_c}$, see next sub-paragraph) using statistical analyses on a data base consisting of 62 specimens. Their model assumes that splitting failure governs (see Eq. 2) and that transverse reinforcement yield strength is mobilised (see relevant discussion in §2).

$$T_s/\sqrt{f_c} = [(\pi l_d A_{tr})/(41.5sn)]f_{yt} \quad (1)$$

$$1/d_b[c_{min}+0.4d_b+(l_d A_{tr})/(10.34sn)]f_{yt} \leq 2.5 \quad (2)$$

where: c_{min}: minimum concrete cover, A_{tr}: area of transverse reinforcement normal to the plane of splitting, f_{yt}: yield strength of transverse reinforcement, s: spacing of transverse reinforcement, and n: number of bars developed or spliced at the same location. The development length expression first incorporated in ACI318-95 was based on this study.

3.2 Darwin et al. (1992)

Darwin et al. (1992) reanalysed the data used by Orangun et al. (1997) and incorporated the effect of the relative maximum and minimum concrete cover (c_{max}/c_{min}), which however didn't affect the transverse reinforcement's influence. Eventually they also expanded the relevant database to include 133 specimens without and 166 with confining reinforcement. These additional data showed that a better for could be achieved by expressing T_b in relation to $f_c^{1/4}$,

compared to $\sqrt{f_c}$ used by Orangun et al. (1977). One new addition was the factors accounting for the influence of relative rib area and bar size, which can be seen in Eq. 4 and 5, here below:

$$T_s/f_c^{1/4} = 53.3t_rt_d(NA_{tr})/n+1019 \quad (3)$$

$$t_r = 9.6R_r+0.28 \quad (4)$$

$$t_d = 0.028d_b+0.28 \quad (5)$$

$$1/d_b[(c_{min}+0.5d_b)(0.1c_{max}/c_{min}+0.9)+(35.3t_rt_dA_{tr})/(sn)] \leq 4.0 \quad (6)$$

where: N: number of transverse stirrups (or ties) within the bond length, t_r, t_d: relative rib area and bar size (respectively) influence factors, and R_r: relative rib area, equal to: R_r = (projected rib area normal to bar axis) / (nominal bar perimeter x center-to-center rib spacing).

3.3 Zuo and Darwin (2000)

Zuo and Darwin (2000) further increased the data base, adding mainly specimens with high-strength concrete (f_c > 55 MPa). Their data base comprised of 171 specimens without and 196 with transverse reinforcement. They concluded that $f_c^{1/4}$ indeed offered a better representation of the effect of concrete compressive strength to the bond resistance of bars not confined by transverse reinforcement, as observed by Darwin et al. (1992). However, their calibration also proved that the use of $f_c^{3/4}$ in estimating T_s offered a much better fit for bars with confining reinforcement, based on below expressions:

$$T_s/f_c^{1/4} = [9t_rt_d(NA_{tr})/n+744]\ f_c^{1/2} \quad (7)$$

$$t_r = 9.6R_r+0.28 \quad (8)$$

$$t_d = 0.03d_b+0.22 \quad (9)$$

$$1/d_b[(c_{min}+0.5d_b)(0.1c_{max}/c_{min}+0.9)+(6.26t_rt_dA_{tr})/(sn)f_c^{1/2}] \leq 4.0 \quad (10)$$

3.4 Eligehausen & Lettow (2006)

Eligehausen and Lettow (2006) proposed an expression to calculate the average bonded bar stress f_{stm} (Eq. 11). A slightly modified version of this expression was finally included in Model Code 2010 (Eq. 12), which also followed the format proposed by Canbay & Frosch (2005). This expression was based on a data base of approx. 850 tests, which was created by supplementing the database of ACI Committee 408 (used in the previous studies) with additional data from mainly European and a few Asian scientific programs. It is a rather extensive database, including both anchorages and lap splices, with or without transverse reinforcement. The first part of this expression (Eq.12) represents the bond strength for some base reference conditions of confinement: minimum cover equal d_b, bonded bar spacing equal to $2d_b$, and no confining reinforcement. The second part of their expression (the one enclosed in the square brackets) modifies the reference bond strength to account for its enhancement due to concrete cover and transverse reinforcement.

$$f_{stm} = 24.2(f_c)^{0.25}(20/d_b)^{0.20}(l_d/d_b)^{0.55}(c_{min}/d_b)^{0.33}(c_{max}/c_{min})^{0.10}[1+10K_{tr}] \quad (11)$$

$$f_{stm} = 54(f_c/25)^{0.25}(20/d_b)^{0.20}(l_d/d_b)^{0.55}[(c_{min}/d_b)^{0.25}(c_{max}/c_{min})^{0.10}+k_mK_{tr}] \quad (12)$$

$$T_s = [54(f_c/25)^{0.25}(20/d_b)^{0.20}(l_d/d_b)^{0.55}k_mK_{tr}]\pi d_b^2/4 \quad (13)$$

where: c_{min}=min{(clear bar spacing)/2, top/bottom or side cover} and c_{max}=max{(clear bar spacing)/2, side cover}. The effectiveness factor k_m can be equal to 12 or 6 for confinement by legs of links perpendicular to the splitting plane or by straight bars inside the cover, respec-

tively, or 0 for other circumstances. $K_{tr}=n_t A_{st}/(n_b d_b s_t) \leqslant 0.05$, where n_t: number of transverse reinforcement legs intersecting the potential failure plane, A_{st}: one transverse reinforcement leg cross section area, s_t: longitudinal spacing of transverse reinforcement, and n_b: number of pairs of spliced bars in the failure plane. The relevant expression is valid for: $f_{stm} \leqslant f_y$ and $f_{stm} \leqslant$(2.5 or 1.25)$\sqrt{f_c}4(l_b/d_b)$ for good or bad bond conditions, respectively, 15 MPa$<f_{cm}<$110 MPa, 0.5$<c_{min}/d_b<$3.5 and 1.0$<c_{max}/c_{min}<$5.0.

3.5 Mancini et al (2018) and Vollum & Goodchild (2019)

Mancini et al. (2018) performed a consistent calibration based on a Monte Carlo method for the reliability assessment of the semi-empirical model of Eligehausen & Lettow (2006), in the form that is included in Model Code 2010. The purpose of their study was to formulate design lap-splice and anchorage length expressions according to a specific level of reliability (compliant with EN 1990). Their work proved that at Ultimate Limit State (ULS), EN 1992 tends to be unsafe for high values of longitudinal reinforcement stress f_{stm}, while Model Code 2010 is too conservative when low levels of f_{stm} should be transferred (see also Figure 3 here below).

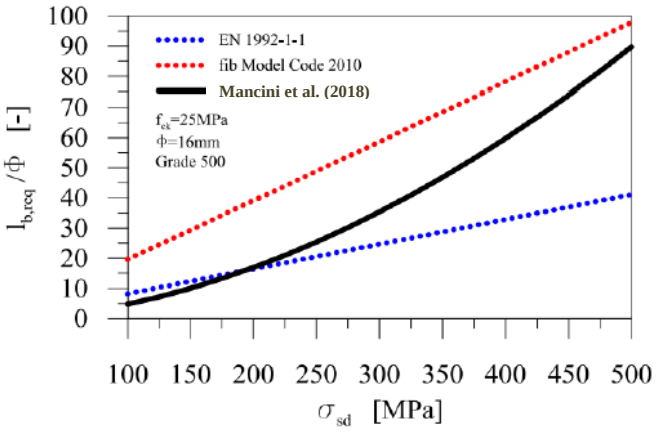

Figure 3: Comparison of Mancini et al (2018) to EN 1992 and Model Code 2010 provisions, according to Gino et al. (2018); Note: $\sigma_{sd} \approx 0.67\ \sigma_{sm}$ (or f_{stm} in this paper).

Vollum et al. (2019) expanded on this previous work, statistically investigating further the relevant Model Code 2010 expression and separating the database into four stress bands based on the measured bonded bar stress $f_{st,test}$: $f_{st,test} <$ 300 MPa, 300 $< f_{st,test} <$ 400 MPa, 400 MPa $< f_{st,test} <$ 500 MPa, 500 MPa $< f_{st,test}$. Each stress range was analysed separately based on the same procedure followed by Mancini et al. (2018). Based on this effort, Vollum & Goodchild were able at the end to calibrate a design expression focused on test results with $f_{st,test}$ values close to 435 MPa (design yield strength of modern steel reinforcements). This expression could be used to support a design method less conservative than the one included in Model Code 2010, but with a suitable reliability level that could be considered for the revision of EN 1992 to be published in 2023 (see also Vollum & Goodchild 2018 for more details on the development of their proposed design method). Based on this separation, they proposed a modified version of Eq. 12 with different probabilistic coefficient ζ_j for each stress range, which if expressed in terms of average bond strength f_{bj} (where j=m: mean, j=k: characteristic, or j=d: design) can be written as:

$$f_{bj} = 2.44\ \zeta_j^{1.82}\ (f_c/25)^{0.45}(20/d_b)^{0.36}[(c_{min}/d_b)^{0.25}(c_{max}/c_{min})^{0.10}+k_m K_{tr}] \quad (14)$$

$$f_{bm} = 2.8\,(f_c/25)^{0.45}(20/d_b)^{0.36}[(c_{min}/d_b)^{0.25}(c_{max}/c_{min})^{0.10}+k_m K_{tr}] \quad (15)$$

$$T_s = [2.8(f_c/25)^{0.45}(20/d_b)^{0.36}k_m K_{tr}]\pi d_b l_d \quad (16)$$

where for $\sigma_{sd} > 435$ MPa, the bond strength should be multiplied by $(435/\sigma_{sd})^{0.82}$, and or $\sigma_{sd} \leq 435$ MPa, bond strength is independent of reinforcement stress, which is unlike the expression used by Mancini et al. (2018) and Eligehausen & Lettow (2006).

4 COMPARISON OF DESIGN MODELS

In Table 2 here below, the parameters affecting the transverse steel contribution to the transverse steel attributed bond force T_s according to each key design model are summarised. A first generic comment on the relevant expressions is that over time researchers have tried to produce more detailed expressions, with individual coefficients and exponents applied to each parameter (e.g. Eligehausen & Lettow 2006), compared with earlier approaches, where a simple theory-based expression was used along with just a few generic experimental correction coefficients (e.g. Orangun et al. 1977). There is also a general agreement on the way that the influence of the transverse reinforcement is estimated, based on the reinforcement area that crosses the potential splitting crack planes. However, there are two main differentiations: a) In earlier models (Orangun et al 1977 to Zuo & Darwin 2000), the total reinforcement area within the bond length is considered by using the ratio of l_d/s or N (see §§3.1 to 3.3), compared to Eligehausen & Lettow (2006), where K_{tr} is calculated based on the number of stirrup legs within the stirrups' spacing (s). This may lead to further differentiations between estimations when the stirrups' spacing is not constant all along the bond length e.g. lap splices longer that the critical regions of columns. b) Eligehausen & Lettow (2006) introduced an effectiveness coefficient k_m, which quantified the widely-accepted common knowledge that poorly detailed and arranged transverse reinforcement may offer no enhancement at all (k_m can take values as low as zero, see §3.4).

Table 2: Parameters affecting transverse reinforcement influence to bond strength considered by each design model; Note: see §3 for parameters' description.

In Figures 4 and 5 here below, the results of a short parametric investigation on the influence of the area of transverse reinforcement is presented. These diagrams were produced using the equations presented in §3, which were solved for T_s (in kN) under the following conditions: R_r=0.056 (typical for B500C rebars with d_b>12mm), d_b=20mm, f_c=25MPa, f_{yt}= 500MPa, and l_d=20d_b or 30d_b. For this comparison, the Eligehausen & Lettow (2006) design

model is used in the form included in Model Code 2010. Eq. 1, 3 and 7 where transformed so that an equivalent parameter to K_{tr} of Eq. 16 could be incorporated in order to make all these equations easily comparable. For this transformation it was assumed that $[K_{tr}]_{Eq.16} = [A_{tr}/(snd_b)]_{Eq.1,3,7}$ and $N = l_d/s$. This analysis show that over time the latest scientific evidence follow a trend in reducing the contribution of passive confinement by transverse reinforcement to bond strength (see e.g. differences between Orangun et al. 1977 and Zuo & Darwin 2000). Contrary to that trend, Eligehausen & Lettow (2006) proposed a model with relatively increased values of additional bond strength due to stirrups, but later studies by Mancini et al. (2018) and Vollum et al. (2019) has proven that a more comprehensive reliability analysis of the same expression, along with a separation of the available database into a stress range closer to modern reinforcement yield strengths (400 to 500 MPa), can lead to less conservative but adequately safe and reliable design provisions.

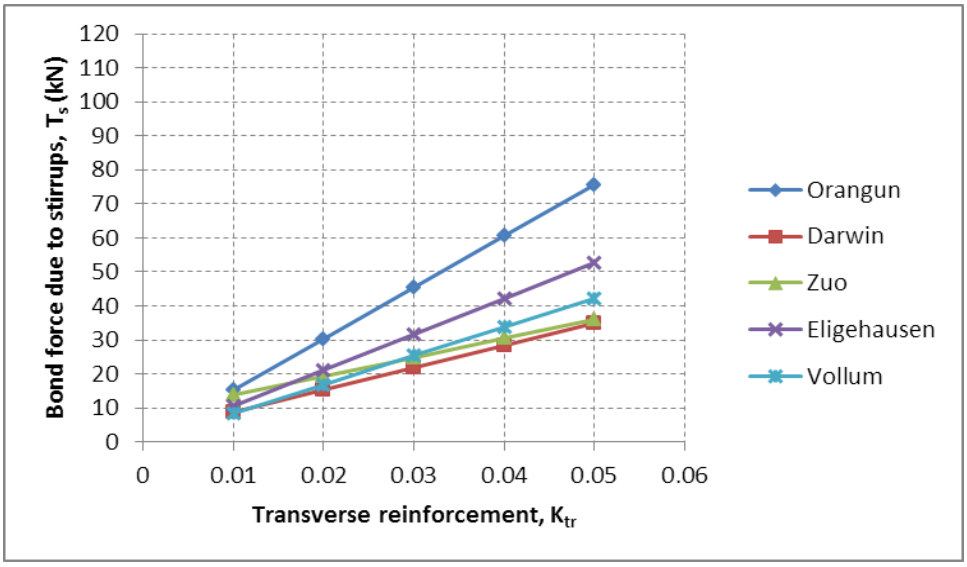

Figure 4: Comparison of the influence of K_{tr} to bond force due to transverse reinforcement for an available bond length of $20d_b$.

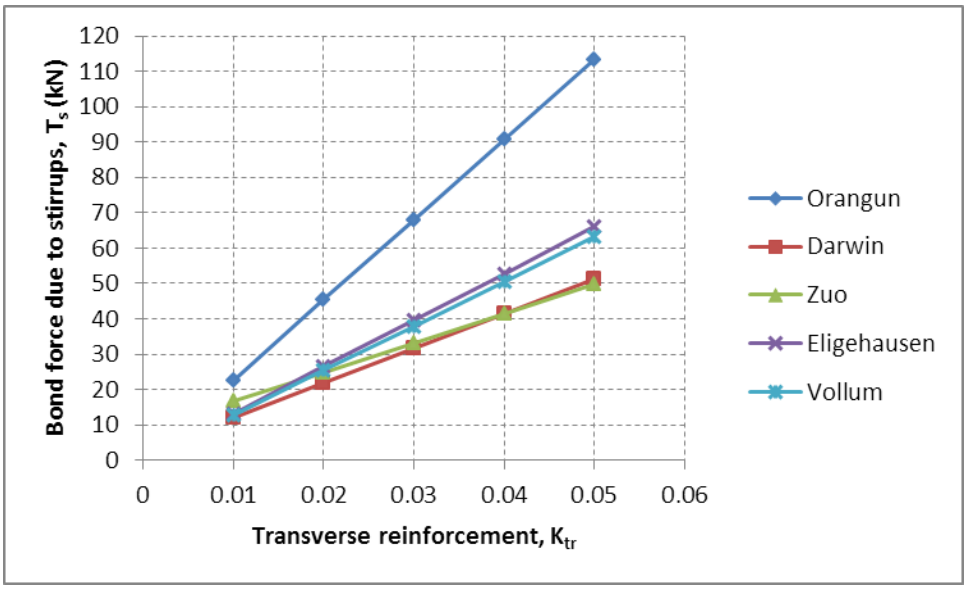

Figure 5: Comparison of the influence of K_{tr} to bond force due to transverse reinforcement for an available bond length of $30d_b$.

5 CONCLUSIONS

Contrary to past scientific knowledge and design codes, nowadays it is widely accepted that the strength of anchorages and lap-splices can be described by the same expressions. For example, today we know that lap-splices do not generate twice the splitting (bursting) force compared to that of an "equivalent" single bar anchorage, as it was predicted by the earlier "hydraulic pressure" physical models. In the last 30 or 40 years, a lot of relevant research was performed, with a lap considered as an almost "double" (in the past, see Model Code 1990) to an almost "single" anchorage (recently, see Model Code 2010), depending on a number of parameters. This shift of the Codes to a more uniform approach regarding both anchorages and lap-splices has been discussed, amongst others, by the authors in Chronopoulos et al. (2012), including a more detailed presentation of design code provisions. One of the conclusions of that study was that almost every 10 years lap-splice related factor values (e.g. the one for percentage of reinforcement lapped in one section) have been gradually reduced to approx. 1,1 (coming closer to the bond resistance of a single bar anchorage). In the present paper, a more detailed comparison of the progression of bond strength estimation models over the past 40 years was presented, focused mainly on the influence of the internal transverse reinforcement. Based on the previous discussion and observations, the following conclusions can be made:

- There is a general consensus that splitting is the governing failure mode in virtually all practical applications of anchorages or lap-splices without active (external) confinement.
- Most recent approaches suggest that the influence of passive confinement, by concrete cover and transverse reinforcement (stirrups, ties, secondary reinforcement, etc.), can be estimated as an enhancement to a basic bond strength corresponding to some minimum confinement conditions.
- Although theoretically reasonable, influence of rib area is excluded by most recent design models (Model Code 2010), mainly due to the relative scarcity of comprehensive test data and reliable calibrations. The opinion of Task Group 4.5 that produced Model Code 2010 argues that rib area has only a modest impact in the presence of some minimum confinement.
- On the other hand, since the early '90s it has been established that both bar size effects and relative maximum and minimum concrete cover affect passive confinement.
- There is an obvious effort to supplement the available bond strength databases with tests on specimens with transverse reinforcement crossing the splitting crack plane, as opposed to earlier design code expressions (e.g. Model Code 1990) which were based on databases that predominantly contained bond strength tests on unconfined bars with short bond lengths.
- As a general conclusion, the most recent scientific investigations of bond strength have shown that there is still room for considerable improvement of the available design code provisions.

Abstract

The lack of effective connections between sets of perpendicular walls often determines the local or global failure of heritage structures in case of seismic event. In order to address this problem, the paper focuses on retrofitting systems for masonry structures undergoing seismic load. Particularly, it concerns the behavior of two different types of anchoring stabilization systems that avoid the out-of-plane collapse mechanism of a masonry wall and restore the box-like behavior. The response of the corner connection between two walls was investigated by numerical simulations. Initially, the model was tested in its original configuration to determine the type and the extent of the failure mode when a base acceleration is imposed. Afterwards, a traditional steel anchoring system was implemented in the corner connection to prevent the relative detachment of the walls for the same seismic input. Finally, a friction-based dissipative device was added to the steel ties to provide ductility to the system by allowing for a controlled relative displacement of the walls and reducing the concentration of stresses. The computational analysis showed that implementation of a dissipative device integrated with traditional steel anchors is effective in delaying the complete failure of the anchoring system. Moreover, it provides energy dissipation capacity through controlled displacement, reducing the stress in the surrounding material and allowing the model to withstand a larger intensity input.

Keywords: Dissipative devices, Friction, Masonry, Energy Dissipation

1 INTRODUCTION

In the last decades, a variety of systems able to dissipate seismic input energy has been designed, enhancing the global response of structures in earthquake prone areas [1] [2]. Historic buildings represent a singular case: the implementation of systems based on the modern concept of ductility and energy dissipation is often in contrast with the limitations promulgated to protect the aesthetic and structural integrity of architectural assets. Therefore, the common retrofitting practice still relies on traditional techniques of intervention and historic centres are still considerably affected by earthquakes [3] [4].

It is recognised that poor-quality connections between orthogonal structural elements greatly affect the dynamic performance of heritage masonry structures causing the relative detachment of masonry panels and ultimately the out-of-plane failure of the structure [5]. A way of tackling this issue is to insert steel cross-ties at the corner of two perpendicular walls in order to restore the box-like behaviour and distribute the seismic forces through all the resisting elements. This practice is not exempt from drawbacks, as the increased local stiffness at the corners might lead to high-stress concentration in case of seismic events and consequently to severe damage to the valuable parent material in which the cross-ties are embedded [6].

Therefore, in the last decades alternative systems have been developed to provide energy dissipation capacity to heritage structures, in line with the modern principle of performance-based design. This approach optimizes the structure for different seismic action level, encouraging the use of devices able to provide ductility by shifting the response of the structure from the elastic-only range to an elasto-plastic one [7].

These innovative systems are tailored for historic masonry structures as they reflect the conservation principles enshrined in international and national guidelines such as the ICOMOS/ISCARSAH principles [8] and the Italian DPCM 2011 [9]. According to these documents, the benefits of possible upgrade interventions in terms of seismic performance must be weighed against the impact on the original aesthetic and structural authenticity of the building. A variety of systems are available [10],[11], [12], but technical codes are vague on design procedures and their implementation hardly follows.

The present work proposes an innovative dissipative anchoring system to improve the global response of historic structures to seismic events. The proposed friction-based anchoring system offers an innovative alternative to traditional systems for the repair and strengthening of heritage structures, using performance-based design principles, i.e. control of displacements and reduction of accelerations and concentration of stress. The innovative system comprises a friction device, shown in Figure 1a, connected to longitudinal stainless steel bars grouted within the thickness of the walls. The assembly is designed to be inserted at the connection between perpendicular walls (Figure 1b): the stainless steel profiles improve the box-like behaviour of the building, while the device allows for a relative displacements between orthogonal sets of walls and the dissipation of the seismic energy input to the structure. The system aims at preventing typical failure mechanism of reinforced and unreinforced masonry buildings under seismic loading, such as punching failure and excessive crack opening.

a) b)

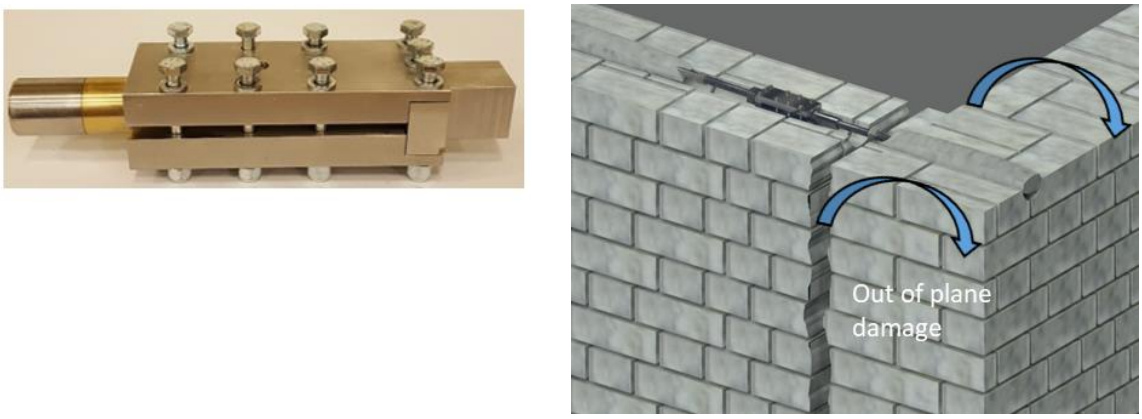

Figure 1: a) Patented design of the dissipative device, b) Insertion of the device at the connection between perpendicular walls (Paganoni 2015)

In the first part of this work, the experimental and numerical activities that led to the development and refinement of the dissipative device are presented. The experimental tests carried out on the device in its isolated configuration allowed for the identification of the meaningful parameters governing the functioning of the device. The dissipative anchoring system was then connected to a brickwork masonry specimen and tested under pseudo-static monotonic loading (pull- out test). The experimental activity demonstrate the beneficial effects of the dissipative anchoring system with respect to his strength-only counterpart.

Drawing on the experimental results, FE models were implemented using the commercial software Abaqus. The numerical simulations led to the refinement of the device's design to obtain a stable and repeatable behaviour. Moreover, the model allows simulating the response of the innovative system to a range of simulated inputs and provides information about the distribution of stresses both in the device and in the masonry wall.

A number of parameters have been analysed to determine which give the best results in terms of computational expediency and accuracy in respect to the behaviour of the laboratory samples.

In the second part of this work, the identified parameters feed in the model of a structure that is used to study the effect of standard and dissipative anchors ties on a larger scale. The building geometry provides a suitable case study as the analyses showed that it could be affected by local/global overturning damage of the walls in case of a seismic event. The model is used to predict the structural response in different scenarios, to guide future experimental activities and to fulfil the computational validation of the dissipative devices with respect to future applications to real case buildings.

2 THE FRICTION-BASED DISSIPATIVE ANCHORING SYSTEM

2.1 Optimization of the friction-based dissipative device

The design of the friction device draws on the Coulomb equation of friction:

$$F_{//} = n\,\mu\,F_{\perp} \tag{1}$$

Where $F_{\perp}$, the perpendicular force, represents the force transferred from the external plates to the internal slider by tightening two lines of bolts that pass through the assembly as shown in Figure 2. The friction force resisting the sliding motion is the combination of the perpendicular force, the friction coefficient, μ, and the number of surfaces in contact, n . The relative motion between the slider and the plates is initiated when the force acting in their own plane, $F_{//}$, exceeds the static friction force. Finally, a steel pin inserted in the device limits the sliding run of the internal part. Figure 2 shows in detail the elements composing the final design and the way the bolt load is transferred.

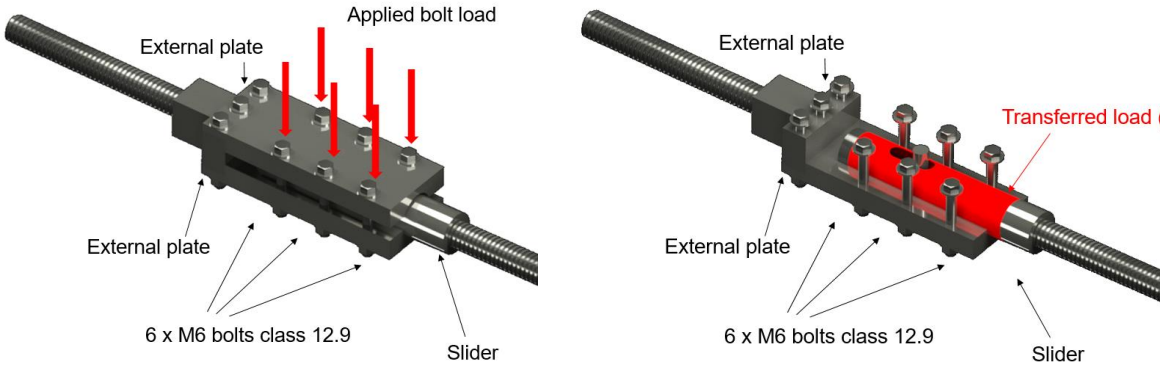

Figure 2: In friction-based device the force is transferred to the internal slider by tightening two lines of bolts

The validation process of the dissipative anchoring system is carried out through experimental and computational activities. Starting from the friction-based device developed by D'Ayala and Paganoni within the partnership between Cintec International and the University of Bath [13], the design was refined on the basis of experimental results conducted at University College London under a new collaboration agreement [14]. The fatigue tests conducted on the initial prototype had shown that the ratio between slip load and applied perpendicular force (Φ) significantly increases with the number of cycles. This variation is mainly caused by the wearing of the contact surfaces, which led to cold welding and interlocking phenomenon. Therefore, a detailed 3D FE model was developed in Abaqus FEA 6 .14 to achieve a more stable and reliable behaviour under cyclic loading. From the analysis of the stress distribution, it was concluded that a cylindrical shape for the sliding leads to a more homogeneous distribution of the shear stresses in the contact area. Figure 3 reports this evidence showing the larger contact area achieved by a cylindrical slider with respect to a squared one [14].

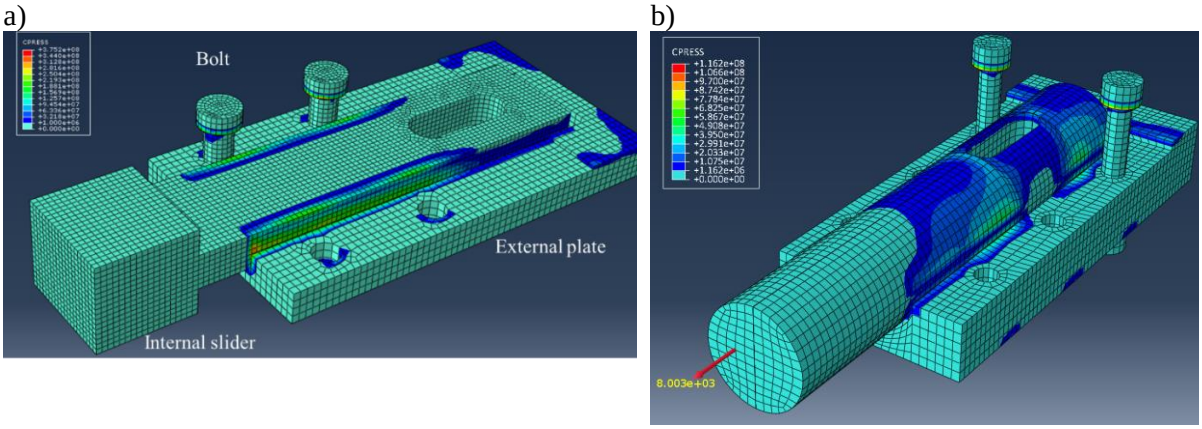

Figure 3: Numerical model: contact area a) of the initial prototype featuring a squared slider and b) of revised prototype featuring a cylindrical slider

2.2 Monotonic pull-out tests – Experimental and numerical analysis

A second experimental campaign aims at evaluating the behaviour of the dissipative device connected in series to a stainless steel bar grouted into a masonry panel. To this purpose a set of pull-out tests were performed to analyse the behaviour of a connection between two vertical elements, i.e. walls, strengthened by the dissipative anchoring system. The focus is on the performance of the anchor, and the damage caused to the wall perpendicular to the anchoring direction by the monotonic action of pull-out. The test set-up consists of the portion of stainless steel anchor embedded in a masonry panel perpendicular to the main seismic action, while the pulling action of the testing apparatus simulates the reaction of the anchor lying within the wall parallel to the main shock direction. Finally, the device is installed as add-on element between the grouted anchor and the pull-out jack as shown in Figure 4.

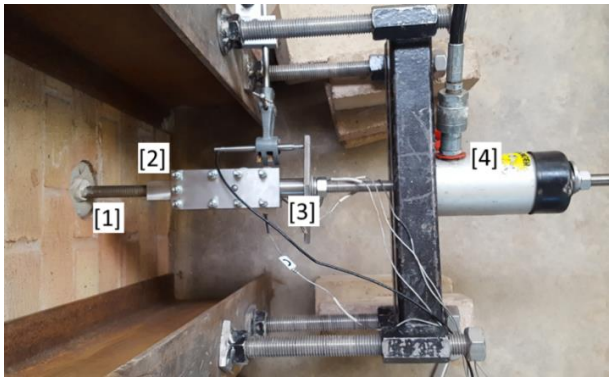

Figure 4: Description of elements composing the testing set up.

After visual inspection of the masonry panel, it was concluded that the devices can address some of the drawbacks that are identified for standard anchors, such as the presence of damage in the substratum, even for small relative displacement between the grouted anchor and the masonry. Conversely, the friction device improves the response of anchors, considerably reducing, or eliminating damage to the parent material. The activation load that initiates its sliding motion can be tuned to the point that almost no relative displacement is detected in the other elements of the anchor assembly.

A Finite Element model is implemented in Abaqus FEA 6.14 to understand the interaction between parent material and anchoring system. This is a central task of the validation process as the bond between the masonry and the grout determines the load at which the failure mode occurs. A numerical model of the dissipative device connected to a steel bar embedded in a masonry wall was generated, as shown in Figure 5.

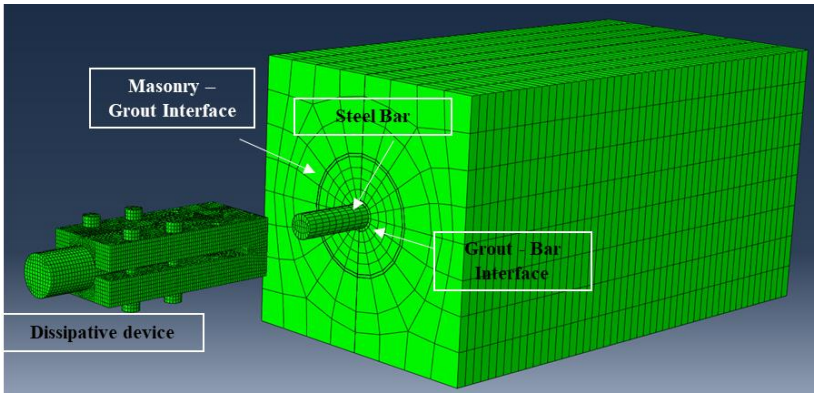

Figure 5: Numerical model – Undeformed shape and components of the model.

Three-dimensional volume elements were used for the mesh since an accurate stress distribution is relevant for a clear understanding of the stress field and of the structural behaviour. The motion of the steel bar is rigidly coupled to the device's end plate. The mesh discretization was defined to achieve a compromise between accuracy and efficiency. Brick elements (C3D8R, eight-node linear brick with hourglass control) are used for the mesh of all the parts, except for the simulation of the bond between different materials, where tri-dimensional cohesive elements (COH3D8, eight nodes in each surface) were used. The generated mesh includes 41309 nodes and 31111 elements.

According to the failure mechanism observed in the experimental activity, interface elements around the steel bar (inner interface) and between the grout and the masonry (outer interface) were included. The interfaces aim to simulate the bonding properties among the single components, i.e. the steel bar, the grout and the masonry. Abaqus FEA allows for the selection of cohesive elements to which a linear elastic traction-separation law before damage has been assigned. When the maximum traction resistance is reached, the interface elements display a progressive degradation, which is driven by a damage process. The numerical parameters defining the mechanical properties of these cohesive elements were calibrated to replicate the experimental behaviour of the sample under out-of-plane loading and reproduce the different failure mechanism.

The shear stiffness of the external interface is defined according to the pull-out tests performed on the specimens of anchors embedded in the masonry wall.. In order to define the traction-separation law that describes the behaviour of the cohesive interface, the values of maximum traction resistance τ_{max} and ultimate dispacement δ_{ult} need to be provided. On the basis of the experimental data, a mean value of F_{max}= 24 KN was considered to compute the maximum shear resistance τ_{max} :

$$\tau_{max} = \frac{F_{max}}{A_{interf}} = 0.29\ MPa \tag{2}$$

The change in stiffness exhibited by the anchors at a recorded displacement of 0.5mm determines the end-point of the linear correlation between the shear stress and the shear deformation. The Shear modulus (G) is therefore equal to:

$$G = \frac{\tau_{max}}{\gamma} = \frac{0.29}{0.25} = 1.16 \text{ MPa} \tag{3}$$

The pull-out tests performed on the anchor embedded in the masonry wall highlighted that the most likely failure was slippage of the bar-socket assembly, caused by the loss of adherence between the grouted socket and the surrounding material. Therefore, the ultimate displacement refers to the relative displacement of the grout with respect to the masonry at which the anchoring system is no longer able to provide any resistance to the pull-out force. According to the experimental data and crack propagation this value was assumed equal to δ_{ult} = 5 mm. The analytical curve implemented in the numerical model shown in Figure 6.

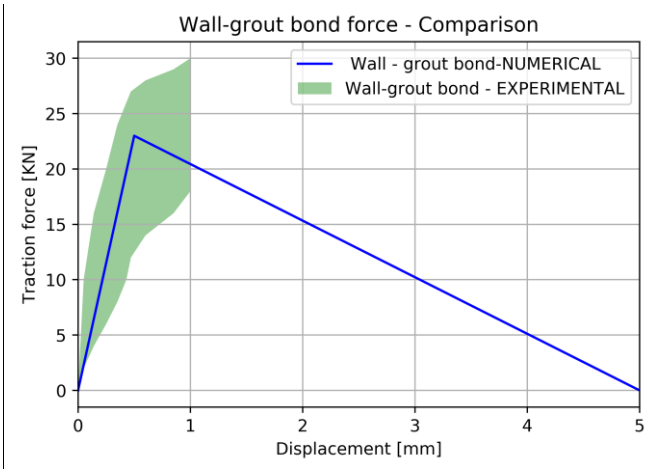

Figure 6: Comparison between the experimental envelope and the numerical analysis

Regarding the physical and mechanical properties of the grout and the steel, information from the technical sheet were used. Table 1 provides the mechanical properties adopted for the materials, as well as the parameters needed to define the traction-separation law for the interfaces.

Part	E	G1	τmax	displacement at τmax	Ultimate damage
	[Pa]	[Pa]	[Pa]	[m]	[m]
Wall	1.50E+09				
OUT Interface	-	1.16E+06	2.90E+05	5.00E-04	5.00E-03
INT Interface	-	2.00E+08	5.00E+07	5.00E-04	5.00E-03
Grout	3.00E+10				
Steel bar	2.10E+11				

Table 1: mechanical properties of model materials

The stress field attained in various parts of the model can be visualised through an analysis run setting a maximum displacement of 40 mm to the internal slider of the device. Figure 7 shows the failure of the outer interface caused by the imposed displacement.

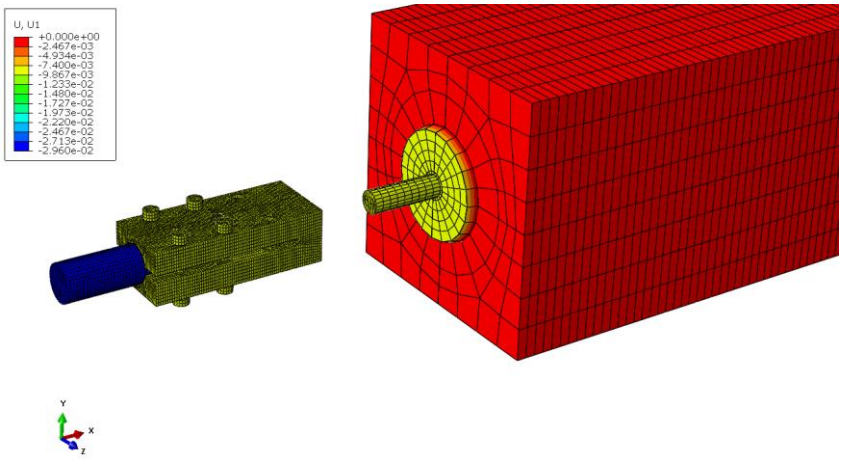

Figure 7: Numerical model – Deformed shape, failure at wall-grout interface.

In conclusion, the FE model of the pull-out test succeeds in replicating the bond failure between the parent material and the grouted element of the standard anchor, this being the failure mode that controls the performance of the whole assembly. The definition of a fictitious

part located between the grouted socket and the parent material and defined by traction-separation low is suitable for this purpose. The material properties of the fictitious part are defined on the basis of experimental results, creating an equivalent stress-strain curve compatible with the chosen failure criterion. Therefore, the numerical model tuned on the obtained experimental results can be considered good approximation of the physical test and can be used as a valid tool for the optimization of an upgrade intervention. Drawing on these conclusions, a second numerical model was developed to investigate the structural behaviour of a portion of an idealized masonry building under seismic loading.

3 FE MODELS OF AN IDEALIZED CASE-STUDY STRUCTURE

The positive outcome of the model of the pull-outs means that the modelling technique of fictitious parts and equivalent material curves can be applied to numerically describe the bonding capacity of a grouted anchor. The parameters identified for the pull-out model are applied for the model of a structure that is used to study the effect of standard and dissipative anchoring system on a larger scale. The analysed structure is composed of a front wall connected to two sidewalls representing an idealized portion of a masonry building with poor quality connection between adjacent walls. The geometry and dimensions of the subassembly are shown in Figure 8.

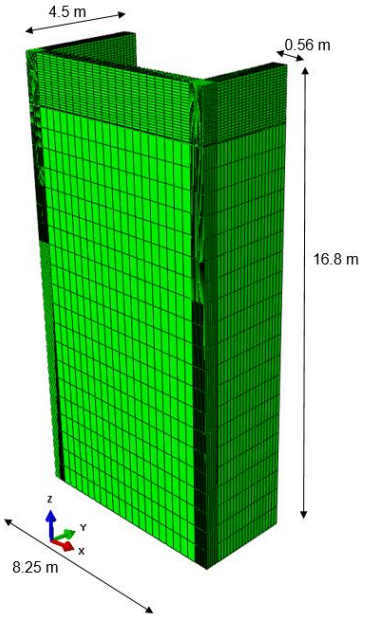

Figure 8: a) Dimensions of the analyzed corner connection

Modelling a smaller portion of the building allows for a more detailed analysis of the behaviour of the connection both in the unstrengthened and strengthened configuration. Three FE models are implemented: a first model represents the original structure, where the connection between the adjacent walls relies on their shear capacity only. A second model represents the structure when traditional grouted ties are inserted at the corner connection. In a last model, a friction-based dissipative device is implemented in series with the strength-only anchors to provide the connection with energy dissipation capacity. The response of the structure is evaluated imposing a seismic base acceleration in the out of plane direction of the front wall. The ground acceleration of the 2009 L'Aquila earthquake (Mw 6.3 main shock), as recorded at the station of L'Aquila – Valle Aterno (station code AQV) is used as input for the analysis. The walls are defined assuming that the mortar joints and brick units are smeared into

one isotropic material, with average mechanical properties according to the principle of macro-modelling [15].

3.1 The original structure

In the first model, the connection between cross walls relies on the equivalent traction resistance of a set of interfaces. An equivalent traction capacity is assigned to these interfaces in the direction of their thickness (T= 0.002m). This allows for the modelling of the shear resistance that opposes the out-of-plane loading that causes the wall's separation. If the external load exceeds the shear force the detachment of the adjacent walls is no longer prevented and the front wall experiences outward tilting. A traction-separation law is assigned to describe the mechanical constitutive behaviour of the interface. According to the Mohr-Coulomb criterion, the linear relationship between the shear strength τ and the normal compressive stress σ is given by the formula:

$$\tau = c + \sigma \tan(\varphi) \tag{4}$$

Where c denotes the cohesion and φ the angle of internal friction. For this study, the average cohesion and friction angle in the bed joints are respectively 0.35 MPa and 0.5 rad. The equivalent traction force ($F_{traction}$) is therefore the integral of the shear stress over the interface's area:

$$F_{\text{traction}} = \int \tau \, dA = \tau \cdot A_{interface} \tag{5}$$

$$\sigma_{\text{traction}} = \frac{F_{\text{traction}}}{A_{interface}} = \tau \tag{6}$$

Therefore for the purpose of this model the traction tress (σ) is equivalent to the the shear stress (τ). The shear stress linearly increases with the compressive stress, which means that the interfaces have higher equivalent traction resistance moving from the top to the bottom of the wall. The graph Figure 9b shows the values of equivalent traction resistance according to the location of the interfaces as measured from a control point (CP), referenced in Figure 9. To consider the damage evolution a post-damage effective separation at failure is defined and a coefficient of friction (μ) is specified to prevent components' penetration. Figure 9a shows the location of the upper cohesive interface with respect to the side and front walls.

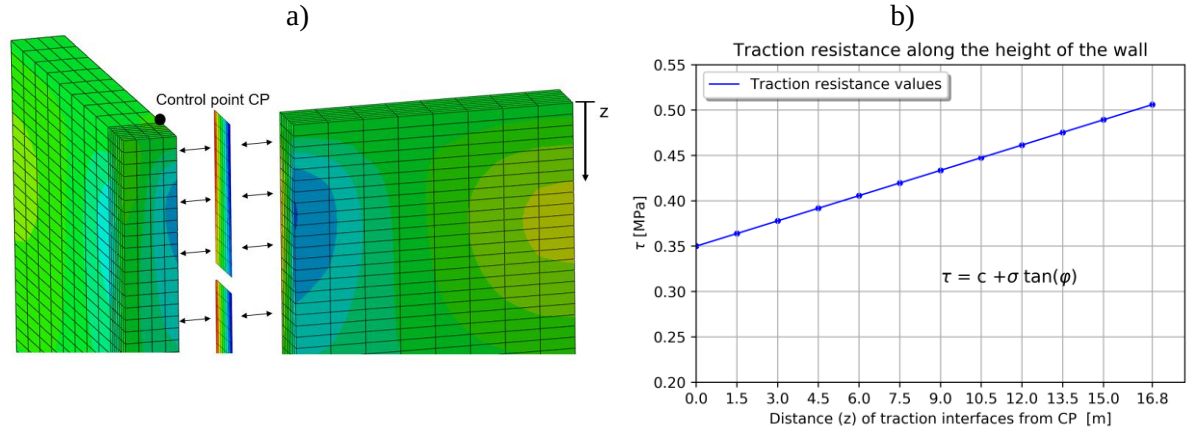

Figure 9: Model of unstrengthened walls: a) location of interface part with respect to walls b) Traction resistance of the cohesive interfaces along with the height of the wall.

As a result of the applied base acceleration shown in Figure 11a, the orthogonal walls separate when the strain in the direction of the interfaces' thickness (T) exceed the maximum strains defined by the traction-separation low. The strain limits depend on the maximum traction stress σ_{max} assigned to the interface according to Equation 4. The computation carried out to determine the ultimate shear resistance for the upper interface are:

$$F = K\,\Delta u = \frac{EA}{T}\,\Delta u \tag{7}$$

$$\sigma_{\text{traction}} = \frac{E}{T}\,\Delta u = \frac{E}{0.002}\,\Delta u = E\,\varepsilon \tag{8}$$

$$\varepsilon_{elastic} = \frac{\sigma_{\text{traction}}}{E} = \frac{3.5\ 10^{6}}{3.0\ 10^{6}} = 0.116 = 11\% \tag{9}$$

$$\varepsilon_{ultimate} = \frac{\Delta u_{max}}{T} = \frac{0.005}{0.002} = 2.5 = 250\,\% \tag{10}$$

Where E and A are the Young modulus and area of the interface, respectively and the maximum elastic strain ($\varepsilon_{elastic}$) and ultimate strain ($\varepsilon_{ultimate}$) are expressed as a percentage of the initial thickness of the interface (T=2 mm). The resulting constitutive laws assigned to the cohesive interface at z = 0 m (upper interface) and the cohesive interface at z = 15 m (lower interface) are shown in Figure 10a.

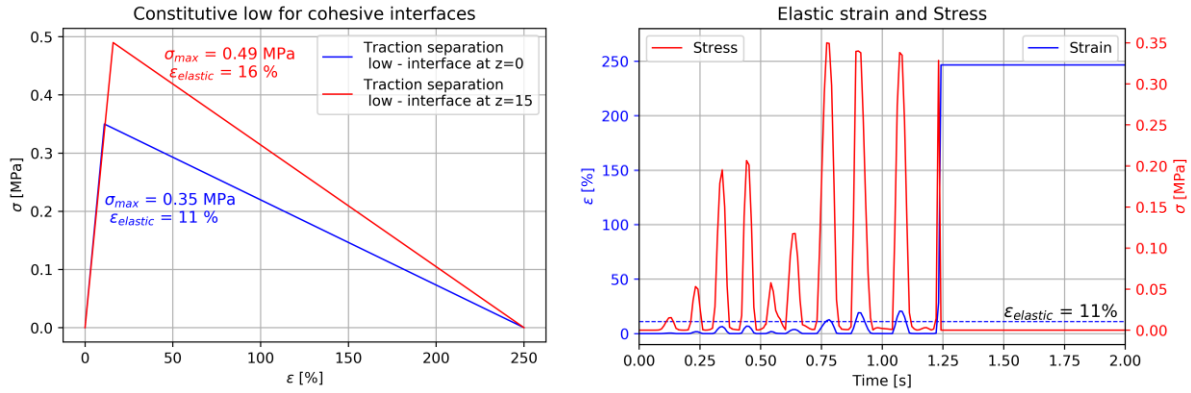

Figure 10: a) Cconstitutive law for the cohesive interface, b) strain and stress field for the upper cohesive interface

The graph reported in Figure 10b shows that the seismic acceleration applied to the base of the model produces in the upper interface a strain field equal to 11% and 250% after 0.76 s and 1.25 s respectively. For these values of strain, the interface elements experience the maximum values of traction stress(0.35 MPa)and the failure. Once the damage is initiated, it propagates down the height of the wall and the orthogonal walls start oscillating independently. The CP experiences a maximum relative displacement from the sidewall of 0.35 m at time step 1.25 s and the height of the separation is 6.8 meters as shown in Figure 11.

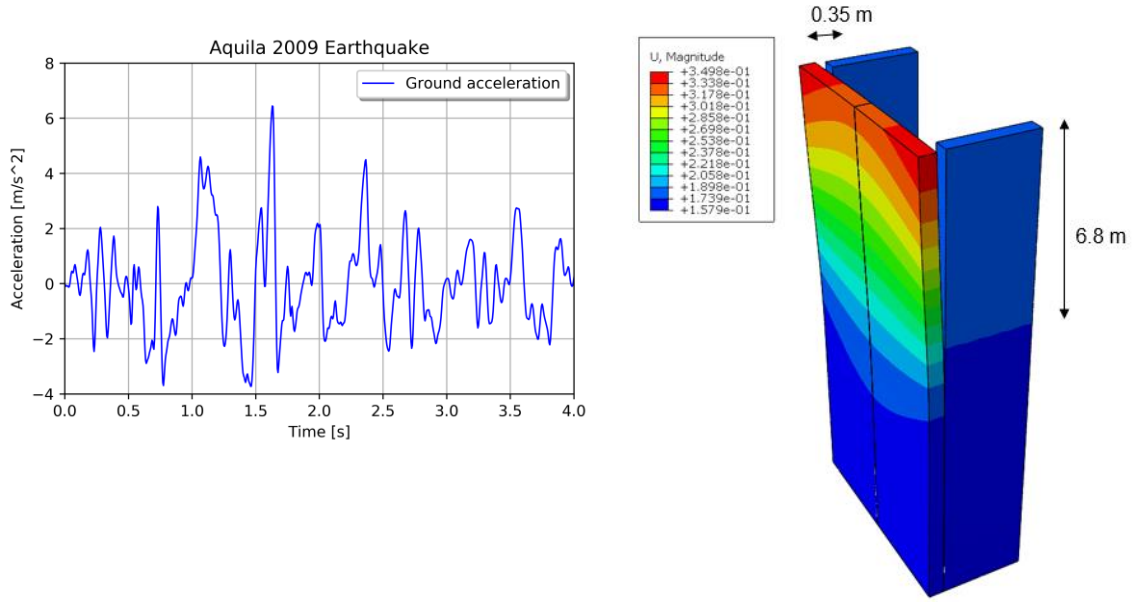

Figure 11: a) Applied base acceleration, b) deformed shape of FE model at time step 1.25 seconds.

These results show that the FE model is able to reproduce the typical failure mechanism detected on site in the aftermath of a seismic event, when major cracks at the interface between cross walls are often observed. The analysis shows that the connection capacity simulated by the interfaces is not sufficient to restrain the walls. The lack of effective lateral constrains determines the façade detachment form the side walls and it deforms similarly to a cantilever beam undergoing bending, as shown in Figure 11b. The model is deemed suitable for predicting the response of the structure in other case scenarios, for instance by inserting the anchors and dissipative devices characterised in section 2.2.

3.2 The strengthened structure

A second model is implemented to investigate the benefit of introducing a reinforcement scheme able to improve the connection between the cross walls that experienced mutual separation. Damage experienced by the structure is accounted for by removing the interfaces for the extent they failed in the previous analysis.

Material properties are the same as for the undamaged model, as cracking is localised and does not affect other parts of the structure; thus, it is not necessary to reduce the stiffness of the parent material. Table 2 provides the mechanical properties adopted for the materials.

Part	E	G1	G2	Density	Maxs Damage	First Damage	Ultimate damage
	[Pa]	[Pa]	[Pa]		normal[Pa]	[m]	[m]
Wall	1.50E+09			2.14E+03			
Interface	3.00E+06	3.00E+06	3.00E+06	1.75E+03	3.50E+05	2.33E-04	5.00E-03
Steel bar	2.10E+11			8.00E+03			

Table 2: mechanical properties of model's materials

A first FE analysis is performed on a model including standard stainless steel ties. A common retrofit practice is to grout the ties within the masonry inside a drilled hole to restore the box-like behaviour of masonry structures. Therefore, in the numerical model the metallic elements run along the whole length of the side walls, reconnecting the sets of perpendicular walls.

Paganoni and D'Ayala [16] used mono-dimensional truss elements to model the ties and a bonded contact was implemented at the interface between truss and elements representing the masonry. In the present work the anchors are modelled by means of three-dimensional elements and an interface part is defined to govern the mutual behaviour between the anchor and the parent material. The insertion of the grouted steel anchors is modelled through cohesive interfaces which reproduce the bonding between the ties and the masonry. A traction-separation law with sub-options governing the post damage behaviour is assigned to the cohesive elements. The parts representing the front and side walls are rigidly connected for 10 meters from the base by numerically defining tie constrains which prevent the relative motion of nodes belonging to the side and front wall. The two parts are disconnected for the remaining 6.8 meters and a frictionless contact coefficient (μ) is specified to prevent components' penetration. This means that, for this portion of the wall, the only link preventing the relative motion of the orthogonal walls is provided by the anchors running through the two parts representing the walls.

Compared to the model without any strengthening solution, the insertion of metallic ties does not improve the overall behaviour of the structure. The interface controlling the bonding capacity between the anchor and the surrounding part reaches the maximum traction capacity after 0.18 seconds and the anchor is pulled out of the front wall after 0.51 seconds when the interface experiences the maximum allowable displacement, namely 5 mm. The pull-out failure does not extend to the whole length of the anchor, but affects instead the portion adjacent to the disconnection, i.e. the portion bridging the vertical crack between front and side wall. Before failure, the maximum stress concentrations are registered in the proximity of the anchorage point on the façade face, as shown in Figure 13. The model shows a punching/pull-out failure at the head of the anchorage, which is a recurring failure mode for this type of retrofitting system in case of weak substratum, as shown in Figure 12.

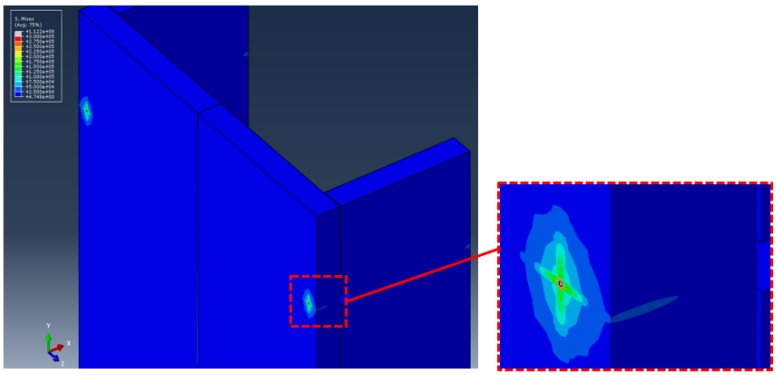

Figure 12: Punching failure of standard metallic ties - FEM

To observe in detail the stress field in the material surrounding the anchorage, the parts composing the model are sectioned along the x-z plane where the longitudinal axis of the anchor lies. Figure 13 shows the stress distribution along the length of the interface. As the front wall tilts outwards, the part representing the grouted bars are bent along their longitudinal axis. This mechanism determines that the maximum tensions are equal in value but opposite in sign as shown in Figure 13.Two critical points in the time history are identified, namely the time steps when the maximum traction and the maximum displacement are reached.

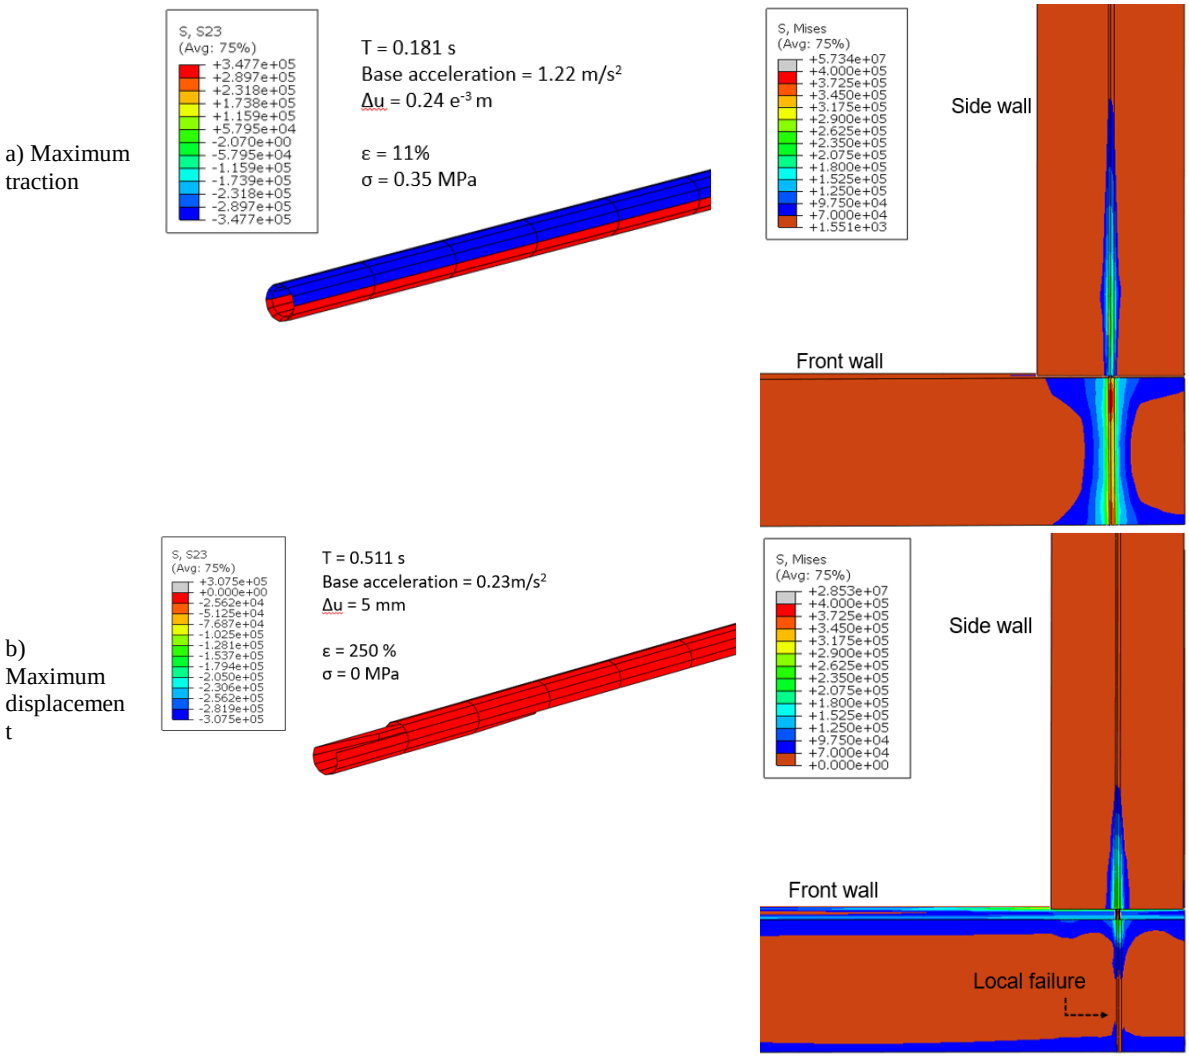

Figure 13: Distribution of Shear stresses along the cohesive interface and V. Mises stresses as transferred from the anchors to the masonry walls

A second model including a friction-based device inserted at the joint between front and side walls undergoes the same input as the model with standard steel ties. The dissipative device is modelled with solid elements reproducing all the parts composing the final assembly and is connected rigidly to the steel bars. The friction force resisting the slider's motion is induced by defining a "bolt load" in the element reproducing the bolts of the real devices. Each bolt-part is loaded with a transversal force equal to 2700 N and the resulting friction force is computed according to Equation 1:

$$F_{//} = n\,\mu\,F_{\perp} = 4 \cdot 0.2 \cdot (4 \cdot 2700) = 8.6\,KN \quad (11)$$

As for the previous model, one cohesive interface connecting the bars to the surrounding elements complete the assembly. Figure 14a shows the sliding motion of the device's slider along with the acceleration experienced at the anchor's location, namely at 14 meters from the base. From the graph, it is clear that the device activates twice depending on the experienced acceleration: the first time at T = 0.26, when it oscillates between its initial position and 2.5 mm and the second time at T = 1.16s when it fully exploits the allowable run of 20 mm. Since the device is tuned to start sliding for a resulting force (8.6 KN) lower than the one that would

cause the pull-out failure of the assembly (11 KN) the stress distribution in the wall's part are lower than the maximum traction capacity.

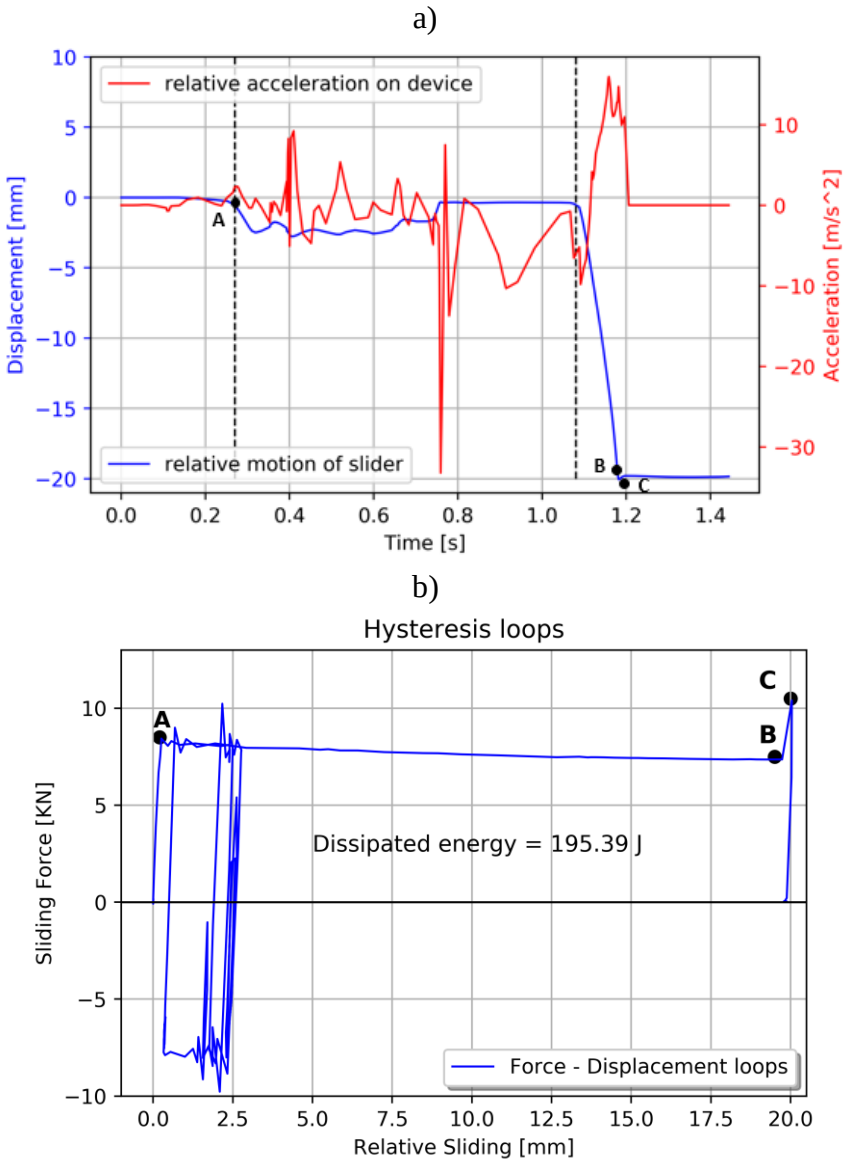

Figure 14: Sliding motion of the internal part and relative acceleration at anchor's location, b) Hysteresis loops of friction-based dissipative device

Figure 14b shows the load-displacement curve experienced by the device. When the sliding force exceeds the friction resistance force (Point A), the sliding central part starts moving according to the direction of the applied base acceleration. In particular, the slider completes a hysteresis loop oscillating between its initial position and 2.5 mm. At T= 1.16s, it slides out for 20 mm, thus reaching the maximum controlled displacement of the device (Point B). Point C in Figure 14 represents the ultimate traction resistance that the interface around the steel bar part can provide, after which the interface displays a gradual degradation. The areas between the force-displacement curve and the x-axis represents the total energy that the system can provide to resist the applied motion.

Figure 15 shows the stress distribution at the time step corresponding to the maximum traction and maximum displacement in the interface part. At time T=1.18 s the frictional sliding occurring in the device is equal to 20 mm and the internal part hits the central pin that controls

the allowed motion of the slider. At time T= 1.20 s the system, now working as a traditional strength-only anchor, fails as the interface between the bar and the masonry has reached the maximum displacement, namely 5 mm. By comparing the stress distribution in the parts surrounding the anchors, it can be noted that the insertion of the dissipative device reduces the shear stresses transferred from the anchor to the walls.

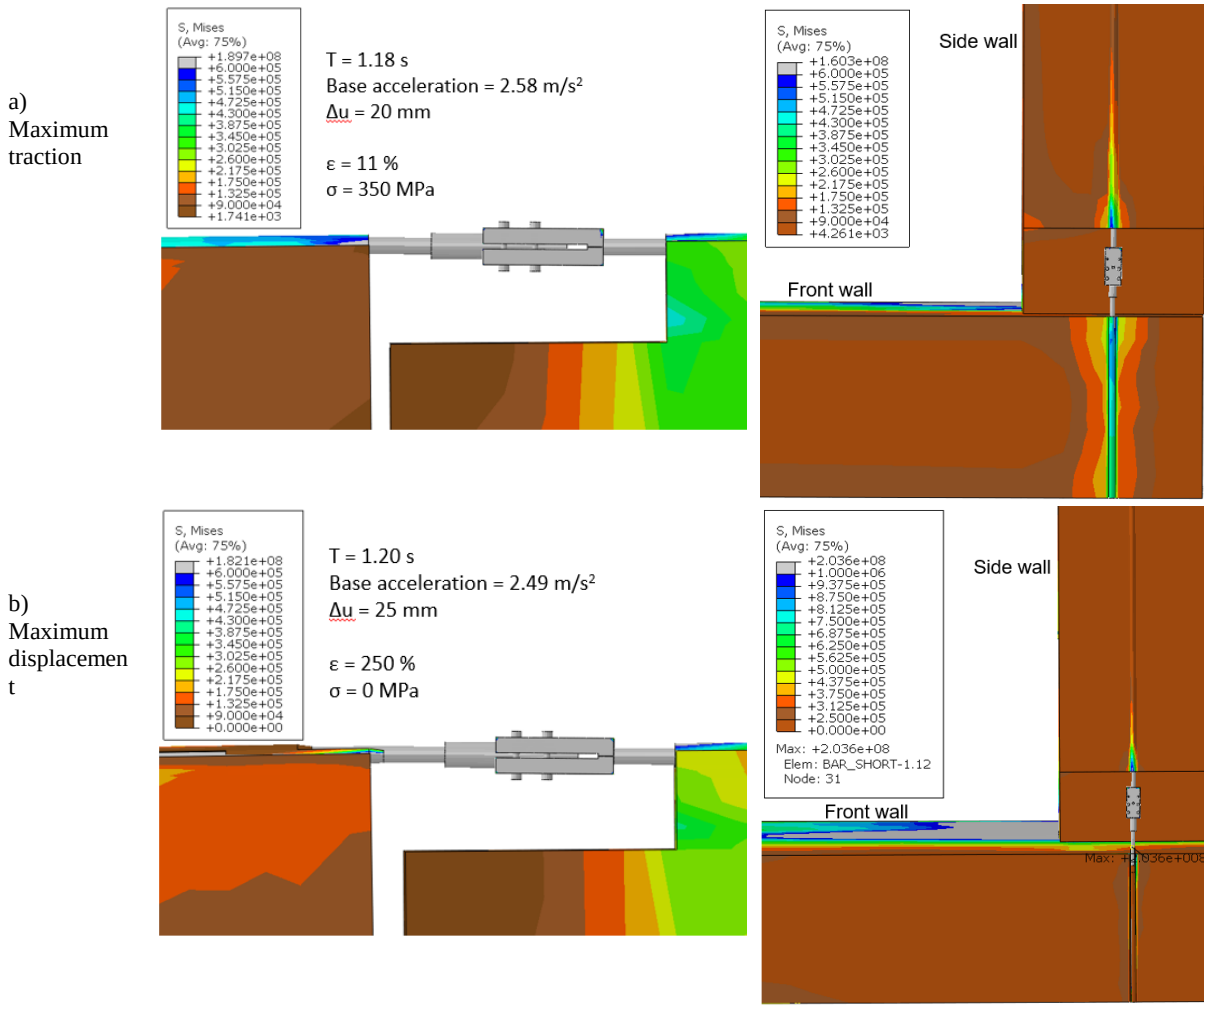

Figure 15: FE model of a corner connection strengthened by means of dissipative anchoring system. Deformed shape and stress distribution at maximum traction and maximum displacement

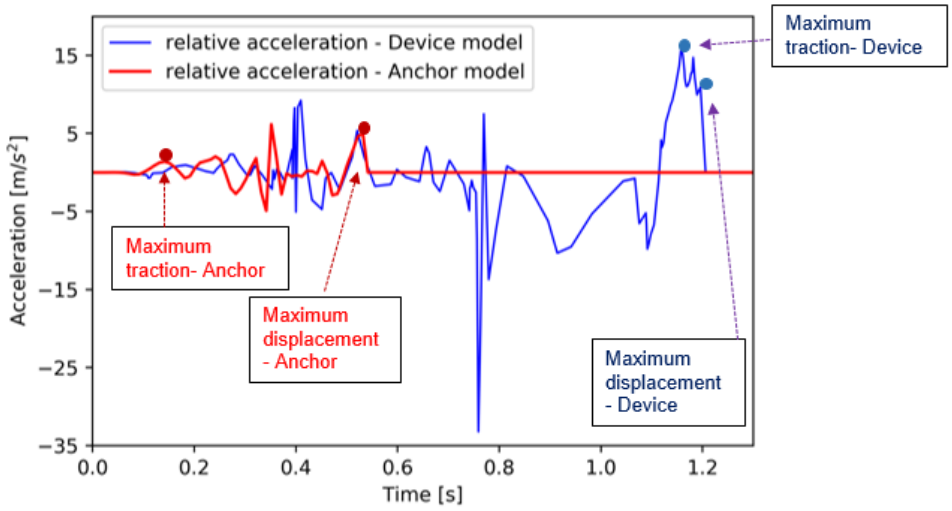
Figure 16a shows the relative acceleration experienced by the orthogonal walls at 14 m from the base, namely where the strengthening systems are inserted. From the graph, it is clear that the corner connection strengthened by means of the dissipative device withstands the applied base acceleration for a longer period. The ultimate failure is reached at T = 1.2 s, whilst it was reached at T= 0.5 s for the traditional anchor.

a)



b)

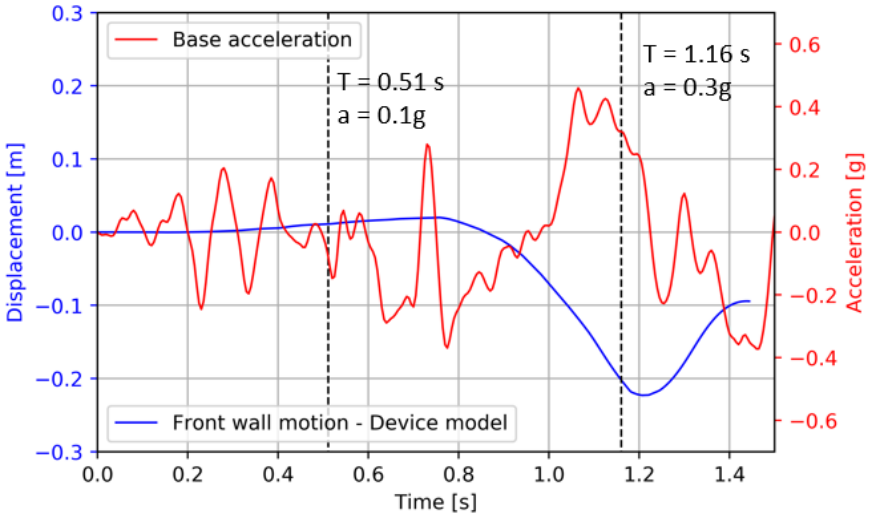


Figure 16: a) Relative acceleration experienced by the strengthening systems, b) base acceleration and displacement time history of front wall

By comparing the time steps at which the ultimate failure takes place, Figure 16b shows that the dissipative anchoring system experiences a pull-out failure for a base acceleration equal to 0.3g while the model representing the traditional strengthening system fails for a base acceleration equal to 0.1g.

4 CONCLUSIONS

The lack of effective connections between perpendicular walls often determines the failure of a historic masonry structure under seismic loading. To restore the box-like behaviour and provide these particular buildings with sufficient ductility to withstand shaking, the authors developed a friction-based dissipative anchoring system.

Such system comprises a device installed in series with standard metallic anchors grouted at the joint between perpendicular sets of walls of historic structures. The purpose of the strengthening system is to reconnect structural elements that might have become detached as

result of seismic events, but also to control relative displacements and reduce accelerations in case of further earthquakes, so that damage to the precious wall finishes can be reduced.

The device provides ductility to the connection, mitigating the width of the cracks in the parent material and preventing fragile failures, such as pull-outs. This, of course, entails allowing a controlled out-of-plane deformation, rather than completely relying on the in-plane stiffness of side walls.

The paper presents the experimental and computational work carried out to assess the performance of the dissipative anchoring system and its applicability to an idealized case study.

A series of FE models were implemented using the commercial software Abaqus to refine the device's shape and optimize its design in terms of stress distribution, stability and reliability

The pull-out tests performed on the device connected to steel bars and embedded in a masonry panel confirmed that the innovative system is effective in reducing the damage propagation to the subtratum in respect to its strength-only counterpart. The experimental results feed in the calibration of a computational model, which reproduces the experimental set up in order to understand better the rules that governs the behaviour of the dissipative anchoring system. A model of a wall panel strengthened by the anchoring devices was created and run and the FE model succeeds in replicating the bond failure between the parent material and the grouted element of the standard anchor, this being the failure mode that controls the performance of the whole assembly. Therefore, the numerical model tuned on the obtained experimental results was used as a starting point to develop a numerical model of an idealized case-study building in need of seismic upgrade. The numerical model reproduces the behaviour of a three-panel corner connection when a seismic base acceleration is applied. The front panel disconnects from the sidewalls for a hight of 6.8 meters and undergo out-of-plane motion. The outward tilting of walls is a recurring mode of failure for historic masonry structures, and the proposed system aims at controlling the opening of cracks and taking advantage of. The model of the corner connection is therefore "strengthened" by implementing an anchoring system with and without the addition of the dissipative device. Fictitious interfaces were used to define the bonding capacity between the parts representing the steel bars and the masonry. This method allows for the definition of an equivalent stress-strain curve compatible with the available experimental results. The dissipative anchoring system experiences a pull-out failure for a base acceleration equal to 0.3g while the model representing the traditional strengthening system fails for a base acceleration equal to 0.1g.

It should be noted that the applied base acceleration caused the pull-out failure of both strengthening systems meaning that the full scale signal was too demanding for traction capacity of the interfaces. Therefore, a future set of analysis will include a parametric study investigating the strengthening systems for smaller range of accelerations. Moreover, in the proposed work only one system was inserted in each corner connection, whilst in a real-case application several devices should be included. Therefore, the reported results will feed into a more complex model where a number of dissipative anchoring system will restrain simultaneously the out-of-plane motion of the front wall.

Abstract

In the last decades Fiber Reinforced Plastic (FRP) have been widely adopted for strengthening and repair of damaged structures. Design indications about the use of FRP materials as external strengthening techniques for structures are available in Italy since 2004, while only in 2015 the Italian Ministry of Infrastructure and Transportation published Guidelines for the qualification of FRP products. This paper summarizes the results of several experimental activities for the qualification of preformed FRP products. Statistical analyses were carried out in order to provide indications on variability of FRP's mechanical properties and assess the reliability of the classes individuated by the Italian guidelines.

Keywords: Preformed FRP products, tensile strength, Young's modulus, probabilistic models, design value.

1 INTRODUCTION

The demand for structural safety in civil construction in Italy is increasingly more widespread, especially after recent seismic events. In the last years, huge progress has been made in understanding the structural behaviour of concrete and masonry structures strengthened by means of innovative materials and techniques. In particular, ever-increasing resources have been used for both the retrofit and the strengthening of existing concrete and masonry structures with externally bonded composite materials, i.e. Fiber Reinforced Plastic (FRP) materials. Such a strengthening technique has been emerging for just over two decades becoming a system widely adopted by professionals and construction companies. Consequently, the Italian Ministry of Infrastructure and Transportation published Guidelines on the qualification of such products in 2015 [3], which were enforced by the end of 2016. These Guidelines add up to previous guidelines specific for the design of structural reinforcement through FRP materials (CNR DT 200/R1, 2013, [2]), with reference to both pre-formed and cured-in-situ (or wet-lay-up) systems.

Currently, any FRP manufacturer interested in the Italian market had to apply to the Ministry for the corresponding qualification, demonstrating the outcomes of the needed testing activity. According to the recent Italian Guidelines [3], the results of the qualification tests in terms of mean value of the Young's modulus E and of characteristic value (5th percentile) of the tensile strength f_{tk} place a given product in a certain class. The nominal classes provided in [3] are listed in *Table 1*.

Class	**Type of fibres**	**E** [GPa]	**f_{tk}** [MPa]
E17	Glass/Basalt	17	170
E23	Glass/Basalt	23	240
G38/600	Glass/Basalt	38	600
G38/800	Glass/Basalt	38	800
G45	Glass/Basalt	45	1000
C120	Carbon	120	1800
C150/1800	Carbon	150	1800
C150/2300	Carbon	150	2300
C190/1800	Carbon	190	1800
C200/1800	Carbon	200	1800
A55	Aramid	55	1200

Table 1: *Classes for pre-formed FRP systems given by Italian Guidelines [3].*

Moreover, the FRP systems' environmental durability should also be checked. In particular, strength to freeze/thaw cycles, humidity, salt water and alkaline environment needs to be investigated with further tensile tests.

In this paper, the results of tensile tests on several pre-formed FRP materials are analysed according to a statistical approach. The main aims of the analysis are: a) check the reliability of the classes suggested by the Italian Guidelines [3], b) assess the best fitting probabilistic model

able to describe the experimental distributions, c) estimate the average and characteristic values, and d) evaluate the safety factors according to Eurocode 0 [9].

The experimental data come from several laboratories, many of which are located in Italian universities, and were collected by the Construction Technologies Institute (ITC) of the Italian National Research Council (CNR).

2 TESTING ACTIVITY

Pre-formed FRP materials are made of fibres pre-impregnated with resins in the form of a sheet, characterized by initial axial rigidity and a mono-directional behaviour. They can be produced by pultrusion or lamination processes according to different shapes and thicknesses and are generally glued to the structural elements through an epoxy adhesive.

The number of pre-formed FRP products collected are listed in *Table* 2. They are all made of carbon fibres. According to the Italian Guidelines [3], the number of single tensile tests required for the qualification of each product is 15, thus obtaining the total number of individual tests shown in *Table* 2. The specimens have width variable in the range 25-70 mm and length from 250 to 350 mm. The recommended range of speed for tensile tests is 0.5-2.0 mm/min. Since the classes C150/1800, C190/1800, and C200/1800 are little populated (1, 2 or 3 products, respectively), the only experimental data belonging to the more populated class, i.e. the class C150/2300 having 5 pre-formed products, have been analysed in detail in this paper.

FRP Mechanical characterization		
Class	N° products	N° of single tests
C150/1800	1	15
C150/2300	5	75
C190/1800	2	30
C200/1800	3	45
Total	11	165

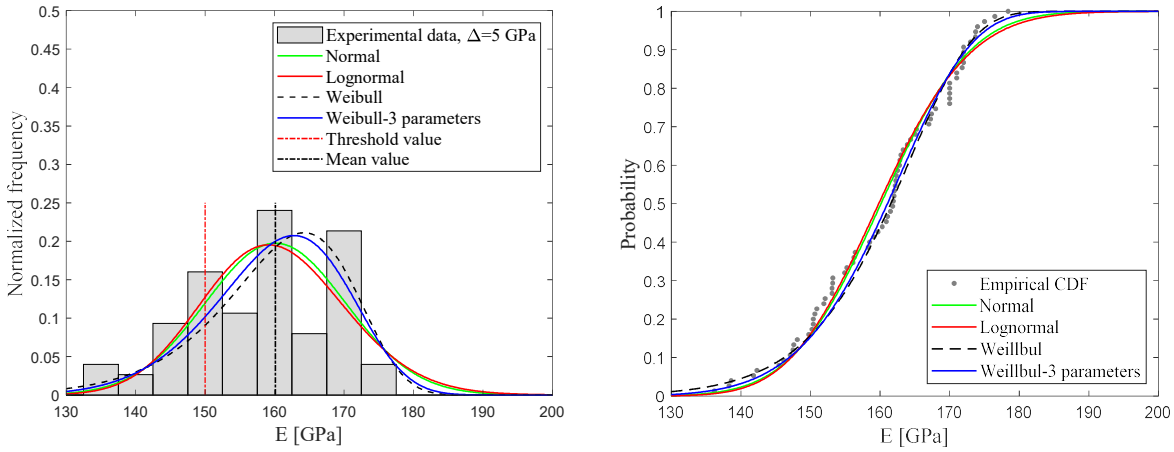
Table 2: *Pre-formed FRP products and number of single tests.*

2.1 Analysis of experimental data of class C150/2300

According to [3], the qualification tests have to be carried out on 15 specimens in order to evaluate the mean value of the Young's modulus, E, and the characteristic value of the tensile strength, f_{tk}. Thus, there are a total of 75 experimental pairs of values of E and f_t for the 5 types of products belonging to class C150/2300.

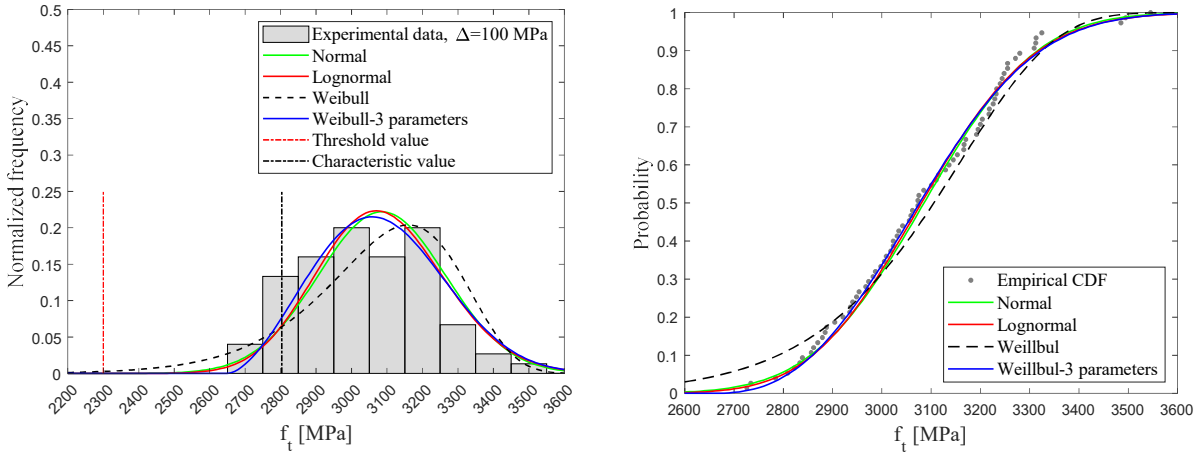
The experimental data were used to construct normalized recurrence histograms, in which the bins have width of 5 GPa for E and 100 MPa for f_t (see Figures 1a and 2a, respectively). Therefore, the Empirical Cumulative Density Function (ECDF) was calculated and plotted for both E and f_t in Figures 1b and 2b, respectively.

The empirical histograms show that the experimental data are more concentrated around values greater than the threshold values provided by [3] for the reference class, i.e. 150 GPa for E and 2300 MPa for f_t, and certainly produce some non-symmetric distributions of experimental data. This would mean that the definition of the threshold values of the classes for FRP pre-formed systems should be reviewed, since all the products exceed them, especially in terms of tensile strength.



(a) (b)

Figure 1 – *Distribution of E for pre-formed FRP systems (class C150/2300) - Comparison between: a) empirical histograms and theoretical PDF; b) empirical and theoretical CDF.*



(a) (b)

Figure 2 – *Distribution of f_t for pre-formed FRP systems (class C150/2300) - Comparison between: a) empirical histograms and theoretical PDF; b) empirical and theoretical CDF.*

Therefore, the experimental data were compared with four theoretical probabilistic distributions: normal, lognormal, 2-parameters Weibull [4, 5] and 3-parameters Weibull [4, 5]. In Table 3, the Probability Density Functions (PDF) and the identifying parameters associated to these distributions are listed. In particular, the normal and lognormal distribution require the calculation of the parameters μ (average value) and σ (standard deviation). Whereas, the Weibull distribution is described by the shape (κ) and scale (λ) parameters, with the addition of a third parameter 'ϑ' for the 3-p Weibull distribution.

The software "SPC for Excel" [6] was used to calculate the parameters associated with the probability law from the experimental data. This software estimates the optimal parameters using the Maximum Likelyhood Estimate (MLE) method. In *Table* 4, the final values of the parameters adopted for data adaptation are listed.

Probability distributions	PDF	Parameters
Normal	$y = f(x \mid \mu, \sigma) = \frac{1}{x \cdot \sigma\sqrt{2\pi}} e^{-\frac{(x-\mu)^2}{2\cdot\sigma^2}}$	μ, σ
Lognormal	$y = f(x \mid \mu, \sigma) = \frac{1}{x \cdot \sigma\sqrt{2\pi}} e^{-\frac{(\ln x-\mu)^2}{2\cdot\sigma^2}}$	μ, σ
Weibull	$y = f(x \mid \lambda, \kappa) = \begin{cases} \frac{\kappa}{\lambda}\left(\frac{x}{\lambda}\right)^{\kappa-1} e^{-\left(\frac{x}{\lambda}\right)^{\kappa}} & x \geq 0 \\ 0 & x < 0 \end{cases}$	k, λ
3-p Weibull	$y = f(x \mid \lambda, \kappa, \vartheta) = \begin{cases} \frac{\kappa}{\lambda}\left(\frac{x-\vartheta}{\lambda}\right)^{\kappa-1} e^{-\left(\frac{x-\vartheta}{\lambda}\right)^{\kappa}} & x \geq 0 \\ 0 & x < 0 \end{cases}$	k, λ, ϑ

Table 3: *Probability models - systems falling in class C150/2300.*

Probability distributions	Variable	Values of fitting parameters		
Normal	*E*	μ = 160.1	σ = 10.1	
	ft	μ = 3085.5	σ = 179.7	
Lognormal	*E*	μ = 5.07	σ = 0.06	
	f_t	μ = 8.03	σ = 0.06	
Weibull	*E*	λ = 164.7	*k* = 18.9	
	f_t	λ = 3171.0	*k* = 17.6	
3-p Weibull	*E*	λ = 60.1	*k* = 6.7	ϑ = 104.2
	f_t	λ = 488.9	*k* = 2.6	ϑ = 2651.2

Table 4: *Parameters of probability models – pre-formed FRP systems (class C150/2300)*

The PDFs and the associated CDFs are plotted in Figure 1a-2a and 1b-2b, respectively, for comparison with experimental data. In order to have a quantitative estimate of the fitting goodness, the Kolmogorov-Smirnov (KS) test was used for comparing the different distributions and choose the most suitable model fitting the experimental data. The test is based on the comparison between the maximum absolute difference between the experimental CDF and the CDF associated with each theoretical probability distribution. Such a difference is calculated as follows:

$$D_{MAX} = \max\{|F(x) - \varphi(x)|\} \quad (1)$$

where F(x) is the ECDF and φ(x) is the CDF of each theoretical probability distribution.

The hypothesis regarding the distributional form is rejected if D_{MAX} is greater than a certain critical value, which depends on the specimen size, N, and the level of significance, α, of the test. There are several values available in the literature for the level of significance; some of them (Massey, 1951; Lilliefors, 1967) [7, 8] are reported in *Table* 5. Typically, the Kolmogorov-Smirnov test has a level of significance of 0.05, which means that in 5% of cases the null hypothesis (the estimation of the difference between the empirical and the theoretical CDF is based solely on chance) is rejected.

The Kolmogorov-Smirnov test was, thus, conducted for both the distribution of tensile strength (see *Table* 6) and Young's modulus (see *Table* 7) by comparing the maximum differences with the critical values suggested by (Massey, 1951; Lilliefors, 1967) [7, 8]. The results reported in *Table* 6 and *Table* 7 show that for both E and f_t the values of D_{MAX} allow do not reject the null hypothesis for the four selected probability distributions and for all significant levels and critical values provided by (Massey, 1951, [7]) and (Lilliefors, 1967, [8]). Note that in (Lilliefors, 1967, [8]) lower critical values are provided. The Normal distribution appears to be the best fitting distribution of the experimental data, since it has the lowest value of D_{MAX} in all cases. However, any of the considered distributions appears to be fairly adequate to describe the experimental data.

Sample size (N)		**Level of significance (α)**				
Massey, 1951 [7]	Over 35	0.20	0.15	0.10	0.05	0.01
		$\frac{1.07}{\sqrt{N}}$	$\frac{1.14}{\sqrt{N}}$	$\frac{1.22}{\sqrt{N}}$	$\frac{1.36}{\sqrt{N}}$	$\frac{1.63}{\sqrt{N}}$
Lilliefors, 1967 [8]	Over 30	0.20	0.15	0.10	0.05	0.01

3 EFFECT OF ARTIFICIAL AGEING

According to Italian Guidelines [3], the FRP systems' environmental durability should also be checked. In particular, strength to freeze/thaw cycles, humidity, saltwater and alkaline

environment needs to be investigated with further tensile tests.

In order to verify the strength to freeze/thaw cycles, the conditioning procedure requires specimens to be placed in environments characterized by Relative Humidity (RH) ≥ 90% and Temperature T = 38 ± 2°C for 7 days, then 20 freeze/thaw cycles are performed. Each cycle consists of 4 hours at a -18 ± 1°C, followed by 12 hours at RH ≥ 90% and T = 38 ± 2°C.

For the other artificial ageing, the conditioning procedures are the following ones:

a) Strength to wet environment: curing at RH ≥ 90% and T = 38 ± 2°C for 1000 or 3000 hours (ASTM D 2247-11 [10] and ASTM E 104-02 [11]);
b) Strength to saltwater environment: immersion in saltwater at 23 ± 2 °C for 1000 or 3000 hours (ASTM D 1141-98 [12] and ASTM C 581-03 [13]);
c) Strength to alkaline environment: immersion in aqueous solution with pH = 12 and T= 23 ± 2 °C for 1000 or 3000 hours (ASTM D7705/D7705M [14]).

After each conditioning process, samples are visually examined in order to describe eventual surface changes and, then, the tensile tests are carried out. If the average values of E and f_t obtained by the tensile tests on the conditioned samples are not lower than 85% of the average values of the not conditioned samples in case of 1000 hours of exposure (80% in case of 3000 hours), the check is considered positive.

Table 8 reports a summary of the results of the unconditioned and conditioned specimens and shows that all the examined products passed the check on the environmental durability. It is worth to note that for each conditioning procedure, 4 conditioned and 4 unconditioned specimens are involved; the unconditioned specimens are extracted from the same batch, but do not correspond to the ones used for the mechanical characterization previously carried out under standard environmental conditions. However, it was verified that the results of such a second series of unconditioned specimens do not significantly differ from the ones of the first series used for the mechanical characterization (see Fig. 1a and 2a).

Artificial ageing effects are summarized in the following sections. In all cases, bins with width of 5 GPa E and 100 MPa for f_t have been adopted. The only Normal, Lognormal and Weibull probabilistic laws were considered, since the 3-p Weibull distribution was not always applicable.

Conditioning	***Elastic Modulus E[GPa]***			***Tensile Strength f_t [MPa]***		
Type	*Mean value unconditioned*	*85% mean value unconditioned*	*Mean value conditioned*	*Mean value unconditioned*	*85% mean value Unconditioned*	*Mean value conditioned*

3.5 Discussion on artificial ageing effects

Table 17 and *Table 18* summarize the values of D_{MAX} for the theoretical distributions related to the different effects of artificial aging. It is worth to note that for the Young's modulus, E, the minimum values of D_{MAX} occurs for the lognormal distribution for whatever aging procedure. Conversely, for the tensile strength f_t, the minimum values of D_{MAX} occurs again for the lognormal distribution for exposure to humidity and saltwater, while for exposure to freeze/thaw cycles and to alkaline environment the best fitting distributions are the Weibull and the Normal ones, respectively.

Distribution	*Freeze/thaw*	*Humidity*	*Saltwater*	*Alkaline enviroment*
Normal	0.088	0.088	0.155	0.128
Lognormal	**0.086**	**0.086**	**0.145**	**0.122**
Weibull	0.119	0.142	0.207	0.156

Table 17: *Minimum values of D_{MAX} for the best fitting distributions of E.*

Distribution	*Freeze/thaw*	*Humidity*	*Saltwater*	*Alkaline enviroment*
Normal	0.208	0.090	0.167	**0.121**
Lognormal	0.213	**0.090**	**0.156**	0.127
Weibull	**0.180**	0.097	0.221	0.155

Table 18: *Minimum values of D_{MAX} for the best fitting distributions of f_t.*

Consequently, the 5th percentile, f_{t5}, of the tensile strength was calculated with reference to the best distribution for each condition of artificial aging, in particular by adopting the Weibull probability model for *Freeze/Thaw* effect, the Lognormal probability model for *Humidity* and *Saltwater* effects, the Normal probability model for *Alkaline environment* effect. In *Table 19*

the experimental and theoretical mean value of the Young's modulus E and the 5th percentile, f_{t5}, and the mean value, $f_{tm,}$ of the tensile strength are listed for the reference unconditioned samples and the variously conditioned ones. The experimental and analytical percentual differences between unconditioned and conditioned samples are listed in brackets too.

		Unconditioned	*Freeze/Thaw*	*Humidity*	*Saltwater*	*Alkaline*
E [GPa]	empirical	160	161 (+0.5%)	162 (+0.9%)	162 (+1.2%)	162 (+1.4%)

Table 19: *Mechanical parameters of C150/2300 products – unconditioned and variously conditioned.*

Table 19 shows no substantial variation of the mean value of Young's modulus after all the considered artificial ageing procedures. For both empirical and analytical data, the values vary, indeed, from 0.4% (*Freeze/Thaw*) to 1.4% (*Alkaline environment*).

Analogously, no variations were observed for the mean tensile strength (0.1-1%), while a light reduction of the 5th percentile of the tensile strength, i.e. ranging from -4.0% to -1.2%, was attained for all aging procedures, with exception of exposure to alkaline environment which induced a negligible increase (+0.4%).

In conclusion, ageing effects on the mean value of the Young's modulus and tensile strength of the tested products are negligible, whereas a slight reduction (maximum 4%) of the 5th percentile of the tensile strength is attained, especially in case of freeze/thaw cycles and exposure to humidity.

The Italian Guidelines [1] prescribes environmental conversion factors equal to 0.95, 0.85 and 0.85 for, respectively, indoor, outdoor and aggressive environments in the case of carbon fibres. The obtained experimental results show that for the most aggressive ageing effect (freeze/thaw cycles), the 5th percentile values of tensile strength reduces of only 4%. Such a reduction is slightly lower than the one induced when the highest value of the conversion factor (0.95) is assumed, confirming, thus, that the conversional factors suggested by [1] are safe for preformed carbon FRP products.

4 ASSESSEMENT OF DESIGN VALUE

According to the Eurocode 0 [9], the design value of a product property can be expressed as:

$$X_d = \eta \frac{X_k}{\gamma_m} \tag{2}$$

where X_d is the design value, X_k is the characteristic value (herein the 5th percentile of the probability distribution), η is a conversion factor associated to environmental conditions, and γ_m is the material partial factor. By neglecting in a first stage the conversion factor (i.e., assuming η=1), the material partial factor can be calculated as:

$$\gamma_m = X_k / X_d \tag{3}$$

For the Normal probability law, the characteristic value of the tensile strength of the tested products is f_{t5}=2790 MPa and the mean value is f_{tm}=3086 MPa (see *Table 19*). Since the Normal law is the best fitting distribution for the experimental results, the theoretical 5^{th} percentile value is calculated as follows:

$$f_{t5} = f_{tm} - 1.647 \cdot \sigma = 3086 - 1.647 \cdot 180 = 2790 \text{ MPa} \quad (4)$$

being f_{tm} and σ the mean value and the standard deviation of the distribution of the tensile strength. The experimental value of the 5th percentile of the tensile strength is 2803 MPa, which is practically equal to the theoretical value. The acceptance criteria described in the Italian Guidelines [3] assume the characteristic tensile strength equal to the mean value minus 2 times the standard deviation, as suggested by Eurocode 0 [9]. This procedure leads to f_{t5}=2726 MPa, which, thus, lightly underestimates (-3%) the real 5th percentile of the tensile strength.

Since under ordinary environmental conditions, the Normal probability model resulted the most suitable distribution law for the tensile strength, the corresponding design value, f_{td}, can be expressed as follows:

$$f_{td} = f_{tm} - \alpha_R \cdot \beta \cdot \sigma \quad (5)$$

being α_R the FORM (First Order Reliability Method) sensitivity factor and β the target reliability index. By assuming α_R = 0.8 and β = 3.8 (Consequences Class CC2, Reliability Class RC2, 50 years return period according to EN 1990 [9]), the design value results f_{td}=2450 MPa and, thus, the material partial factor of the tested population can be calculated as:

$$\gamma_m = f_{t5} / f_{td} = 2790/2450 = 1.10 \quad (6)$$

The partial factor suggested by the Italian Guidelines [1] for the strength of reinforcing material is 1.10 for composite kits fully certified, as the preformed ones are, whereas 1.25 is suggested for composites where only materials, not the installation, is certified. The lowest value, 1.10, exactly coincides with the strength partial factor related to the experimental data presented before, while the highest one, 1.25, leads to a more conservative design in order to take into account uncertainties related to operations on the construction site.

5 CONCLUSIONS

The analysis of experimental data related to the qualification of several preformed FRP products allowed to define a global perspective of the main mechanical parameters, i.e. tensile strength and Young's modulus.

Qualification procedures, as well as the values of design parameters, are prescribed in recent Italian guidelines [3]. The analysis of a discrete database, which could certainly be further expanded, allowed to carry out several statistical inquires. The analyses proved that the Normal probabilistic law is able to adequately describe the distribution of tensile strength and Young's modulus, mainly under standard environmental conditions.

Under the artificial ageing procedures prescribed by the Italian Guidelines [3] (exposure to freeze/thaw cycles, humidity, salt water, and alkali environment), the study fails to determine a single distribution law able to interpolate to the best the analysed specimens. This is mainly due to the low number of samples tested and to the higher scattering that affects the conditioned specimens in comparison with the unconditioned ones.

However, the experimental results showed that the ageing procedures did not affect sensibly

both the average and the 5th percentile values of the mechanical properties of the examined FRP products, confirming the reliability of the environmental factors suggested in the Italian guidelines for the design of strengthening interventions with FRP materials [1, 2].

Finally, it was also verified that the safety factors suggested by the Italian Guidelines [1, 2] in case of tensile failure of the FRP materials are safe.

The reliability of the results presented in this paper can be further checked, if more numerous experimental data will be available.

Abstract

Anchoring devices for external strengthening systems made of Fiber Reinforced Plastic (FRP) materials represent a solution to avoid or delay debonding phenomena in concrete and masonry strengthened elements. Several types of anchoring devices were tested by researchers and used in real applications in the last years, but clear design indication for estimating the effectiveness of each anchoring type are still not available.
Basing on the examination of the available experimental results of bond tests in concrete and masonry specimens externally bonded with FRP materials, this paper is aimed to furnish design indications for calculating the effectiveness of two types of common end anchoring systems in term of theoretical debonding load increase: 1) transversal FRP strips and 2) FRP spike anchors.

Keywords: FRP materials, externally bonded reinforcement, concrete, masonry, debonding load, anchoring devices.

1 INTRODUCTION

Anchoring devices for external strengthening systems made of Fiber Reinforced Plastic (FRP) materials represent a solution to avoid or delay debonding phenomena in concrete and masonry strengthened elements. The increase of failure loads may be, thus, attained by placing anchoring devices at the end of flexural or shear externally bonded FRP reinforcements. Moreover, anchoring devices may be useful also for increasing the ductility of the strengthened elements, since debonding is usually a very brittle failure mode, which often does not allow exploiting the full tensile strength of fibres (CNR DT 200/R1, 2013, [12]; *fib* bulletin 90, 2019, [15]).

Several types of anchoring devices were tested by researchers and used in real applications, but clear design indication for estimating the effectiveness of each anchoring type are still not available. Effectiveness of anchoring into increase strength and ductility of the strengthened elements depends on strengthening configuration (flexural, shear, confinement), type and geometry of the anchoring devices, mechanical properties of the substrate.

Design indications for predicting end debonding load in concrete and masonry elements externally bonded with FRP materials are now well consolidated, since the amount of available experimental tests are very relevant and allowed reliable statistical analysis and 'design by testing' calibrations used in code indications (CNR DT200/R1, 2013, [12]; fib bulletin 90, 2019, [15]).

Basing on the examination of the available experimental results of bond tests in concrete and masonry specimens externally bonded with FRP materials, this paper is aimed to furnish design indications for calculating the effectiveness of two types of common end anchoring systems in term of theoretical debonding load increase: transversal FRP strips and FRP spike anchors. Predictions are separately furnished for concrete and masonry elements.

2 LITERATURE REVIEW ON EFFICIENCY OF ANCHORING SYSTEMS

For flexural and shear strengthening configurations the most common anchorage system is given by a FRP sheet or a FRP or steel laminate glued transversally to the strengthening direction (Fig.1). This may be a reliable solution when the FRP-to-concrete width ratio, b_f/b, is lower than 1, because the transversal strip allows extending the width of concrete covered by the FRP strengthening (Ceroni and Pecce, 2010, [9], Ceroni et al., 2008, [10]; Al-Mahaidi and Kalfat, 2011, [2]). Conversely, when the ratio b_f/b increases, the effectiveness of the transversal strip reduces and becomes unhelpful when it approaches to 1. In these cases, U-shaped fiber sheets might be successfully used (Ceroni 2010, [6]; Khan and Fareed, 2014, [18]; Al-Amery and Al-Mahaidi, 2006, [1]; Buyle-Bodin and David, 2004, [4]; Orton et al., 2008, [25]; Spadea et al., 1998, [30]). For such an application, sharp edges of the section are recommended to be mechanically rounded with a minimum radius of 30 mm.

An alternative solution is represented by fiber spike systems, which are becoming a very diffuse anchoring system for wet-lay-up FRP reinforcements bonded to concrete and masonry elements (Ceroni and Pecce, 2010, [9]; Niemitz et al., 2010, [24]; Eshwar et al., 2008, [13]; Zhang and Smith, 2012, [31]; Zhang et al., 2012, [32]; Caggegi et al., 2014, [5]; Fagone et al., 2014, [14]; Ceroni, 2017, [7]) for several strengthening configurations, i.e. flexural reinforcement (Orton et al., 2008, [25]; Smith et al., 2011, [28]; Smith et al., 2013, [29]), confinement (Karantzikis et al., 2005, [17]), and shear reinforcement (Kim et al., 2011, [19]; Koutas and Triantafillou, 2013, [22]; Jinno et al. 2001, [16]; Kobayshi et al., 2001, [21]).

Fiber spike systems are usually made of a dry fiber cord or by a rolled dry fiber sheet (Fig.2a); carbon or glass fibers are usually adopted, even if some applications with steel cords

are also available (Prota et al., 2005, [27]). One end of the spike is impregnated by epoxy resin in order to form a dowel. A hole is drilled in the substrate on the same plane of the strengthening and the dowel is forced through the FRP reinforcement into the predrilled hole (Fig.2b). The fibers of the not impregnated end are splayed outwards over the reinforcement in order to form a fan with variable angle of splaying (α in Fig. 2b) and, then, fixed with epoxy resin. Fibers of the fan may be splayed parallel to the loading direction, in the opposite direction or along both of them (bow-tie configurations, Zhang and Smith, 2012, [31]). Other geometrical parameters of the spike anchor influencing its effectiveness are: the diameter, ϕ, of the cord, the embedded length of the dowel, l_{emb}, and the splaying radius, r, of the fibers.

The great advantage of such a system is the possibility to be applied also when b_f/b=1 or tends to 1, since it is a punctual anchoring system applied orthogonally to the reinforced surface. The effectiveness of the spike anchors may be influenced by details and accuracy of application procedures too.

2.1 Effectiveness of end anchoring in concrete elements

2.1.1. Transversal and U-shape strips

The good performance of transversal strips as end anchoring system was proved by bond tests on concrete elements externally bonded with CFRP sheets (Ceroni and Pecce, 2010, [9], Ceroni et al., 2008, [10]; Al-Mahaidi and Kalfat, 2011, [2]). In all these tests, the bonded length was comparable with the effective one as defined in (Chen and Teng, [11]; CNR DT 200/R1, 2013, [12]) or higher.

In particular, in the bond tests carried out by (Ceroni and Pecce, 2010, [9]) for specimens with b_f/b = 0.67, the increase of maximum load of the anchored specimens ranged in 10-20%, while for b_f/b = 0.33, the strength increase was even higher (+52-57%). Analogously, in (Ce-

roni et al., 2008) for specimens with b_f/b = 0.33, a load increase of 55% was observed for the anchored specimens in comparison with the not anchored ones.

Also in the bond tests of (Al-Mahaidi and Kalfat, 2011, [2]), for specimens with b_f/b=0.4, a relevant load increase was attained in presence of transversal strips (+39-43%).

As the experimental results evidenced, when the FRP-to-concrete width ratio increases, the effectiveness of the transversal strip reduced and becomes unhelpful when it approaches to 1; in these cases U-shaped fiber sheets might be used. In (Ceroni, 2010, [6]) the use of U-shaped strip at the end of RC beams strengthened in bending with carbon FRP sheets led to an increase of the ultimate load of 5-10% depending on the steel reinforcement percentage (1% or 1.5%). In case of U-shaped strips distributed along the beam, a higher increase of ultimate load was attained, i.e. 10-20% for the same values of steel percentage. Nevertheless such a limited load increase, the use of end and especially of distributed U-shaped strips allowed increase ductility even greater than 50% at failure compared with the not anchored strengthened beam.

Also, in (Khan and Fareed, 2014, [18]) the effect of U-shaped fiber sheets to strengthen RC beams in bending was studied. The beams were characterized by different value of the span-to-depth ratio (a/d) and the end anchorages was wrapped all along the cross-section of the beam. It was observed a load increase of 6% and 15% for the anchored beams compared with the reference ones for the ratio a/d=3.4 and 2.5, respectively.

Further research conducted by (Al-Amery and Al-Mahaidi, 2006, [1]) evidenced that the use of the CFRP U-jackets, 200 mm spaced along the length of the beam, reduced the interfacial slip between the CFRP reinforcement and the concrete by up to only 1/10 of the values attained without anchoring devices. Moreover, the U-jackets allowed the full utilization of the CFRP flexural tensile capacity with an increase of the flexural strength up to 95% compared with the unstrengthened beam and up to 15% compared with the strengthened beam without the U-jackets.

In (Spadea et al., 1998, [30]), flexural tests on CFRP-strengthened RC beams with U-shaped steel anchors were carried out. The anchoring devices were installed both at the plate ends and distributed throughout the span, aimed to improve especially the ductility. In presence of anchoring devices, the experimental strains in the fibers at failure reached the 80% of their maximum strain with an enhancement of 67% compared with the not-anchored beam. Moreover, in the strengthened beams without anchorage the ductility reduced by 70–80% in comparison with the unstrengthened beams, whereas, in presence of anchoring devices, the loss of ductility ranged in 45–70%.

In (Mofidi et al., 2012, [23]), externally bonded CFRP strip and mechanically fixed double-aluminum-plates were used as end anchoring systems for concrete beams strengthened in shear by means of externally bonded CFRP sheets. The load increase attained in the anchored beams respect to the not anchored strengthened beam was 18% and 14%, respectively, for the two systems.

2.1.2. Spike anchors

Several pull-out tests aimed to check the effectiveness of spike anchors in concrete elements were carried out by (Özdemir, 2005, [26]). Basing on the experimental results, the following suggestions were provided: 1) anchors have to be inserted at least 50 mm into the core of the concrete (depth of 130–150 mm); 2) the cross-sectional area of anchor has to be at least two times greater than the cross-sectional area of the longitudinal sheet; 3) splitting the anchor into as many smaller anchors at about a 40 mm spacing as possible.

In (Ceroni and Pecce, 2010, [9]), bond tests on concrete specimens bonded with CFRP sheets with b_f = 100 mm (b_f/b = 0.67), provided that 1 spike anchor made of carbon fibesr

(ϕ=10mm, r=50 mm, α=90°, l_{emb}=50 mm) allowed a debonding load increase of 28% in comparison with equal not anchored specimens.

The bond tests of (Eshwar et al., 2008, [13]) evidenced similar bond strength increase; in particular, the increase was 25% in case of 1 spike anchor made of glass fibers (ϕ=10 mm, r=50 mm, α=360°) with l_{emb}=50 mm or 75 mm. A more significant load improvement (+230%) was attained in case of two adjacent glass anchors with the same geometry and l_{emb}=75 mm.

In the bond tests of (Niemitz et al., 2010, [24]), several configurations for two spike anchors made of carbon fibers were tested. When the two anchors (ϕ=13 mm, r=25mm, α=360°, l_{emb}=150 mm) were positioned side by side along the reinforcement width (Fig. 3a), the load increase was about +70%, while, when they were placed along a row (Fig. 3b), the efficiency was lower (+47%). The efficiency of the row configuration resulted improved (load increase +61%), if the diameter of the cord and the splaying radius were both increased (i.e., ϕ=19 mm, r=30mm).

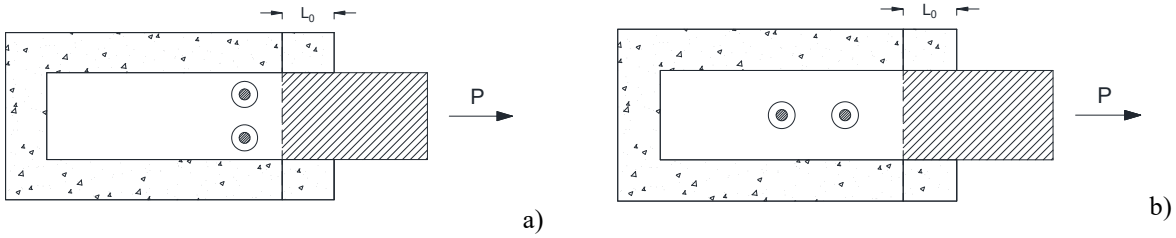

Figure 3: Spike anchor configurations in the test of (Niemitz et al., 2010 [24]): a) side by side configurations; b) row configuration (L_o is an unbonded length).

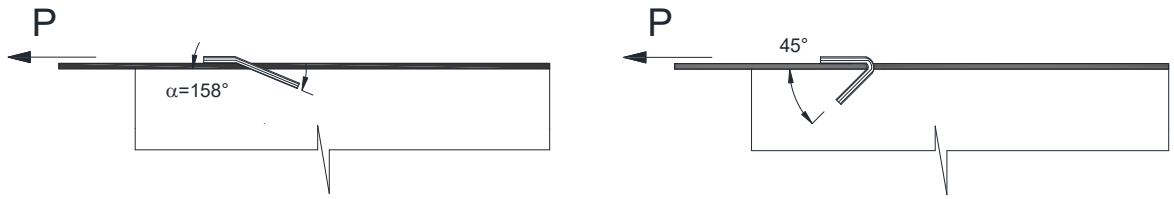
In the bond tests of (Zhang and Smith, 2012, [31]; Zhang et al., 2012, [32]) on concrete specimens bonded with CFRP sheets with b_f = 50 mm, a load increase ranging in 73-100% was attained when a single spike anchor made of carbon fibers (ϕ=12 mm, r=50 mm, α=60°, l_{emb}=40 mm), with the fibers splayed in the direction of load, was applied. Conversely, for the same anchor geometry, when the fibers were splayed in the reverse direction of the load, the increase was only 60%. Moreover, when a bow-tie configuration for the same anchor geometry was used, the load increase was again 100%, but, clearly, the fiber content was twice in this case. In case of single spike anchor made of glass fibers (ϕ=12 mm, r= 50 mm, a=60°, l_{emb}=40 mm) splayed in the direction of load, the load increase was 53%.

In the tests carried out by (Zhang and Smith, 2012 [31]), the influence of the dowel angle respect to the load direction was also investigated by ranging it in 45° - 157°. As the angle of the anchor dowel was increased, the failure load increased more relevantly. In particular, the highest effectiveness (+160% of load increase in comparison with the not anchored specimen) was attained for an angle of 157° (Figure 4a) and the lowest (+24%) for an angle of 45° (Figure 4b). However, it was observed that the ductility of the joint decreased when the dowel angle increased, as observed from the brittle anchor failure and the lack of a post-peak behavior. When the anchor dowel angle exceeded 90°, indeed, the anchor tended to rupture simultaneously with complete debonding of the reinforcement, the strength of the joint was increased, but at the expense of ductility loss. Conversely, for dowel angles less than 90°, the anchor remained intact and was able to accommodate large slippage with a lower strength increase.



a) b)

Figure 4: Inclination of spike dowel in the tests of (Zhang and Smith, 2012, [31]): a) α=157°; b) α =45°.

In (Orton et al., 2008, [25]), attention was focused on the constructive detailing for warrant the best efficiency of spike anchor systems. In particular, bending tests on concrete beams strengthened with CFRP were conducted to evaluate the size, number, and spacing of spike anchors and to compare the performance of not anchored beams with beams provided of spike anchors or U-wraps. The experimental results showed that, without additional anchorage, the CFRP sheets debonded at about 37% of the tensile strength of fibers. Two single layer U-wraps placed at both ends of the strengthened beam allowed to increase the tension in the CFRP sheet up to 70% of its capacity, induced debonding of the flexural reinforcement and shear failure of the U-wraps, and led to a load increase of 75% in comparison with the not anchored beam. Two double layer U-wraps allowed a load increase of 150%, while two rows of three spike anchors (10 mm diameter) allowed developing the CFRP sheet's full tensile capacity with a final load increase of 170%. In addition, it was found that a greater number of smaller anchors and reduced spacing were more effective than larger spacing, which did not anchor the entire width of the FRPs and did not allow avoiding a partial debonding.

The bending tests conducted by (Smith et al., 2011, [28]) investigated the strategic use of different types and positions of spike anchors made of carbon fibers with bow-tie configuration to increase both strength and deflection capacity of strengthened slabs. A load increase variable between 24-30% in comparison with the reference not-anchored strengthened specimen was attained by using several spike anchors (r= 50 or 100 mm, α=60°, l_{emb}=50 mm) distributed along the span length with different spacing. The anchors allowed a relevant increase of ductility, which increased until 110 % in comparison with that of the unanchored strengthened slab.

Smith et al., 2013, [29] carried out further bending tests on concrete slabs in order to check the efficiency of single and bow-tie spike anchors located at the end or distributed along the reinforcement into increase strength and ductility. As in (Smith et al., 2011, [28]), the spike were made of carbon fibers with r = 50 mm, α= 60°, l_{emb}=50 mm and a suitable configuration of the anchors allowed to attained a load increase of 44%.

Spike anchors were used also in shear strengthening according to several configurations by (Jinno et al., 2001, [16]; Kobayshi et al., 2001, [21]) to solve the problem of passing fibers of reinforcement through the web of a 'T-section' and anchor the fibers of the shear reinforcement in the compressive zone of the section.

Analogously, in (Kim et al., 2011, [20]) 'T-section' beams were reinforced in shear by applying 'U-shaped' CFRP strips anchored using spike anchors made of carbon fibers just below the flange. A 40-45% increase in shear strength was observed.

In (Koutas and Triantafillou, 2013, [22]), a wide experimental investigation was carried out in order to check the effectiveness of various types of spike anchors into increase the capacity of concrete beams strengthened in shear by 'U-shaped' FRP sheets. Orientation of the cord, number and spacing of anchors, type of fibers constituent the anchors (carbon or glass) were the investigated parameters. With refer to the beam strengthened in shear without any anchors, the use of different lay-out of spike anchors led to the following load increase: +8%

for three horizontal anchors, +46% and +53% for three or five inclined anchors (angle of inclination approximately 25° with respect to the vertical). In case of five anchors, the increase in effectiveness of the jacket was only 53% because the anchors placed not above the shear cracks were not activated.

For confinement of columns where walls physically obstacle the complete wrapping of the elements, application of spike anchors (Jinno et al.2001, [16]; Kobayshi et al. 2001, [21]) can be used for giving continuity to the reinforcement.

Spike anchors provide a low cost solution also to anchor the confinement jacket to the existing structure, especially for the attachment of FRP jackets at the reentrant corners of L-shaped cross section columns, as tested in (Karantzikis et al., 2005, [17]). Experimental tests evidenced, indeed, that in FRP jacked specimens without anchors the strength increase respect to the reference specimen ranged in 32%-48% when the jacket was made of lightweight or heavyweight FRP sheets. In case of partial depth spike anchors, the strength increase respect to the not-anchored specimens ranged in 59-72%, and, in case of full depth anchors, the strength increased by 97% in both case of lightweight or heavyweight jacketing sheets.

2.2 Effectiveness of end anchoring in masonry elements

For masonry elements externally bonded with FRP materials, the efficiency of end-anchoring systems into improving the failure load may depend on the substrate typology.

Several bond tests were carried out by (Caggegi et al., 2014, [5]) and (Fagone et al., 2014, [14]) in order to analyze the performance of spike anchors applied to a brick substrate reinforced with CFRP sheets, as well as the influence of different test apparatus implementing the same test set-up. Different configuration for the spike anchors, made of carbon fibers, were considered varying the splaying angle of the fan (α=75° or 360°), the number of fan (1, 2 or 3), the diameter of fan radius splayed over the reinforcement (r = 25 or 40 mm). In all cases, the embedded length was l_{emb}=50 mm.

In the tests of (Caggegi et al. 2014, [5]), the load increase ranged between 26-87% respect to the not anchored specimen, with the higher increase (+87%) attained for the specimens with three anchors with r=25 mm and α=75°; such a configuration allows covering the whole width of the FRP reinforcement. A lower efficiency (+66%) was attained when two anchors with r=40 mm and α=75° were applied, even if also this configuration allowed entirely covering the FRP reinforcement. Conversely, similar load increases (26-31%) were attained when a single anchor was applied either with r=25 mm or 40 mm and α=75° and with r=40 mm and α=360°. In case of r=40 mm and α=75°, the use of two anchors allowed doubling the efficiency compared to the case of only one (+66% vs. +31%).

In (Fagone et al., 2014, [14]) the same specimens and testing configuration used by (Caggegi et al., 2014, [5]) were adopted. The same operators prepared the specimens. Nevertheless, the maximum loads attained in the tests of (Fagone et al., 2014, [14]) resulted higher than those obtained in the tests of (Caggegi et al., 2014, [5]) with differences ranging from 10% to 30%. Such differences were due the different deformability of the test set-up used by (Caggegi et al., 2014, [5]). In particular, for the same anchor configurations previously described, the load increases ranged in 34-116% instead of 26-87%, in the case of three anchors, while were variable in 34-48% instead of 26-31% in case of single spike anchor.

In (Ceroni, 2017, [7]), the effectiveness of spike anchors made of carbon fibers (ϕ=10 mm) was tested by means of bond tests on both single tuff stones and clay brick prisms. Tuff is a volcanic stone very used for buildings in the Southern Italy. For specimens made of single tuff stone, a similar effectiveness in terms of failure load increase (about +18%) was registered when a single anchor with α=360° and r=50 mm or two anchors with α=75° and r=40

mm, both having an embedded length of l_{emb}=80 mm, were applied. Conversely, in case of longer embedded length of the cord (i.e., 180 mm), the effectiveness of two anchors with α=75° was higher compared with a single fan with α=180° (i.e., +25% vs. 17%). It is worth to note that the effectiveness of the spike anchors in tuff stones was, however, limited by the very low tensile strength of the tuff, which make it sensible to shear/tensile failures in the blocks (Figure 5).

Figure 5: Failure surface at the end of anchored specimens made of tuff stone (Ceroni, 2017, [7]).

In (Ceroni, 2017, [7]), the efficiency of spike anchors was tested also on prisms made by clay bricks externally strengthened with carbon fibers. For these specimens, a similar effectiveness was experimentally observed when two spike anchors made of carbon fibers with ϕ=10 mm, α=75° and r=40 mm or when a single anchor with ϕ=10 mm, α= 360° and r=50 mm, both with l_{emb}=80 mm, were used (the load increase ranged, indeed, in 37-40%).

The experimental load increase observed for such specimens (+40%) was higher than the one observed in the specimens made of tuff stones (+25%) for similar anchoring configurations, showing again the sensibility of the failure load to the mechanical properties of the masonry support also when the anchoring devices are present. For both types of specimens, a squared quadriaxial sheet made of carbon fibers (side 100 mm) was applied over the anchors in order to improve their correct placement during the curing of the epoxy adhesive.

3 DESIGN INDICATIONS

Basing on the literature review previously discussed, some proposals of design indications are furnished for two types of anchoring systems for wet-lay-up FRP externally reinforcements, i.e. transversal strips and spike anchors, which are two of the most common used in practical applications.

For strengthening of concrete elements, both use of transversal strips and spike anchors are suggested, while for masonry elements, only design indications for spike anchors are proposed due the higher experimental data available for such an anchoring system. Since the effectiveness of spikes in terms of failure load increase depends strongly both on the anchor geometry and on the mechanical properties of the substrate, different strengthening configurations and design indications are suggested for concrete and masonry substrates.

For each selected anchoring configuration, with refer to common existing bond strength models (i.e., CNR DT200/R1, 2013, [12] or fib bulletin 90, 2019, [15]), an increasing of the theoretical debonding load is suggested basing on the experimental outcomes previously discussed.

A typical strength model for calculating the maximum stress in the FRP reinforcement in case of end debonding is the well-know one adopted by several authors and codes (Chen and Teng, 2001, [11]; CNR DT200/R1, 2013, [12]; fib bulletin 90, 2019, [15]):

$$f_{fb} = \beta_l \sqrt{\frac{2E_f \cdot G_f}{t_f}} \tag{1}$$

where β_l is a factor that depends on the bond length l_b, (i.e., it is lower than 1, if l_b is lower than the effective length), E_f and t_f are Young's modulus and thickness of the external reinforcement, G_f is the fracture energy associated to the reinforcement/substrate interface failure.

Starting from the general approach given by Eq. (1), most design formulations provide numerical coefficients derived from statistical regression analysis of experimental results of bond tests. In the new version of *fib* bulletin for external strengthening of concrete elements with FRP materials (*fib* bulletin 90, 2019, [15]), the following expression is suggested for calculating the mean debonding strength, $f_{deb,m}$, in the FRP reinforcement in case of debonding at the end anchorage zone:

$$f_{deb,m} = k_m \cdot k_b \cdot \beta_l \sqrt{\frac{2E_f}{t_f} \cdot f_{cm}^{2/3}} \qquad \text{[N, mm]} \qquad k_b = \sqrt{\frac{2 - b_f / b}{1 + b_f / b}} \tag{2}$$

where f_{cm} is mean compressive strength of concrete. The coefficient k_m= 0.25 was calibrated by (Bilotta et al., 2011, [3]) according to a statistical procedure as the least-square coefficient minimizing the difference between theoretical values and experimental results.

A similar approach is adopted also by (CNR DT200/R1, 2013) for predicting the end-debonding stress for strengthening of both concrete and masonry elements according to the following expression:

$$f_{deb,m} = \sqrt{\frac{2 \cdot E_f}{t_f} \cdot t_f \cdot k_b \cdot k_{G,m} \cdot \sqrt{f_{cm} \cdot f_{tm}}} \qquad k_b = \sqrt{\frac{3 - b_f / b}{1 + b_f / b}} \tag{3}$$

where the coefficient $k_{G,m}$ was differently calibrated according to the substrate (concrete or different types of masonry, i.e. tuff stones, limestone, calcarenite, clay bricks). An upgraded calibration of such a coefficient is provided in (Ceroni et al., 2017 [33]) for different masonry substrates, taking into account also the effects of the mortar joints on the bond strength.

The increased bond strength provided by each anchoring system can be used for calculating the global capacity of concrete or masonry strengthened elements in case of reinforcement configurations based on bond behavior and, thus, affected by end-debonding failure (i.e., mainly flexural and shear reinforcement). For both shear and flexural strengthening, the load increase provided by the anchoring system depends, indeed, not only on its type and geometry, but also on the original capacity of the not-strengthened element and the amount of external reinforcement. Thus, it is not simple to generalize the efficiency of an anchoring system, since it depends on the strengthening configuration. Conversely, with refer to the only bond behavior and, thus, to the end-debonding load, it is simpler to provide a generalized methodology for calculating the efficiency of the anchoring system into increase the bond strength for end debonding.

3.1 Design indications for concrete elements

3.1.1 Transversal strips

For transversal strips having the same width of the element, b, or U-shaped strips, the following increase of the theoretical end debonding load can be considered:
- +40% for strengthening configuration with $b_f/b = 0.33$;
- +20% for strengthening configuration with $b_f/b = 0.67$;
- linearly interpolated values between 20% and 40% for $0.33 < b_f/b < 0.67$.

For strengthening configurations with $b_f/b > 0.67$, the use of a transversal strip is not suggested as end anchoring system, but other configurations should be used.

3.1.2 Spike anchors

Basing on the experimental outcomes previously described, the following anchoring configurations can be considered:

1) for strengthening made of FRP sheets with b_f=100mm:

1a) single spike anchor made of carbon fibers with ϕ=10mm, r=50mm, α=360° and l_{emb}=100mm (Fig. 3a). For this configuration, an increase of the theoretical failure load of 25% can be assumed, safely based on the results of (Ceroni and Pecce, 2010, [9]; Eshwar et al., 2008, [13]);

1b) two adjacent spike anchors made of carbon fibers with ϕ=12mm, r=25mm, α=360° and l_{emb}=100mm (Fig. 3b). The two anchors have to be spaced of 50 mm in order to cover all the reinforcement width, b_f. For such a configuration, an increase of the theoretical failure load of 50% can be assumed, safely based on the results of (Niemitz et al., 2010, [24]);

2) for strengthening made of FRP sheets with b_f=50mm:

- 1 spike anchor made of carbon fibers with ϕ=12mm, r=50mm, α=60° and l_{emb}=100mm (Fig. 3c). For such a configuration, an increase of the theoretical failure load of 50% can be assumed, safely based on the results of (Zhang et al., 2012, [32]; Zhang and Smith, 2012, [31]).

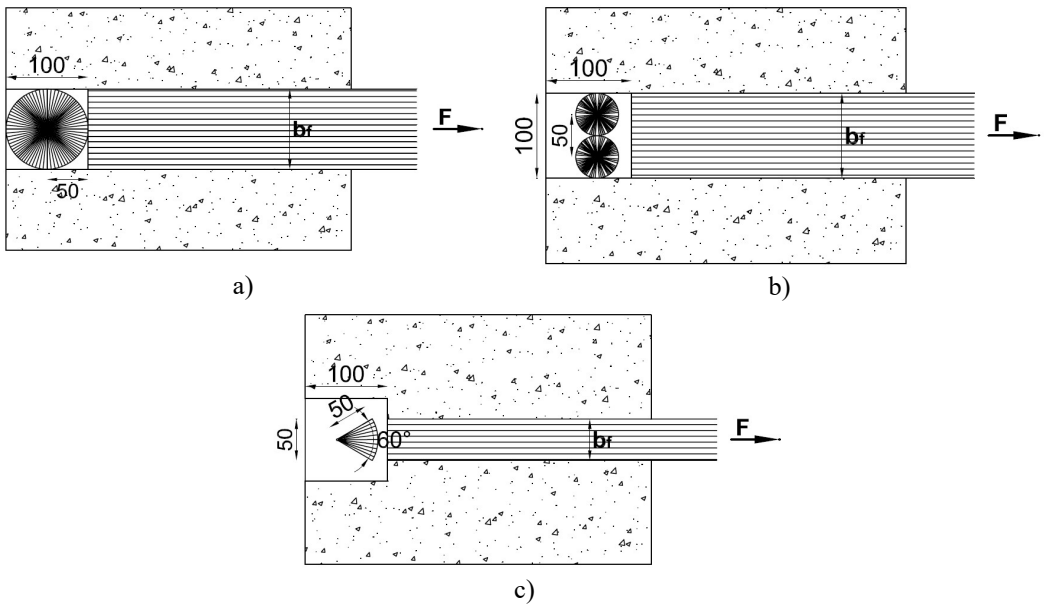


Figure 6: Recommended geometrical configurations for spike anchors in concrete elements: for b_f=100 mm a) 1 spike anchor with l_{emb} =100 mm, α = 360°, r = 50mm, and b) 2 spike anchors with l_{emb} =100 mm, α = 360°, r = 25 mm; for b_f=50mm c) 1 spike anchor with l_{emb} =100 mm, α = 60° e r =50 mm (dimensions in mm).

As further detail, for whatever spike anchor configuration, it is suggested to:

- apply a square quadriaxial FRP sheet (side 100 mm) over the splayed fibers in order to improve their correct placement during the curing of the epoxy adhesive;
- smooth the hole contour in order to avoid local failure of the splayed fibers.

3.2 Design indications for masonry elements

Bond behaviour of FRP strengthening systems applied on masonry substrates depends on masonry typology (Ceroni et al., 2014, [8]) with refer to both their mechanical and physical properties. Due to the variability of these properties, univocal design indications for whatever masonry substrate cannot be provided. Moreover, due to the wide variability of masonry substrates, especially in case of natural stones, which can be very variable depending on the geographical area, a consistent number of experimental results is not always available for each masonry substrate. Thus, basing on the most numerous experimental results now available, attention will be focussed on only two masonry substrates: clay bricks and tuff stone.

Clay bricks represent a very common building material all over the world, while tuff is a volcanic stone typical of the Southern Italy and very used in that area for realizing buildings, mainly because of its lightness and workability. These two materials are rather different both for the physical (unit weight, porosity) and mechanical properties (Young's modulus, compressive and tensile strength). Different indications will be provided for these two types of substrates basing on the outcomes of the experimental results described in section 2.2.

For masonry elements made of tuff stones and strengthened with FRP sheet having width b_f=100 mm, the following anchor configuration is suggested (see Figure 7a):

- 2 spike anchors made of carbon fibers with diameter of cord ϕ= 10 mm, embedded length l_{emb} = 150 mm, angle of splaying α=75°, and radius r = 40 mm.

The two spikes have to be applied at a distance of 50 mm in order to do not overlay each other and cover the reinforcement width as larger as possible. For such configuration, an increase of the theoretical debonding load of 25% can be considered, basing on the results of (Ceroni, 2017).

For masonry elements made of clay bricks and strengthened with FRP sheet having width b_f=100 mm, the following anchor configurations are suggested:

- 1 spike anchor made of carbon fibers with diameter of cord ϕ= 10 mm, embedded length l_{emb} = 80 mm, angle of splaying α=75°, and radius r = 40 mm (Figure 7b);
- 2 spike anchors made of carbon fibers with diameter of cord ϕ= 10 mm, embedded length l_{emb} = 80 mm, angle of splaying α=75°, and radius r = 40 mm. The two anchors have to be applied with a spacing of 50 mm in order to not overlap each other and to cover most part of the reinforcement width (Figure 7c).

For these two configurations, the increase of the theoretical failure load may be safely estimated in 30% and 50%, respectively, basing on the results of (Ceroni, 2017, [7]; Fagone et al., 2014, [14]; Caggegi et al., 2104, [5]).

As previously indicated for concrete elements, for both types of masonry substrates and for whatever spike anchor configuration, it is suggested to apply a squared quadriaxial FRP sheet (side 100 mm) over the splayed fibers and smooth the hole contour.

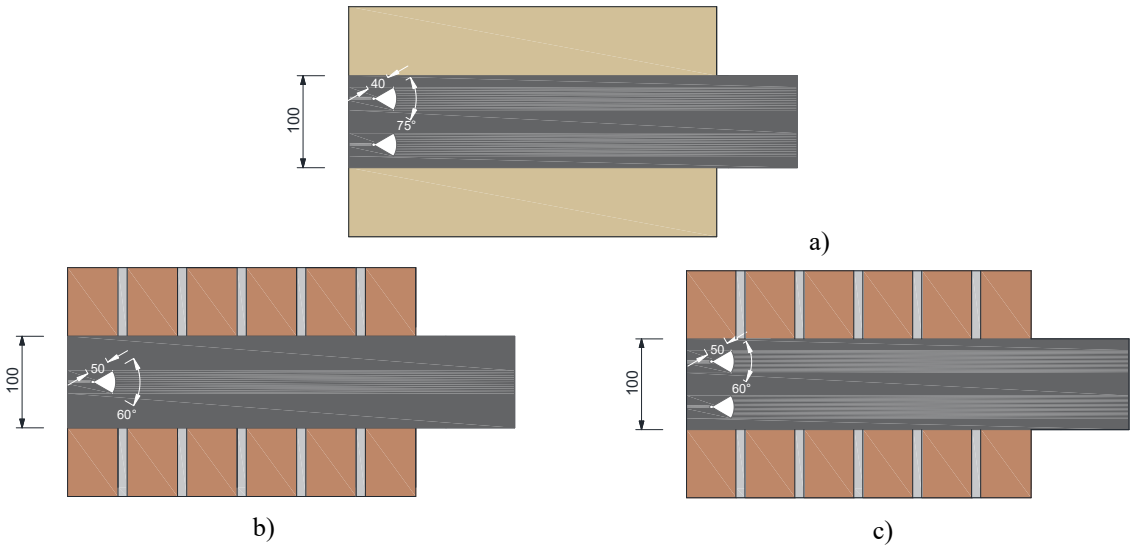

Figure 7: Recommended geometrical configurations for spike anchors in masonry elements for b_f=100 mm: a) 2 spike anchors for tuff stones with l_{emb} = 150 mm, α = 75°, r = 40 mm; b) 1 spike anchor for clay bricks with l_{emb} =80 mm, α = 60° e r =50 mm; c) 2 spike anchors for clay bricks with l_{emb} =80 mm, α = 60° e r =50 mm (dimensions in mm).

4 CONCLUSIONS

The paper presents a detailed state-of-art of the knowledge about the effectiveness of different types of anchoring systems for externally bonded FRP materials applied to concrete and masonry substrates.

The analysis of technical literature evidenced that the efficiency of anchoring systems varies sensibly according to both the strengthening configuration (flexural, shear, confinement) and type and geometry of the anchoring systems. Also detailing can influence the efficiency of each anchoring system.

The design indications proposed in this paper represent suggestions for calculating an increase of the theoretical end-debonding load provided by two common anchoring systems, i.e. transversal strips and spike anchors, since for these two devices more homogeneous and numerous experimental data are now available. The theoretical end-debonding load can be calculated with refer to existing well-established bond strength models for end-debonding failure.

The increased bond strength in presence of anchoring devices can be, indeed, used for calculating the global capacity of concrete or masonry elements strengthened with FRP materials in shear or bending, i.e. for strengthening configurations governed by the bond behavior at the FRP-substrate interface and eventually affected by end-debonding failure.

Extension of similar design indications to other types of anchoring devices request, clearly, availability of homogeneous experimental results.

Abstract

This paper presents the results of the work carried out in an ongoing Research Project, funded by the Italian Civil Protection Department, aimed at computing the risk of collapse of existing masonry buildings. Other papers submitted to this conference describe the overall Research Project [1], its different areas of application ([2][3][4][5][6]), the overall seismic risk calculation procedure, the seismic hazard assessment and the ground motion selection process followed to identify the recorded ground motions used for nonlinear dynamic analyses. Several unreinforced masonry buildings were considered, characterized by stone and clay masonry, regular and irregular geometries and number of storeys varying from two to seven. These buildings were retrofitted according to the prescriptions of different Italian seismic codes, applying commonly adopted retrofit techniques (e.g. floor stiffening, injection of masonry, addition of tie beams, etc). The paper presents the results for a single case study building. Equivalent frame models are used to simulate the in-plane response, whereas out-of-plane failure modes are prevented by the selected strengthening interventions. Pushover analyses are performed to estimate the capacity in terms of a properly selected engineering demand parameter, whereas the demand is obtained by multi-stripe nonlinear dynamic analyses for ten different earthquake's return periods. The results allow to understand the different level of risk implicit in buildings retrofitted according to various codes and strategies.

Keywords: Unreinforced masonry, Nonlinear static and dynamic analysis, Equivalent frame models, Multi-stripe analysis, Seismic retrofit.

1 INTRODUCTION

RINTC-e is an ongoing research project, funded by the Italian Civil Protection Department, aimed at computing the risk of collapse of existing buildings. As a continuation of the previous work, which concerned new buildings [7], [8], [9], this paper focuses on understanding the different level of risk implicit in existing unreinforced masonry (URM) buildings retrofitted according to the prescriptions of different Italian seismic codes.

Several building configurations, realised with stone and clay masonry, with regular and irregular geometries, a number of storeys ranging from two to seven, and located in three different towns (L'Aquila, Naples and Rome) were analysed within the project. These buildings were retrofitted adopting common retrofit techniques aiming at improving wall-to-wall and wall-to-diaphragm connections, at increasing the in-plane stiffness of diaphragms and, in some cases, enhancing the strength of masonry by grout injections or other techniques.

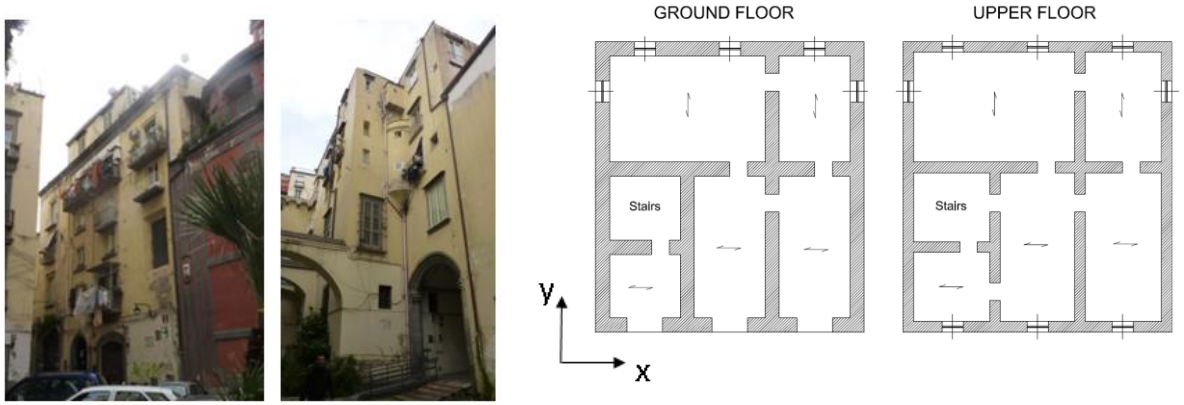
The risk assessment in terms of global failure was performed by multi-stripe nonlinear dynamic analyses for ten different earthquake's return periods. The equivalent frame model implemented in the Tremuri program [10] was adopted, using the available macroelement models ([11], [12]). Pushover analyses were performed to estimate the capacity in terms of maximum wall inter-storey drift. Out-of-plane failure modes were not considered, as strengthening interventions are supposed to be appropriately designed to prevent their activation.

The results shown in this paper refer to one of the case study structures analysed, located in Naples and representative of a typical typology of the late nineteenth century.

2 IDENTIFICATION OF THE SELECTED CASE STUDY

The case study discussed in this paper consists of a 5-storey unreinforced yellow tuff masonry structure, with flexible wooden floors and different wall thicknesses and inter-storey heights (Table 1).

Figure 1 (a) shows two photos of the existing building and the corresponding plans of the ground and upper floors (Figure 1b), whereas Figure 2 shows the elevations views, obtained from a slight simplification of the real situation.



(a) (b)

Figure 1: Photos of the considered existing building prototype (a) and corresponding plans (b), obtained from a simplification of the real building. X and Y indicate the directions of analysis.

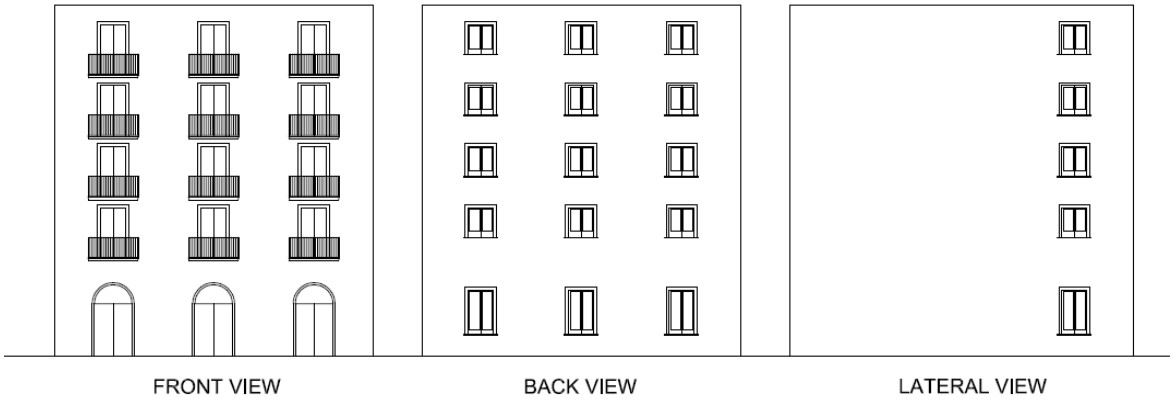


Figure 2: Elevations of the considered building, obtained from a simplification of the real building.

	Ground Floor	1st - 2nd Floor	3rd Floor	4th Floor
Wall thickness [m]	0.8	0.6	0.4	0.4
Inter-storey height [m]	4.5	2.7	2.7	3
Total Length [m]	15.2			
Total Height [m]	15.6			
Total Width [m]	16.4

3 DESIGN OF RETROFIT SOLUTIONS USING DIFFERENT CODES

The retrofit interventions on the considered URM buildings were designed according to the "Code for repair and strengthening of buildings damaged by earthquakes," issued by the Ministry of Public Works in 1981 (D.M. 1981, [13]), and the associated guidelines [14], incorporating the POR method, originally proposed by Tomaževic [15] for the seismic analysis of retrofitted URM buildings. Such documents were published after the 1976 (Friuli), 1979 (Norcia) and 1980 (Irpinia) earthquakes and extensively used in the reconstruction phase. The procedures presented in this code were then included, with minor modifications, in the national seismic codes and largely implemented in the retrofit interventions designed in the last two decades of the 20th century.

Interventions were also alternatively designed according to the Italian building code issued in 2008 (NTC08, [17]) and its guidelines [18], which came into force after the 2009 L'Aquila earthquake. Eventually, retrofit interventions were assessed according to the code update published in 2018 (NTC18, [19]) and its guidelines [20].

3.1 D.M. 1981 (POR method)

The POR approach is an equivalent static, simplified nonlinear assessment method, proposed and developed by Tomaževič [15]. The method, which has undergone several refinements in the subsequent years, is based on the so-called "storey-mechanism" approach, which assumes that failure occurs only in the piers (shear failure), without any damage in the spandrels. Each masonry pier is modelled by a linear elastic-perfectly plastic shear spring, with limited ductility and effective height equal to the net height of the openings, as indicated in [14]. Alternative definitions of the effective height aiming at accounting for the orientation of

cracks at the pier edges and for the deformability of spandrels were proposed for example by Dolce [16].

Applying the POR method, according to the guidelines in force at the time of construction of the building [14], the effects of the following seismic retrofit strategies were investigated and verified:

- realisation of a reinforced concrete ring beam at the storey levels;
- stiffening of the floors by casting collaborating reinforced concrete rigid slabs.

Figure 3 shows the definition of the equivalent frame mesh of two significant walls of the numerical model adopted for the analyses according to the POR method.

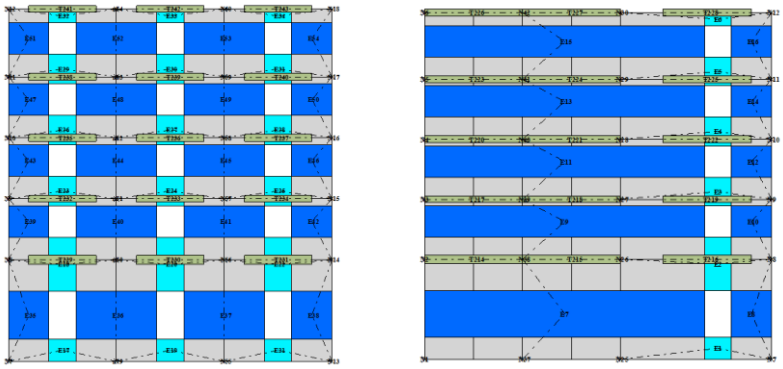

Figure 3: Equivalent frame mesh for two significant walls of the numerical model adopted in the analyses according to the POR method for the selected building.

The mechanical properties of masonry were assumed based on the values proposed in the guidelines [14] for tuff masonry. The adopted values are summarized in Table 2, in which f_m is the mean compressive strength of masonry, τ_0 is the mean shear strength of masonry, E and G the mean values of the elastic and shear moduli of elasticity and w is the masonry specific weight.

f_m [MPa]	τ_0 [MPa]	E [MPa]	G [MPa]	w [kN/m^3]
2.5	0.1	660	110	16

Table 2: Adopted mechanical properties of tuff masonry, assumed according to [14].

To be consistent with the assumptions of the POR method, the maximum shear strength of the structure was calculated under the hypothesis of fixed floor rotations, performing nonlinear static analysis (pushover), with a force distribution proportional to the first vibration mode. The seismic demand was computed as a percentage of the building weight, depending on the degree of seismicity of the considered area (Table 3).

Seismic Zone	Building weight, W_{tot} [kN]	Seismic Force, F_t [kN]	F_t / W_{tot} [-]
3	11489	1838	0.16

Table 3: Seismic forces computed according to [14].

Figure 4 shows the results of the analyses, in terms of shear strength normalized with respect to the weight of the structure (V/W_{tot}) versus top displacement. Since the strength in both

the directions of analysis clearly exceeds the seismic demand (dashed red line), the adopted retrofit strategies satisfy the code requirements of the period.

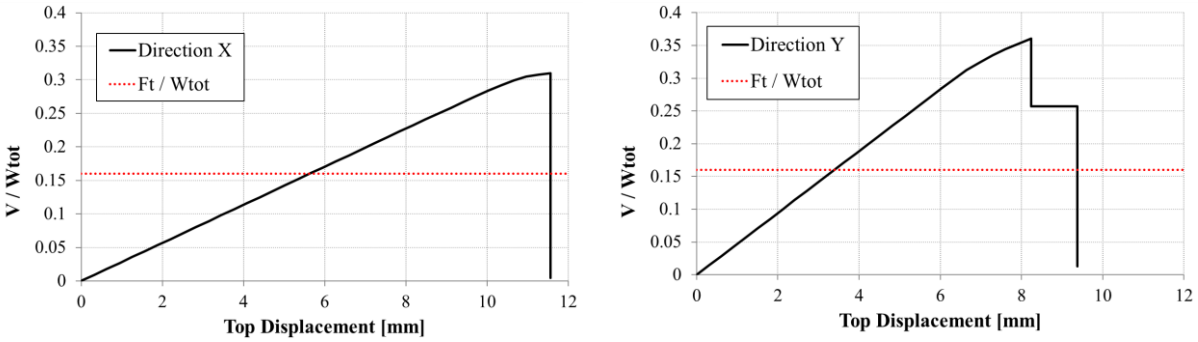

Figure 4: Results of the POR method, in terms of shear strength normalized to the weight of the structure versus top displacement: comparison between the strength of the structure in both the directions of analysis (longitudinal (left) and transversal (right)) and the seismic demand (dashed red line).

3.2 NTC08

For the same building prototype, different retrofit solutions were designed and analysed to fulfil the prescriptions of NTC08.

In particular, the effects of the following seismic retrofit strategies were investigated:

- stiffening of the floor diaphragm by adding a reinforced concrete collaborating slab, with lightweight concrete;
- improvement of the masonry quality by grout injections;
- enhancement of the wall-to-diaphragm connections by means of L-shaped steel ring beams at each floor level, except for reinforced concrete ring beams at the roof level;
- steel framing of all the openings of the longitudinal wall at the back (Figure 1b) by S275 HEB100 profiles.

These retrofit strategies were verified by applying the adopted equivalent-frame modelling strategy implemented in the 3Muri program and based on an elastic-perfectly plastic constitutive law of the structural element [10]. Figure 5 shows the 3D views of the numerical model of the retrofitted building.

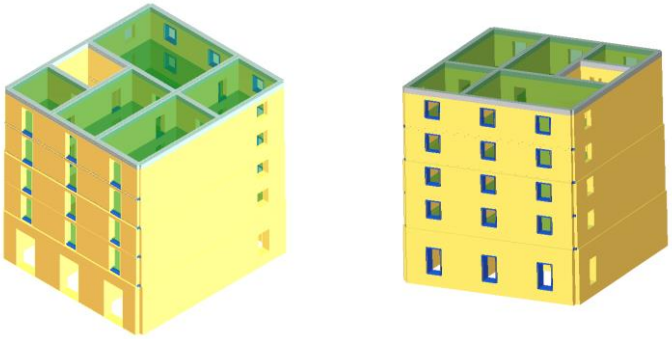

Figure 5: 3D views of the numerical models of the structures retrofitted according to NTC08.

The mechanical properties of masonry were defined based on the values proposed by the guidelines for NTC08 [18] for tuff masonry, assuming a confidence factor of 1.2 (knowledge level 2). The selected building was analysed in Naples, soil type A and C (topographic category T1). Figure 6 reports the pushover curve and damage pattern of one significant wall, ob-

tained in one of the critical analyses (minimum capacity over demand ratio) carried out according to NTC08 (soil type C). A damage concentration at the ground storey can be observed, with shear failure and flexural damage of the masonry piers of the longitudinal wall at the back (the one with steel profiles around all the openings).

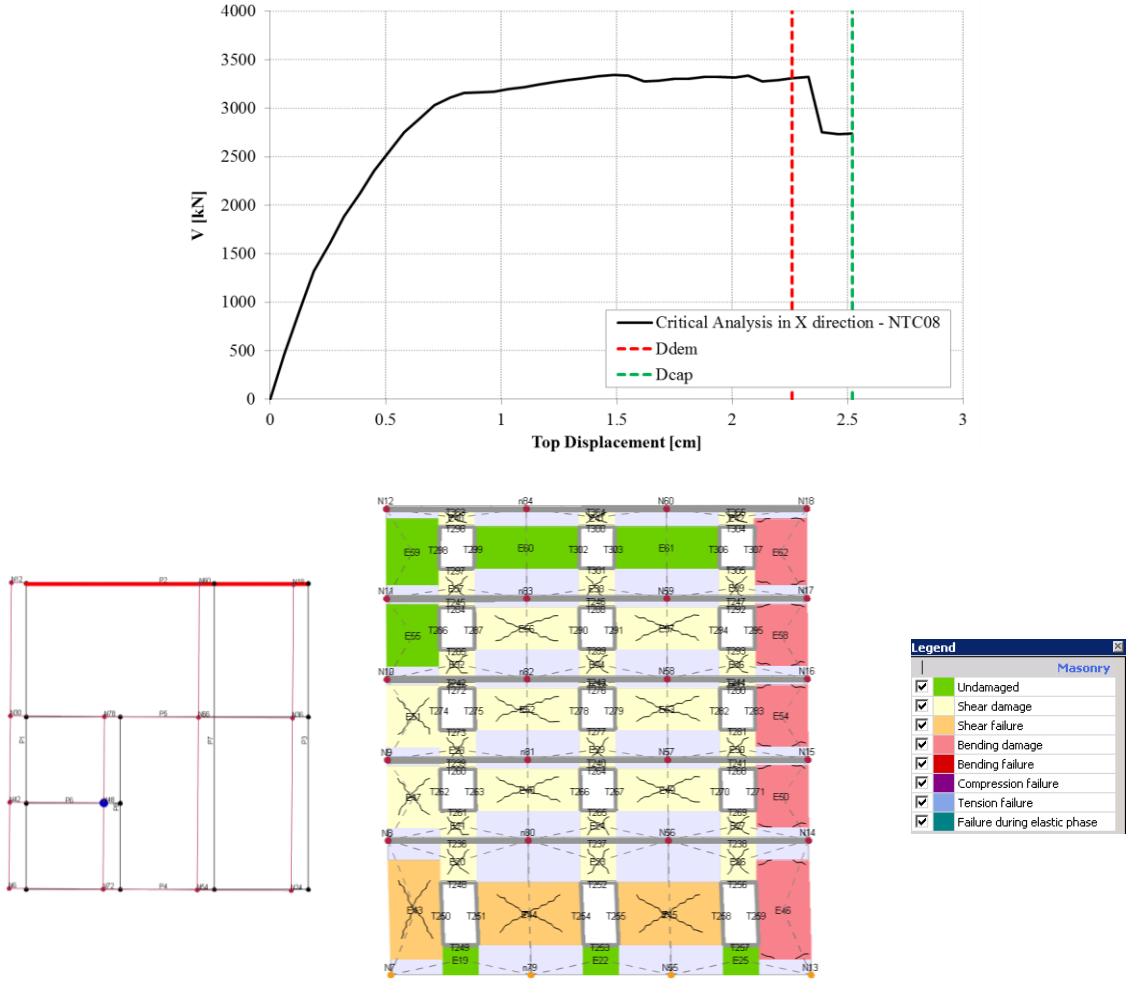

Figure 6: Results obtained for the critical analysis in the X direction (Figure 1), soil type C, for the building retrofitted according to NTC08: damage pattern of one significant wall (bottom) and pushover curve with indication of the demand (D_{dem}) and capacity (D_{cap}) displacement thresholds (top).

The retrofitted model was checked to fulfil also the prescriptions of NTC18 for both soil type A and C, for the two ultimate limit states of life safety and collapse. In particular, for the analyses carried out for soil type C, the maximum ratio between the maximum seismic capacity of the structure and the maximum seismic demand used for the design of new buildings (ζ_E) resulted equal to 90%, satisfying the requirements of the code ($\zeta_E \geq 80\%$).

4 SEISMIC PERFORMANCE OF RETROFITTED BUILDINGS

4.1 D.M. 1981

The seismic vulnerability of the retrofitted building was assessed by means of nonlinear static (pushover) and dynamic analyses, using the equivalent frame macroelement approach

implemented in the computer program Tremuri [10] and adopting for the piers an improved version [21] of the macroelement proposed by Penna *et al.* [11].

The mechanical properties of the macroelement model were calibrated starting from experimental tests on masonry of similar characteristics [22], consisting of in-plane cyclic shear-compression tests carried out on specimens made of cement mortar and tuff units obtained from demolished buildings erected in Naples in the last two centuries.

Figure 7 reports the comparison between the experimental results (black curve) and the numerical simulation (red curve), obtained for two of the unreinforced masonry piers tested.

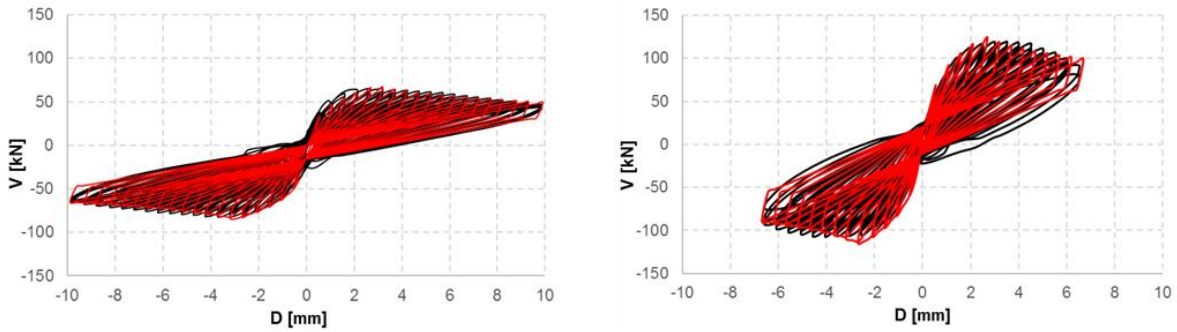

Figure 7: Comparison between the experimental results (black curve) and the numerical simulation (red curve), obtained for two of the unreinforced masonry piers tested by [22]: specimen T1-1 (left) and T1-3 (right).

Based on the comparison with experimental results, it was possible to calibrate only the parameters related to shear failure modes, since all experimental specimens failed in shear. The missing flexural parameters were derived from indications reported in the literature [24].

The seismic vulnerability was assessed in terms of frequency of exceedance of given thresholds of a selected Engineering Demand Parameter (EDP). As in [9], the maximum inter-storey drift (among all walls and all stories), accounting for the average rotations of the nodes of the storey, was selected as EDP. The EDP thresholds were computed by pushover analyses with an inverse triangular load pattern, considering the different behaviour of the building in the two directions of analysis, X and Y (positive and negative). The maximum inter-storey drift was evaluated separately for each direction and the EDP was calculated as the minimum value between the positive and negative direction for X and Y separately.

Two different limit states were considered: usability-preventing damage, UPD, evaluated according to the multi-criteria approach discussed in [1], and global collapse, GC, corresponding to a total base shear loss equal to 50% of the maximum base shear.

Figure 8 shows the pushover curves in the two directions of analysis, with the identification of the thresholds for the considered limit states (Table 4).

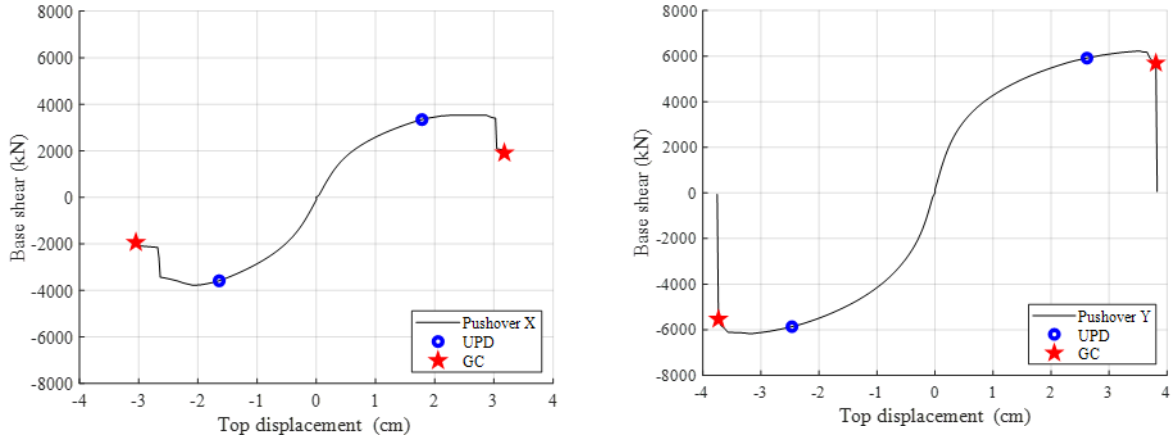

Figure 8: Pushover curves in the two directions of analysis for the building retrofitted according to D.M. 1981, with the identification of the thresholds for the considered limit states.

UPD threshold [%]		GC threshold [%]	
X direction	**Y direction**	**X direction**	**Y direction**
0.125	0.193	0.525	0.516

Table 4: Values of EDP thresholds corresponding to usability-preventing damage (UPD) and global collapse (GC) limit states, for the building retrofitted according to D.M. 1981.

The criterion governing the UPD limit state was the one associated with the attainment of 95% of the building lateral strength, corresponding to a condition in which the structure is still fully capable of withstanding horizontal forces. Figure 9 shows the damage in the structural elements at the end of analyses (GC limit state).

By means of nonlinear dynamic analyses, it was possible to calculate the percentage of exceedance of the two considered limit states, for increasing values of the return period. The time history analyses were carried out with a set of accelerograms (representative of the seismicity of Naples) selected for buildings with a fundamental period close to 0.25s, since the building fundamental vibration periods in undamaged conditions is about 0.28s in one direction and 0.2s in the other. A set of 20 ground motions was selected for each of the 10 return periods considered. The results in terms of frequency of exceedance of the two limit states are reported in Figure 10.

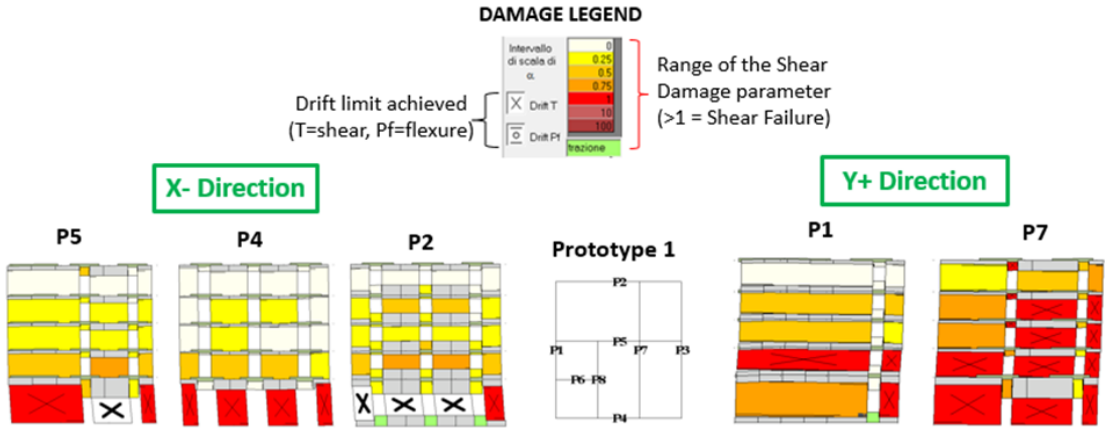

Figure 9: Damage in meaningful structural walls of the building retrofitted according to D.M. 1981 at the end of the pushover analyses carried out in the two directions of loading.

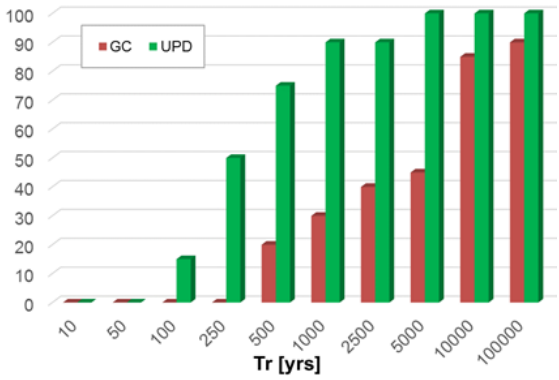

Figure 10: Frequency of occurrence (%) of UPD and GC limit states, as a function of the return period, for the building retrofitted according to D.M. 1981 (soil type C).

4.2 NTC08

The same approach described before was followed to assess the seismic performance of the building retrofitted according to NTC08. The mechanical properties of the macroelement were calibrated starting from the experimental campaign already considered for D.M. 1981, considering only the specimens strengthened by grout injections [22].

Figure 11 reports the comparison between the experimental results (black curve) and the numerical simulation (red curve), obtained for two of the considered walls.

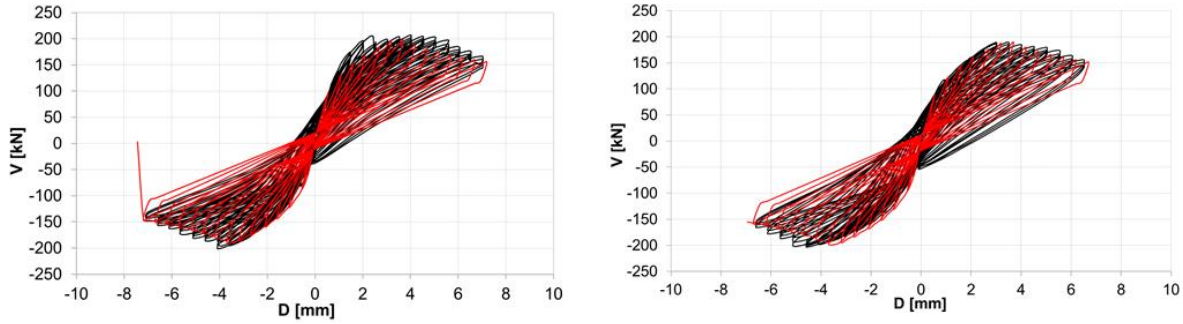

Figure 11: Comparison between the experimental results (black curve) and the numerical simulation (red curve), obtained for two of the retrofitted masonry piers tested by [22]: specimen T3-7 (left) and T3-9 (right).

The in-plane and out-of-plane stiffness of the floors was modelled assuming equivalent mechanical properties, calibrated on experimental shaking table tests on full scale stone masonry buildings with floor diaphragms and ring beams of similar characteristics [25].

Figure 12 shows the pushover curves obtained in the two directions of analysis, with the identification of the thresholds for the considered limit states (Table 5). The higher displacement capacity exhibited, with respect to the building retrofitted according to D.M. 1981 (Figure 8), is mostly due to the development of a global behaviour and failure mechanism different from what observed with the retrofit strategies designed in that case.

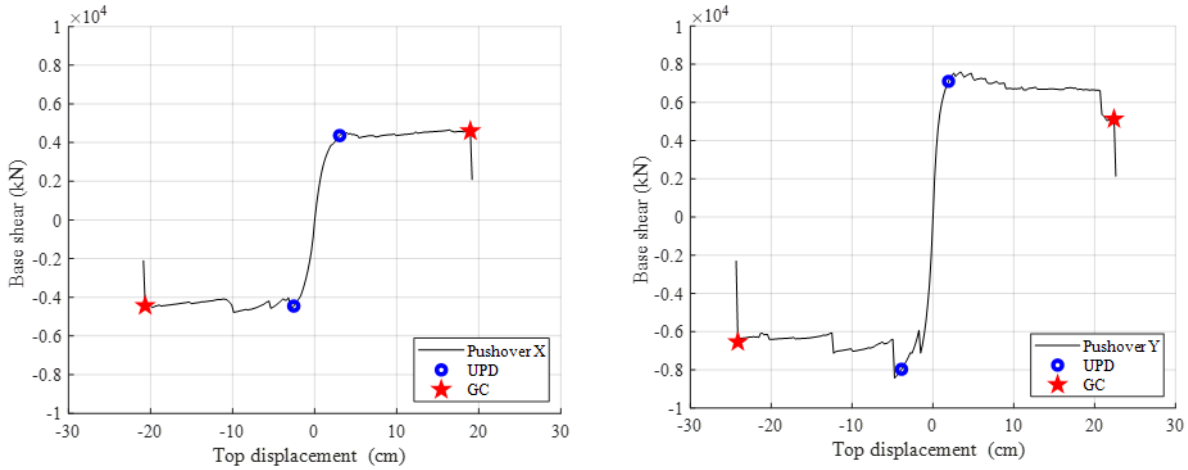

Figure 12: Pushover curves in the two directions of analysis, for the building retrofitted according to NTC08, with the identification of the thresholds of the considered limit states.

UPD threshold [%]		GC threshold [%]	
X direction	**Y direction**	**X direction**	**Y direction**
0.153	0.135	1.125	0.943

Table 5: Values of EDP threshold corresponding to the considered limit states for the building retrofitted according to NTC08

Also in this case, the dominant criterion identifying the attainment of UPD was associated with the attainment of 95% of the peak shear strength. The damage occurred in the structural elements at the end of the analyses (GC limit state) is reported in Figure 13.

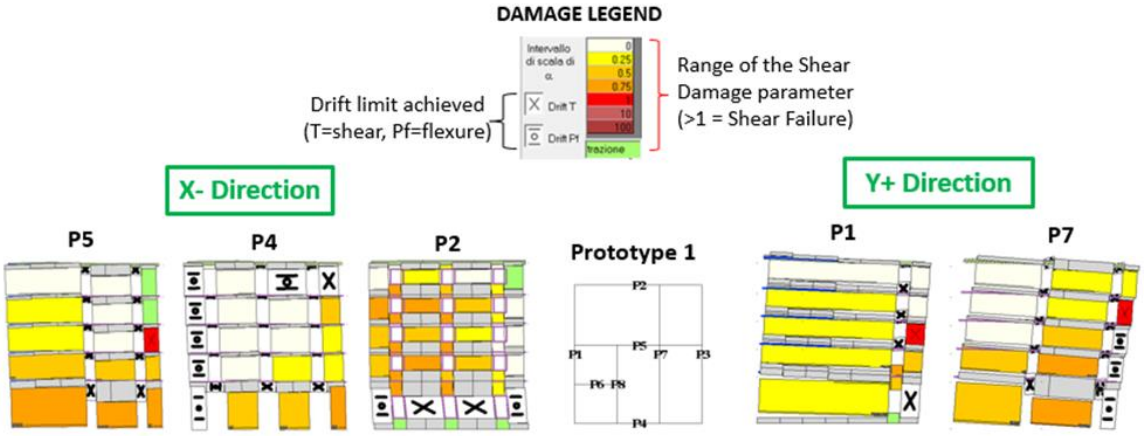

Figure 13: Damage observed in significant structural walls of the building retrofitted according to NTC08 at the end of the pushover analyses carried out in the two directions of loading.

Nonlinear time history analyses were then performed using the same two sets of ground motions of D.M. 1981, to obtain the percentage of exceedance of the two considered limit states (UPD and GC), for increasing values of the return period. Figure 14 shows the results for a reference period of 0.25 s and soil type C.

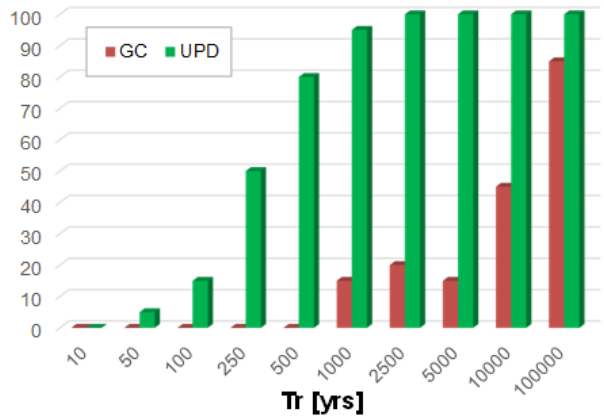

Figure 14: Frequency of occurrence (%) of UPD and GC limit states, as a function of the return period, for the building retrofitted according to NTC08.

5 DISCUSSION AND CONCLUSIONS

The assessment of the seismic performance of the building retrofitted according to the prescriptions of the two considered codes and associated hazard, allows to conclude that, for the considered case study, the vulnerability at the global collapse (GC) limit state is lower in the case of retrofit strategies designed according to NTC08, with respect to D.M. 1981. On the contrary, similar performances were obtained at the usability-preventing damage (UPD) limit state. This difference could be in part explained by the different global behaviour and failure mechanisms exhibited by the structure: a global rocking behaviour with failure of most of the spandrels occurred in case of NTC08, whereas the activation of an evident soft-storey mechanism, with shear failure of the piers, was observed in case of D.M. 1981. Observation of the global displacement capacity of the pushover curves confirms these results, showing in the two cases similar EDP thresholds for the usability preventing damage limit state and different thresholds for the global collapse limit state.

ACKNOWLEDGEMENTS

The study was developed between 2017 and 2018 in the framework of the ReLUIS-DPC and EUCENTRE-DPC projects, funded by the Italian Civil Protection Department (DPC).

LONG-TERM SEISMIC RESPONSE OF BUILDINGS WITH ISOLATION DEVICES AFFECTED BY DETERIORATION EFFECTS

Fabio Mazza[1]

Abstract

Base-isolation technique has long been used worldwide but seismic codes generally do not take into account ageing and environmental effects on the evolution and extent of the deterioration of elastomeric (e.g. high-damping-rubber bearings, HDRBs) and friction (e.g. flat sliding bearings, FSBs) isolators during their lifetime and on their impact on the nonlinear seismic behaviour of the superstructure. The aim of the present work is to investigate the effects of variability of the mechanical properties of elastomeric and sliding bearings on the nonlinear dynamic response of base-isolated reinforced concrete (r.c.) framed structures, focusing the attention on ageing and air temperature effects. First, six-storey base-isolated r.c. framed structures are designed in accordance with the current Italian code in a high-risk seismic zone, considering nominal values of mechanical properties of the isolation system. Specifically, nine structural configurations are examined, considering two alternative arrangements: i) elastomeric base-isolation (EBI) systems, with three different elastomer compounds for the HDRBs (i.e. soft, normal and hard); ii) hybrid elastomeric-sliding base-isolation (ESBI) systems, with the aforementioned elastomer compounds of the HDRBs and two friction coefficients (i.e. low and medium) of the FSBs. Then, based on experimental results from accelerated ageing tests at high temperature, mathematical models are implemented to account for oxidation of elastomers and friction changes. The variability of mechanical properties at different mean temperatures, due to seasonal thermal variations, are also considered. The results of nonlinear time-history analysis are used to build fragility curves based on simple regression in the logarithmic space of structural response versus seismic intensity.

Keywords: Ageing Effects, Air Temperature Effects, Elastomeric Bearings, Sliding Bearings, Nonlinear Seismic Analysis, Fragility Curves.

1 INTRODUCTION

During the lifetime of the elastomeric (e.g. high-damping-rubber bearings, HDRBs) and sliding (e.g. flat sliding bearings, FSBs) bearings, representing some of the most widely used types of isolation systems, ageing and air temperature are important factors that affect the degradation of rubber and friction coefficient of the sliding surface, respectively. The introduction of the property modification factor approach to bound the likely seismic response of isolators has first been applied in the American code for new buildings [1], while a similar approach is implemented in the European code for bridges [2]. In detail, maximum or minimum factors for each type of event (e.g. ageing, air temperature and variations observed during testing) and an adjustment factor, taking into account the reduced probability of cumulative effects during an earthquake, are multiplied in order to define upper- and lower-bound force-displacement laws. However, other codes (e.g. the Italian code, [3]) are limited to establish the maximum variation of the mechanical properties of the isolators, vis-à-vis the corresponding nominal values, only for the purpose of qualification tests.

The mechanical properties of the HDRBs change uniformly along the radial direction of the isolator in a relatively short time, until a stable equilibrium state is reached in the inner region bounded by an external critical depth [4], the latter being an exponential function of the temperature [5]. The outer region is also affected by an oxidation process, related to time and depending on the amount of oxygen, which produces a degradation of properties whose effects diminish moving towards the critical depth. Moreover, the HDRBs considerably increase their horizontal and vertical stiffnesses for decreasing values of the air temperature through rubber crystallization due to prolonged exposure to cold weather, while their cyclic behaviour does not change significantly at high air temperatures [6]. Finally, it should be noted that ageing [7, 8] and air temperature [9] do not affect the equivalent viscous damping ratio of the HDRBs significantly. On the other hand, the friction coefficient of the FSBs presents an age-related increase that can be considered because of changes in the adhesive properties depending on creep of materials and subsequent increase in the contact area between the sliding pad and sliding plate [10]. In particular, creep affects the static friction coefficient during lifetime of the isolator while at the onset the dynamic friction coefficient remains almost unchanged. The significant frictional heating during seismic loading moderates the effects of low temperatures at the sliding interface that combined with isolators placed in normal environment obviates the air temperature effects on the friction coefficient [11].

While the analytical and experimental studies above-mentioned have provided considerable insight into how to predict the long-term behaviour of elastomeric and sliding bearings when subjected to aging and air temperature effects, more investigation is required to evaluate the effects of these phenomena on the nonlinear seismic analysis of base-isolated buildings. This study is also devoted to investigate the level of reliability of the property modification factor approach adopted in ASCE 7-2016 [1] predicting, conservatively, the nonlinear seismic response of base-isolation system and superstructure. First, six-storey r.c. framed structures, base-isolated with HDRBs acting alone or in combination with FSBs, are designed in accordance with the current Italian code [2] in a high-risk seismic zone, considering nominal values of mechanical properties of the isolation system. Specifically, nine structural configurations are examined, combining three elastomer compounds of HDRBs (i.e. soft, normal and hard) and two sliding friction coefficients of FSBs (i.e. low and medium). The results of nonlinear time-history analysis are used to build fragility curves based on simple regression in the logarithmic space of structural response versus seismic intensity [12], considering ground motions selected from the Pacific Earthquake Engineering Research center database [13] and scaled in line with the design hypotheses adopted.

2 AGEING EFFECTS ON THE ISOLATION SYSTEM

Mechanical properties of the HDRBs inevitably change over time and tend to cause an increase of the horizontal and vertical stiffnesses, with a reduction of the fundamental vibration periods that may affect the seismic response of a base-isolated structure. Ageing is dependent on the rubber compound and improper vulcanization and substantially increases for either very high damping or very low shear modulus [14]. Assuming linear material behaviour, the nominal horizontal (K_{H0}) and vertical (K_{V0}) stiffnesses of an HDRB can be evaluated as function of the initial (unaged) shear (G_0) and axial (E_0) moduli

$$K_{H0} = \frac{G_0 \cdot A}{t_r} = \frac{G_0 \cdot \pi \cdot D^2}{4 \cdot t_r}; K_{V0} = \frac{E_0 \cdot A}{t_r} = \frac{E_0 \cdot \pi \cdot D^2}{4 \cdot t_r} \tag{1a,b}$$

A and D being the cross-sectional area and the diameter of a circular bearing, respectively, and t_r the total thickness of the rubber. The ageing depends on chemical reactions and diffusion rate of oxygen and is characterized by a fast stage during which the mechanical properties change almost uniformly over the whole area and a slow stage governed by oxidation of the external part until a critical depth [4]

$$d^* = \alpha \cdot e^{\beta/T} \tag{2}$$

increasing for lower values of air temperature [15], where coefficients α(=1.2x10^{-4} mm) and β(=3.82x10^3 K^{-1}) can be evaluated with thermal oxidation tests [7]. That is why the aged shear modulus (G(t)) depends on the position inside the bearing and the horizontal stiffness can be expressed as

$$K_H(t) = \frac{Q_H(t)}{t_r} \tag{3}$$

having

$$Q_H(t) = \int G_{aged} \cdot dA = G_0 \cdot \int_0^{2\pi D/2} \int_0 f(r,\theta) \cdot dr \cdot d\theta \tag{4}$$

where $f(r,\theta)$ is a function describing the spatial variability of the shear modulus because of ageing. More specifically, Equation (4) can be divided in internal

$$Q_{Hi}(t) = 2 \cdot \pi \cdot G_0 \cdot \int_0^{R-d^*} (1 + \Delta f_{fast}) \cdot r \cdot dr \tag{5a}$$

and external

$$Q_{He}(t) = 2 \cdot \pi \cdot G_0 \cdot \int_{R-d^*}^{R} [1 + \Delta f_{fast} + w(r) \cdot \Delta f_{slow}] \cdot r \cdot dr \tag{5b}$$

contributions calculated on the corresponding reduced circular areas. In detail, fast and slow increases of the initial shear modulus are governed by the following expressions [7]

$$\Delta f_{fast} = 88.4 \cdot e^{-1887.2/T}, \ \Delta f_{slow} = 9.3 \times 10^{-4} \cdot t_{ref} \tag{6a,b}$$

where t_{ref} is the equivalent ageing time (expressed in days) at the reference temperature T_{ref} (expressed in degree Kelvin) of accelerated ageing tests while T represent the temperature under the service condition. It should be noted that constant parameters of Equations 6a and 6b

are assumed equal to the values proposed by [7] on the basis of investigation on different rubber compounds. Moreover, a parabolic law describes the spatial variation of Δf_{slow} in the external part of a circular bearing with radius R. Finally, an equivalent aged shear modulus can be evaluated for each elastomer compound as

$$G(t) = \frac{K_H(t)}{K_{H0}} \cdot G_0 \tag{7}$$

by which an equivalent aged axial modulus can be assessed

$$E(t) = \left(\frac{1}{6 \cdot G(t) \cdot S_1^2} + \frac{4}{3 \cdot E_b} \right)^{-1} \tag{8}$$

where E_b represents the volumetric compression modulus of the rubber (e.g. E_b=2000 MPa), whose variation over time is neglected, and S_1=D/(4t) is the primary shape factor, t being the thickness of the single layer of elastomer. Finally, the corresponding vertical stiffness is

$$K_V(t) = E(t) \cdot A / t_r \tag{9}$$

On the other hand, time variation of the static friction coefficient during the stick-slip phases has been experimentally studied through durability tests [10], highlighting an increase attributed primarily to creep of the materials and a corresponding increase in the contact area between sliding pad and sliding plate; moreover, negligible changes of the dynamic friction coefficient have been observed. Specifically, the following expression has been proposed to represent variability of the static friction coefficient over time:

$$\mu_s(t) = \mu_{s0} + 0.016 \cdot t^{0.1} \tag{10}$$

μ_{s0} being the initial (unaged) value of the static friction while t is the age, measured in years.

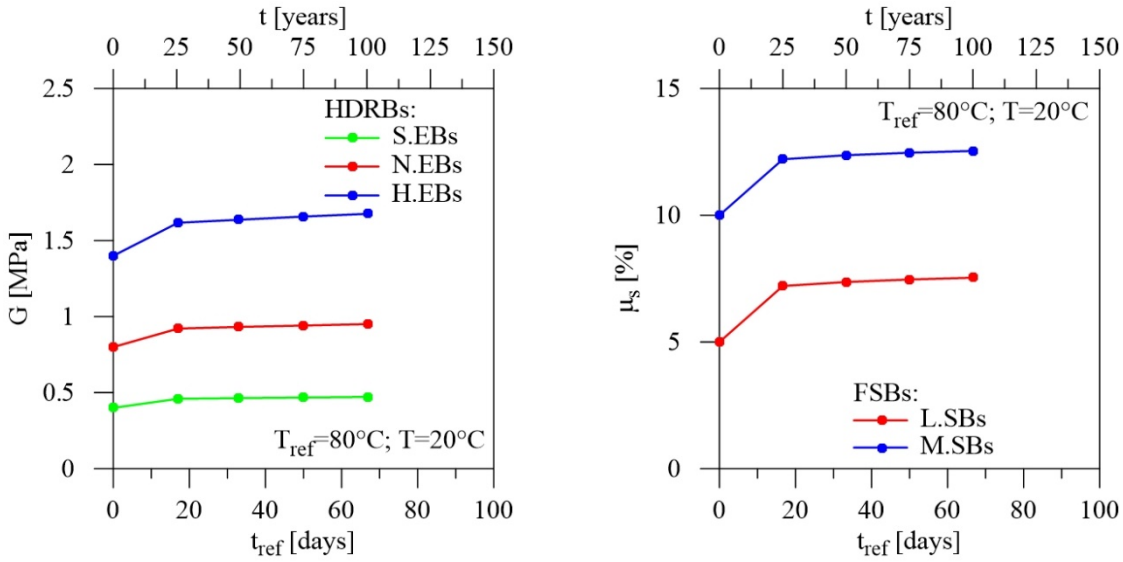
In line with International codes (e.g. [16]), the accelerated ageing process of elastomeric and sliding bearings are based on exposure of specimens to high temperatures T_{ref} (typically in the range 60°-80°) in a vacuum for known (generally relatively short) periods of time t_{ref}. However, the age of the treated specimens represented in these laboratory tests is not specified, confirming that this approach can be useful in the comparison of various rubber compounds but is unsuitable for the prediction of life expectancy of the elastomeric bearings [17]. For just that purpose, in the present work the Arrhenius methodology is adopted to correlate the accelerated ageing results with the ageing under service conditions [18, 19]:

$$\ln\left(t_{ref} / t\right) = E_a / R_g \cdot \left(T_{ref}^{-1} - T^{-1}\right) \tag{11}$$

t being the real time; E_a(=9.04x10^4 J/mol) the activation energy of the rubber; R_g(=8.31 J/mol/K) the gaseous constant.

Curves representing variability of the mechanical properties with time of accelerated ageing (t_{ref}), at the controlled temperature T_{ref}=80°C and service mean temperature T=20°C, are plotted in Figure 1. Specifically, shear modulus of the HDRBs (i.e. G(t) in Figure 1a), for three elastomer compounds (i.e. soft, S, normal, N, and hard, H) and static friction coefficient of the FSBs (i.e. μ_s(t) in Figure 1b), for low- (L) and medium (M) friction, are represented starting from the nominal (unaged) value. As a comparison, an additional axis of abscissa is reported in order to represent the equivalent time of ageing obtained with the Arrhenius method. It is worth noting that heat ageing tests after an expected time of 17, 33, 50 and 67 days correspond to 25, 50, 75 and 100 years when T_{ref}=80°C is considered, but an unrealistically high value of the reference time should be considered for the prediction of the life expectancy

when T_{ref}=60°C or T_{ref}=70°C are assumed. As expected, an increase of stiffness (Figure 1a) and friction threshold (Figure 1b) is observed for increasing values of t_{ref}.



(a) HDRBs. (b) FSBs.

Figure 1: Effects of ageing on mechanical properties of the isolation system.

3 AIR TEMPERATURE EFFECTS ON THE ISOLATION SYSTEM

Mechanical properties of the HDRBs can also change significantly due to weather conditions: i.e. variations in the environmental temperature over long periods of time, such as wide variations in air temperature between winter (e.g. with a mean value of 10°C) and summer (e.g. with a mean value of 25°C). Specifically, experimental tests carried out on the HDRBs show that both the stress level and the area encompassed by the hysteresis loop increase more than linearly while air temperature is decreasing, especially when the temperature drops below zero [6]. Moreover, at a given temperature, these effects increase from soft-to-normal and from normal-to-hard elastomer compounds [9]. Furthermore, undetectable sensitivity of the cyclic behaviour to the thermal history of the specimen is observed, while the equivalent viscous damping remains practically unchanged over the whole range of air temperature. The results also indicate that the lateral stiffness increases more than linear when the air temperature falls significantly compared to the mean working condition (i.e. T=20°C); at the same time, rising temperatures do not lead to abrupt variations in lateral stiffness. Based on the experimental curves at 100% of shear strain [9], the secant shear modulus variability with air temperature (T) can be expressed by the following polynomial laws, distinguishing soft (SC)

$$G_{SC}=0.508-9.779\cdot10^{-3}\cdot T+3.603\cdot10^{-4}\cdot T^2-8.843\cdot10^{-6}\cdot T^3+8.967\cdot10^{-8}\cdot T^4 \ [MPa] \quad (12)$$

normal (NC)

$$G_{NC}=1.039-1.468\cdot10^{-2}\cdot T+4.204\cdot10^{-4}\cdot T^2-2.275\cdot10^{-5}\cdot T^3+4.29\cdot10^{-7}\cdot T^4 \ [MPa] \quad (13)$$

and hard (HC)

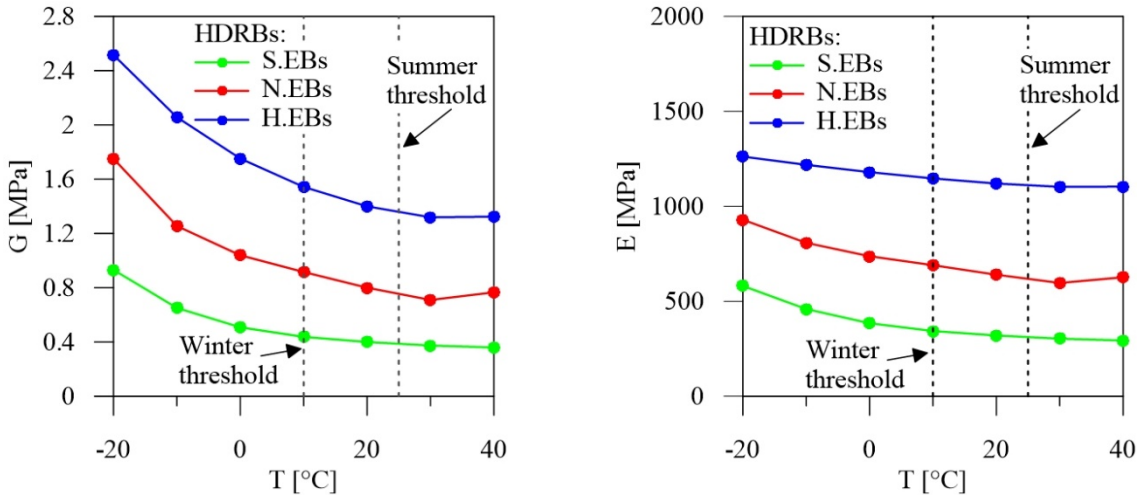
$$G_{HC}=1.752-2.493\cdot10^{-2}\cdot T+4.704\cdot10^{-4}\cdot T^2-7.452\cdot10^{-6}\cdot T^3+1.147\cdot10^{-7}\cdot T^4 \ [MPa] \quad (14)$$

elastomer compounds. It should be noted that the selected compounds (i.e. SC, NC and HC) present the nominal values of the shear modulus (i.e. 0.4 MPa, 0.8 MPa and 1.4 MPa) provided by FIP [20] when the selected temperature corresponds to the mean working temperature

(i.e. T=20°C). The corresponding axial moduli are evaluated through an expression similar to Equation 8

$$E_{..}(T) = \left(\frac{1}{6 \cdot G_{..}(T) \cdot S_1^2} + \frac{4}{3 \cdot E_b} \right)^{-1} \tag{15}$$

Curves representing variability of mechanical properties of HDRBs with air temperature are plotted in Figure 2. Specifically, shear (Figure 2a) and axial (Figure 2b) moduli of the HDRBs for SC, NC and HC elastomer compounds are represented in the range of temperatures from -20°C to 40°C. Vertical lines corresponding to winter and summer mean seasonal temperatures are also reported as threshold values considered in the numerical study. As can observed, the rate of reduction of the axial modulus with temperature (Figure 2b) is less evident than that observed for the shear modulus (Figure 2a) as a result of Equation 10 where $G_{..}(T)$ only concerns the first part of $E_{..}(T)$.



(a) Shear modulus. (b) Axial modulus.

Figure 2: Effects of air temperature on the mechanical properties of the HDRBs.

Finally, experimental results corresponding to different pressure-velocity couples of values highlight the fact that the dynamic friction coefficient decreases for increasing values of the air temperature [21]. Specifically, the rate of reduction is greater at low-to-medium (i.e. -10°C to 20°C) than from medium-to-high (i.e. 20°C to 50°C) temperatures, highlighting a decrease of about 2.5 times in the rate when the dynamic fast (μ_{fast}) instead of dynamic low (μ_{low}) friction coefficient is considered. Moreover, the dynamic friction coefficient is practically independent of the contact pressure. However, variation of the dynamic friction coefficient with temperature is significantly reduced in the range from 10°C to 25°C and therefore will not be considered in the present study.

4 TEST STRUCTURES

Six-storey residential buildings with a reinforced concrete (r.c.) framed structure isolated at the base by twenty identical HDRBs (i.e. elastomeric isolation system) or fourteen HDRBs combined with six FSBs (i.e. hybrid isolation system) are considered for the numerical investigation (Figure 3). In view of the symmetric plan of the building, only the plane frames orientated along the horizontal ground motion direction (Y), perpendicular to the floor slab direction (X), are considered as reference.

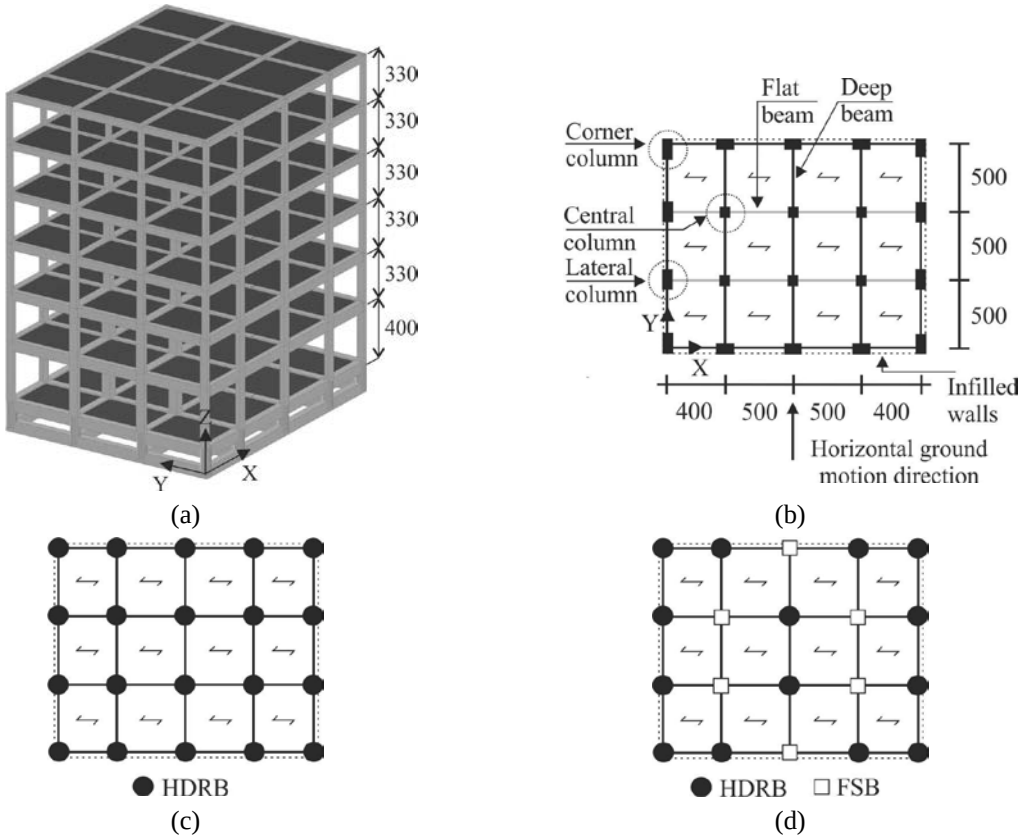


Figure 3: 3D view and plans and of the base-isolated structures (units in cm).

The design vertical loads are divided in structural dead loads and non-structural live loads equal, respectively, to 3.5 kN/m^2 and 2 kN/m^2 at all floors. Non-structural dead-loads are also applied, assuming: 1.67 kN/m^2, for the sixth floor; 3.47 kN/m^2, for the zero floor, and 3.07 kN/m^2, for the other floors. Non-structural masonry infills are taken into account through an additional dead load of 2.70 kN/m^2 along the perimeter. A cylindrical compressive strength of 25 N/mm^2 for the concrete and a yield strength of 450 N/mm^2 for the steel are assumed for the r.c. frame members. Horizontal and vertical seismic loads are evaluated in line with the current Italian code [3], assuming: high risk seismic zone; elastic response of the superstructure (i.e. behaviour factors for the horizontal and vertical seismic loads, q_H=q_V=1.0); medium subsoil type (i.e. subsoil class B); flat terrain (i.e. topographic class T1). The fundamental vibration period of the base-isolated structures is assumed equal to 2.1 s in the horizontal direction. The dimensions of the cross sections assumed for the beams and columns are reported in Table 1 where masses at the floor levels (i.e. m_i) are also presented. The design of the superstructure is carried out at the LS limit state so as to satisfy minimum conditions for the r.c. frame members in line with the provisions imposed by NTC18 [3].

Storey	Corner column	Lateral column	Central column	Deep beam	Flat beam	m_i
6	30x30	30x30	30x30	30x45	40x25	2.600
5	30x35	30x40	40x40	30x45	40x25	2.846
4	30x40	30x50	50x50	30x50	50x25	2.989
3	30x40	30x50	50x50	30x55	50x25	3.123
2	30x50	30x60	60x60	40x60	60x25	3.458
1	30x50	30x60	60x60	40x70	60x25	3.671
0	-	-	-	50x100	50x100	4.418

Table 1: Geometrical properties of the superstructure (units in cm and ton).

The elastomeric base-isolation (EBI) systems consist of three elastomer compounds for the twenty identical HDRBs and comply with the CP limit state, assuming a seismic design displacement equal to 28.9 cm and a nominal stiffness ratio α_{K0}(=K_{V0}/K_{H0}) equal to 800. Specifically, soft (S.EBs, Figure 4a), normal (N.EBs, Figure 4b) and hard (H.EBs, Figure 4c) compounds are characterized by an unaged shear modulus (G_0) equal to 0.4 MPa, 0.8 MPa and 1.4 MPa, respectively, and a volumetric compression modulus of the rubber (E_b) equal to 2000 MPa. All three compounds ensure the same values of the equivalent viscous damping ratio for the EBI systems: i.e. ξ_H=10%, in the horizontal direction; ξ_V=5%, in the vertical direction. The following geometrical properties of the HDRBs are reported in Table 2: diameter of the steel layer (D_s) and that of the elastomer (D_e); total thickness (t_e) and thickness of the single layer (t_i) of elastomer; number (n_{si}) and thickness (t_{si}) of the interior steel shims; thickness of the exterior steel plates (t_{se}); total height of the bearing (h).

Hard (H)	46	46	22.4	0.5	45	0.40	3	45.9

Table 2: Geometrical properties of the HDRBs for the elastomeric isolation systems (units in cm).

Six hybrid elastomeric-sliding base-isolation (ESBI) systems are designed at the CP limit state, given fourteen identical HDRBs, with three elastomer compounds (i.e. S.EBs, N.EBs and H.EBs), acting in parallel with six FSBs (four internally placed and two along the perimeter) and characterized by low- (i.e. L.SBs in Figures 5a-5c) and medium-type (i.e. M.SBs in Figures 5d-5f) friction properties. This arrangement corresponds to a value 0.37 for the nominal sliding ratio α_{S0}(=$F_{S0}/F_{S0,max}$) of the FSBs under gravity loads, defined as the sliding force (F_{S0}) of the entire sliding system divided by the maximum sliding force ($F_{S0,max}$) corresponding to a sliding bearing below each column of the test structure. The nominal stiffness ratio adopted for the ESBI systems is the same as the EBI ones (i.e. α_{K0}=800). The set of static (μ_s) and dynamic (μ_{slow} and μ_{fast}) friction parameters of the FSBs assumed in the analyses are reported in Table 3, where axial loads in the quasi-permanent combination (P_{sd}) are also shown. It should be noted that for FSBs with medium-type friction the coefficients are twice those for low-type friction. Damping properties of the ESBI systems are shown in Table 4, where: $W_{s,HDRBs}$ and $W_{s,FSBs}$ represent the strain energies at the secant stiffness corresponding to the design displacement; $W_{h,HDRBs}$ and $W_{h,SBs}$ represent the hysteretic energies in a cycle of motion at the same displacement. Finally, Table 5 summarises the geometrical properties for HDRBs of the ESBI systems with reference to low- and medium-type friction of the FSBs. Further details about the design of the test structures can be found in a previous work by the author [22].

4. NUMERICAL RESULTS

A numerical study is carried out to investigate the effects produced by the variability of the mechanical properties of elastomeric (EBI systems) and hybrid elastomeric-sliding (ESBI systems) bearings due to ageing and air temperature. In order to reflect the increase of both stiffness of the HDRBs and static friction coefficient of the FSBs over their lifetime, different ageing times (i.e. t_{ref}=17, 33, 50 and 67 days) are taken into account in the accelerated thermal oxidation test at reference temperature of T_{ref}=80°C. Moreover, the sensitivity of the HDRBs to air temperature variations is evaluated by referring to mean seasonal (i.e. T=10°C in the

winter and T=25°C in the summer) and annual (i.e. T=20°C) values. For comparison, system properties modification factors proposed by the American code for new buildings [1] are also considered. Specifically, all the maximum or minimum λ factors for each event are multiplied together [11]

$$\lambda_{\min} = \left[1 - f_a\left(\lambda_{ae,\min} - 1\right)\right] \cdot \lambda_{test,\min} \cdot \lambda_{spec,\min} \tag{16a}$$

$$\lambda_{\max} = \left[1 - f_a\left(\lambda_{ae,\max} - 1\right)\right] \cdot \lambda_{test,\max} \cdot \lambda_{spec,\max} \tag{16b}$$

where factors λ_{ae}, λ_{test} and λ_{spec} encompass, respectively, ageing and environmental effects, variation observed during tests and specification tolerances, while adjustment factor f_a provides for the reduced probability that several additive effects occur simultaneously. In the present work, different modification factors are applied to the HDRBs (i.e. $\lambda_{min,HDRBs}$=1 and $\lambda_{max,HDRBs}$=1.225) and FSBs (i.e. $\lambda_{min,FSBs}$=1 and $\lambda_{max,FSBs}$=1.42), on the assumption that λ_{test}=λ_{spec}=1.0 and with reference to ordinary buildings (i.e. f_a=0.75).

A lumped plasticity model based on the Haar-Kàrmàn principle is used to describe the inelastic behaviour of r.c. frame members of the superstructure [23], assuming a bilinear moment-curvature law with hardening ratio equal to 3%. Plastic conditions are checked at the potential critical sections of beams (i.e. end, quarter-span and mid-span sections of the sub-elements in which a beam is discretized) and columns (i.e. end sections). With a view to studying the effects of advanced nonlinear modelling of the EBI and ESBI isolation systems, the formulations of the HDRBs and FSBs described in a previous paper [22] are implemented through a computer code already proposed [23]. In the Rayleigh hypothesis, the damping matrix of the superstructure is assumed as a linear combination of the mass and stiffness matrices, assuming horizontal and vertical viscous damping ratios (i.e. $\xi_{H,S}$ and $\xi_{V,S}$) equal to 2% with reference to the corresponding fundamental vibration periods (i.e. T_{1H} and T_{1V}). Nonlinear dynamic analyses of the EBI and ESBI structural systems, subjected to the horizontal and vertical components of near-fault earthquakes, are terminated once the ultimate state of the superstructure (in terms of curvature ductility of beams and columns) and ultimate shear deformations (i.e. $\gamma_{tot,u}$=1.5x5=7.5 and $\gamma_{s,u}$=1.5x2=3) and ultimate axial loads (i.e. P_{cr} and P_{tu}) of the HDRBs are attained.

The twenty near-fault ground motion records selected for this numerical investigation are selected from the Pacific Earthquake Engineering Research center database [13] and are classified as pulse-type in accordance with a pulse indicator [24]. Specifically, the two-sided (i.e. forward-directivity) long-period horizontal velocity pulses are characterized by shear-wave velocity of the subsoil in the top 30 m, generally within the range corresponding to the subsoil type at the site in question (i.e. subsoil class B, 360m/s ≤ $V_{s,30}$ ≤ 800m/s). The Modified Acceleration Spectrum Intensity (MASI) measure is evaluated for both the horizontal components, integrating spectral values of acceleration in the range of vibration periods between a lower limit (i.e. 0.5·T_{BI}=1.05s), accounting for the contribution of higher modes to structural response, and an upper limit (i.e. 1.25·T_{BI}=2.63s), including the lengthening of vibration period due to the nonlinear structural behaviour [25]. This structure-specific integral seimic intensity measure can be considered efficient for predicting engineering demand parameters [26]. Note that only the horizontal component with the highest value of MASI is considered in the nonlinear dynamic analyses. In Table 6 the main data of the selected near-fault motions are shown: i.e. earthquake location, date, recording station, magnitude (M_w), closest distance to the fault (Δ), peak ground acceleration (PGA_H) and $MASI_H$ of the selected horizontal component.

Table 6: Main data of the selected ground motions.

First, the nonlinear dynamic analysis of the EBI and ESBI structural systems subjected to the set of twenty unscaled ground motion histories is performed. For each record, the final instant of simulation is assumed as that corresponding to the attainment of an ultimate condition of r.c. frame members of the superstructure and/or HDRBs of the base-isolation system in the conventional design configuration (i.e. t=0 days and T=20°C). Afterwards, in order to make the results comparable, the analyses are repeated assuming this value as the final instant of simulation for each ground motion and base-isolated system. The cloud method is adopted for the fragility analysis [12], based on fitting a linear regression model in the logarithmic scale to the pairs of an engineering demand parameter (EDP), representative of the structural response, versus an intensity measure (IM) for a suite of unscaled ground motions. In Figures 6 and 7 are reported cloud data of the EBI and ESBI structures, respectively, obtained by combining a scalar demand to capacity ratio of the EDP, that is equal to unity at the onset of the ultimate limit state, with an IM [27]. In particular, maximum values of ductility demand at the end sections of the beams (Figures 6a,b,c and 7a,b,c) and total shear strain of the HDRBs (Figures 6d,e,f and 7d,e,f) are plotted against the MASI values corresponding to the elastic response spectra of acceleration of the interrupted records. Plots refer to three elastomer compounds of the HDRBs (i.e. the EBI.S, EBI.N and EBI.H structures) which may be combined with low friction of the FSBs (i.e. the ESBI.SL, ESBI.NL and ESBI.HL structures). The dependence of mechanical properties of the HDRBs on air temperature variations is taken into account by considering winter (T=10°C) and summer (T=25°C) mean values of temperature, in the aged state corresponding to t_{ref}=33days and T_{ref}=80°C. Results for the lower (λ_{min}) and upper (λ_{max}) bound limit values of the ASCE modification factor are also presented for comparison.

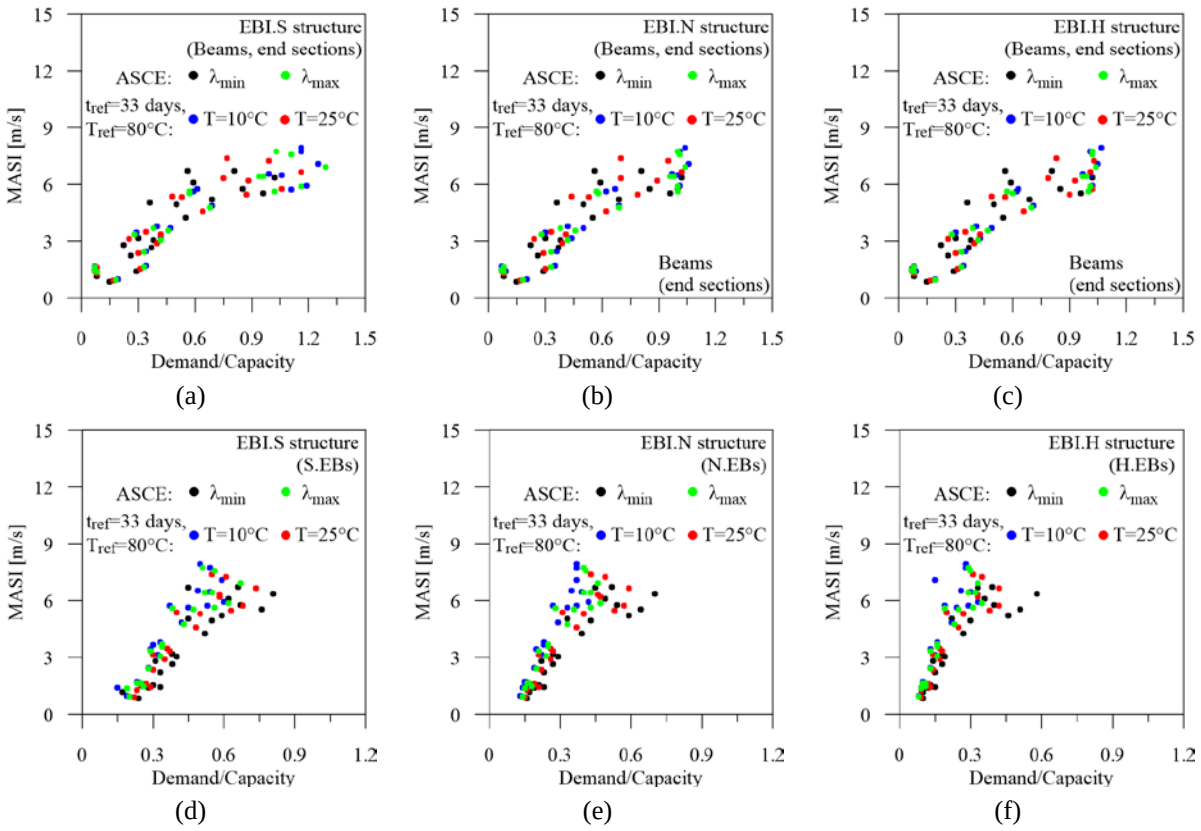

Figure 6: Cloud data of the structural systems with elastomeric base-isolation system: (a, b, c) ductility demand of beams; (d, e, f) total shear strain of HDRBs.

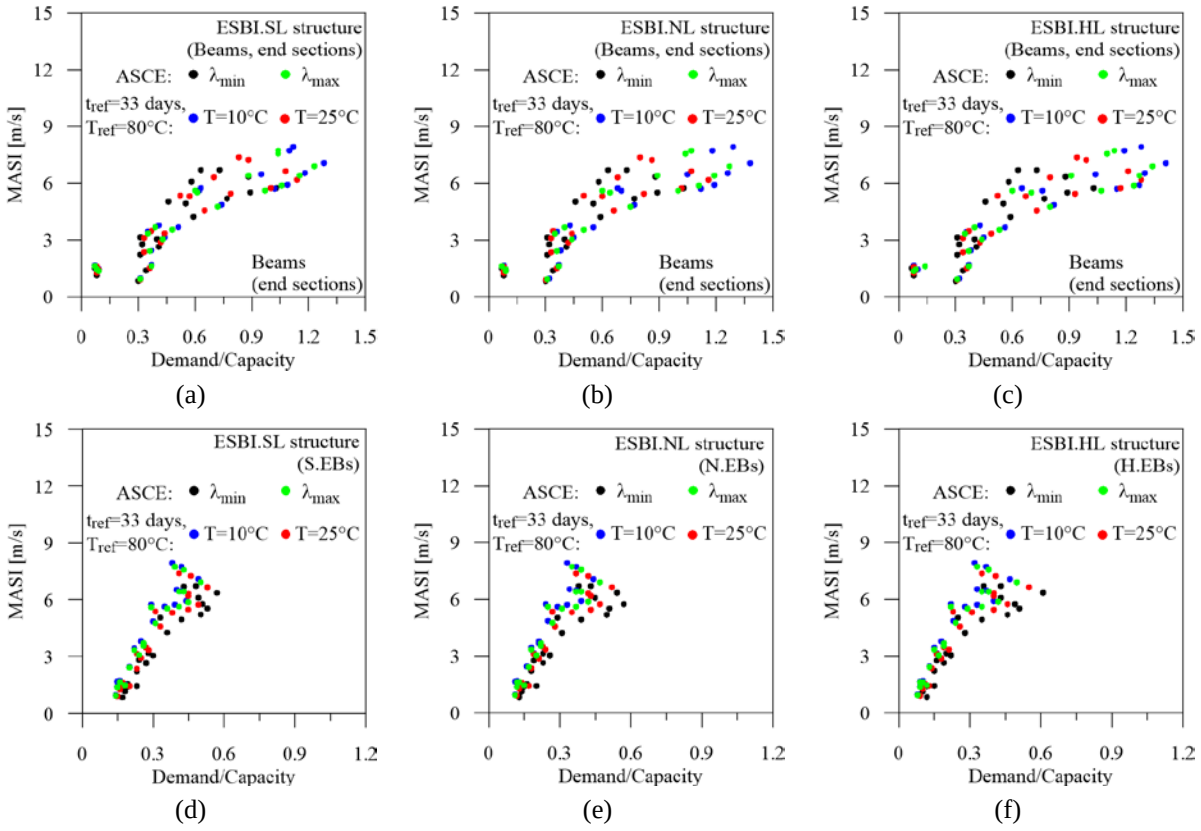

Figure 7: Cloud data of the structural systems with hybrid elastomeric-friction base-isolation system: (a, b, c) ductility demand of beams; (d, e, f) total shear strain of HDRBs.

As can be observed, the significant dispersion in the MASI values of the selected ground motions and the occurrence of a number of demand to capacity EDP ratios greater than unity leads to reasonable fragility estimates. Specifically, the maximum ductility demand of beams at the lower storeys of the test structures is always responsible for the conventional structural failure at t=0 days and T=20°C, (i.e. λ_{min}). The decrease in temperature leads to an increase of the ductility demand (see blue points in Figures 6a,b,c and 7a,b,c), while the opposite happens for the total shear strain when air temperature rises (see red points in Figures 6d,e,f and 7d,e,f).

In order to estimate the probability that a given level of damage will occur in the EBI and ESBI structures, undergoing a given ageing time at different air temperatures, fragility analysis needs to be developed. To this end, a robust fragility software based on the cloud data above described, is adopted for an efficient fragility assessment [27]. Fragility curves of the EBI and ESBI structures are reported in Figures 8 and 9, respectively, with reference to the superstructure and base-isolation system. Namely, the fragility curves plotted in Figures 8a,b,c and 9a,b,c provide information about the probability of exceeding a particular state of damage of the superstructure conditioned on ductility demand, while total shear strain-based fragility functions return a similar result for the base-isolation system (Figures 8d,e,f and 9d,e,f). It is noted that fragility curves referring to the minimum (λ_{min}) and maximum (λ_{max}) values of ASCE modification factors almost always envelope curves which are the effects of the long-term behaviour of the superstructure (i.e. blue and red lines in Figures 8a,b,c and 9a,b,c), unlike base isolation systems of the EBI (Figures 8d,e,f) and ESBI (Figures 9d,e,f) structures whose fragility curves for T=10°C exceed those related to λ_{min}. Furthermore, the selection of different elastomer compounds produces a significant variability of fragility curves of the HDRBs while less pronounced effects are observed for the superstructure.

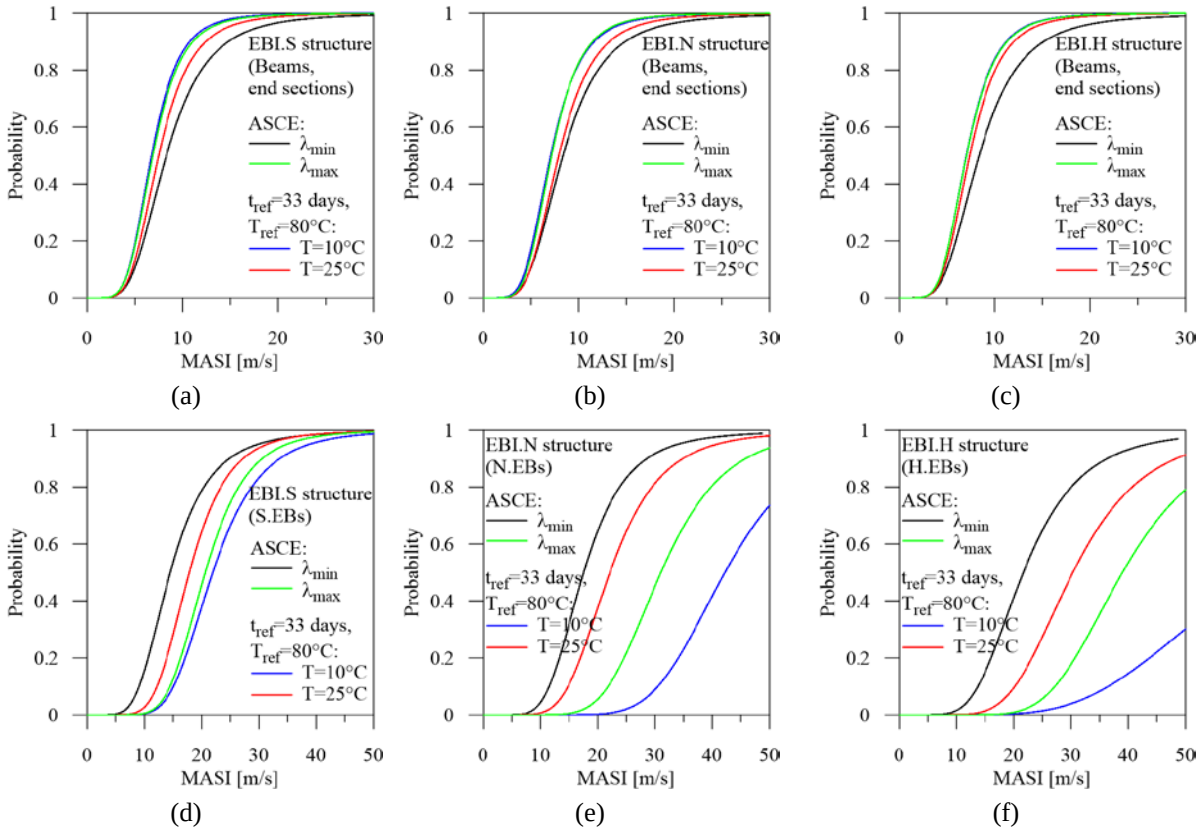

Figure 8: Fragility curves of the structural systems with elastomeric base-isolation system: (a, b, c) ductility demand of beams; (d, e, f) total shear strain of HDRBs.

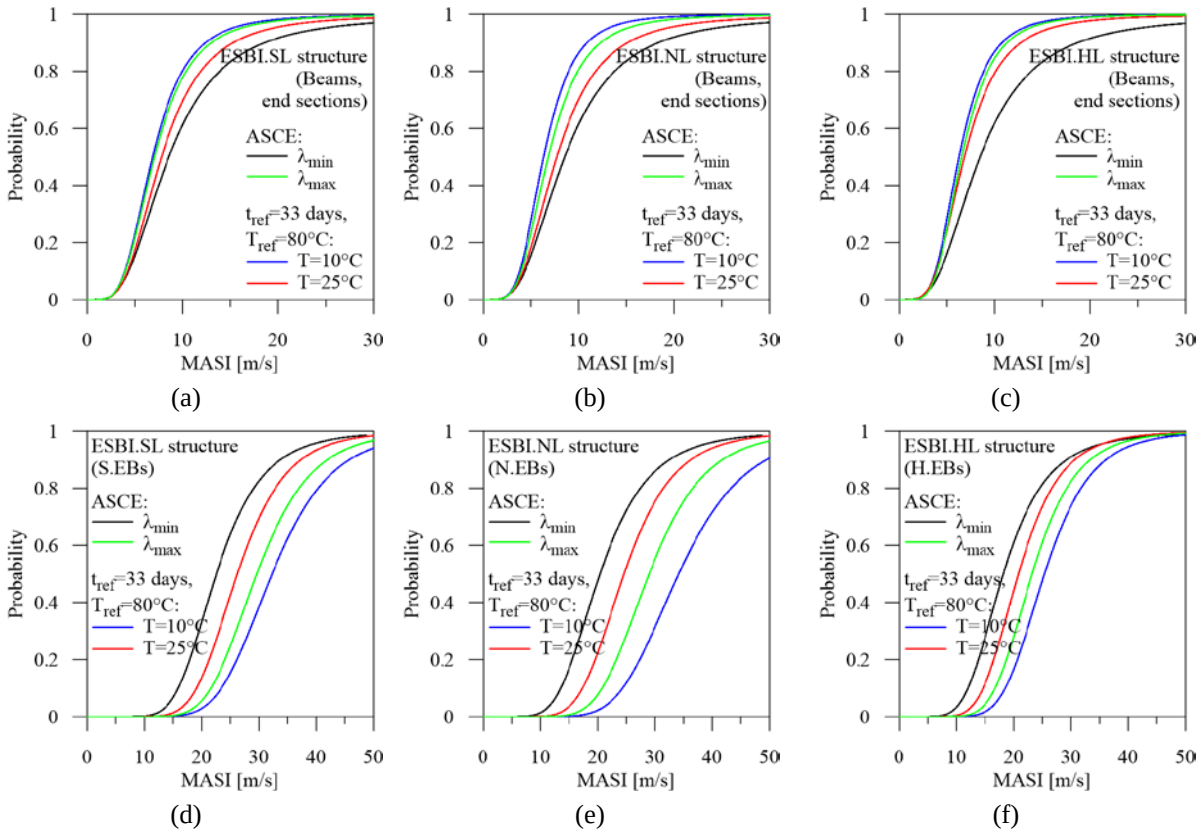

Figure 9: Fragility curves of the structural systems with hybrid elastomeric-friction base-isolation system: (a, b, c) ductility demand of beams; (d, e, f) total shear strain of HDRBs.

5 CONCLUSIONS

With the aim of quantifying the effects of mechanical property variability in elastomeric and sliding bearings on the nonlinear seismic response of base-isolated r.c. framed structures, a numerical model is proposed based on experimental results available in literature. Specifically, the influence of ageing and air temperature on the horizontal and vertical stiffnesses of the HDRBs and friction coefficient of the FSBs are investigated, while the equivalent viscous damping ratio of the HDRBs was found non-sensitive to these effects. First, nine structural solutions for the base-isolation system of six-storey r.c. framed structures are designed assuming nominal values of mechanical properties and considering two alternative arrangements: i) elastomeric base-isolation (EBI) systems, with three different elastomer compounds for the HDRBs (soft, normal and hard); ii) hybrid elastomeric-sliding base-isolation (ESBI) systems, with the aforementioned elastomer compounds of the HDRBs and two friction coefficients (low and medium) of the FSBs. Finally, fragility analysis of the test structures subjected to the horizontal components of unscaled earthquakes is carried out together with nonlinear dynamic analysis under the horizontal and vertical components of earthquakes scaled at the ultimate limit state. The results for the lower and upper bound property modification factors proposed by ASCE provide a comparison. The following conclusions can be drawn from the results presented in this study. Curves representing effects of accelerated ageing confirm that an increase of the horizontal stiffness of the HDRBs, and to a lesser extent vertical stiffness, and static friction coefficient of the FSBs is obtained for increasing values of the reference time. The equivalent time of ageing obtained with the Arrhenius method highlights that 25, 50, 75 and 100 years correspond to 17, 33, 50 and 67 days, respectively, when accelerated heat ageing tests at T_{ref}=80°C are considered, but an unrealistically high value of t_{ref} should be as-

sumed for the prediction of life expectancy when T_{ref}=60°C or T_{ref}=70°C is assumed. Variability of shear and axial moduli of the HDRBs is observed for mean seasonal and annual temperatures, with an increase moving from summer to winter values. However, variation of the dynamic friction coefficient of the FSBs with temperature can be neglected. Fragility curves referring to the minimum (λ_{min}) and maximum (λ_{max}) ASCE values almost always envelope curves representing effects of the long-term behaviour of the superstructure, unlike for the base isolation systems of the EBI and ESBI structures whose fragility curves for T=10°C exceed those related to λ_{min}. The selection of different elastomer compounds produces a significant variability of fragility curves of the HDRBs while less pronounced effects are observed for the superstructure.

Abstract

This study presents an application of tuned vibration absorbers (TVAs) to reduce dynamic response of tall buildings under multiple excitations such as wind and earthquake ground motion. A finite element model of a typical tall building is prepared with rotational degrees of freedom reduced by static condensation. Mechanical models of TVAs are incorporated in the model. The coupled equations of motion are formulated and solved using numerical methods. The uncontrolled building (NC) and the controlled building are subjected to a number of near fault earthquake ground motions and wind forces (mass excitations). The effectiveness of using multiple TVAs as opposed to a single TVA (STVA) is investigated. The design parameters affecting the effectiveness of the TVA arrangements are chosen to investigate optimal setups. It is observed that STVA are more effective for wind response mitigation than seismic response mitigation of tall buildings. Multiple TVAs are, however, found to be effective for controlling both wind and earthquake induced vibrations. It is concluded that optimally designed TVAs are effective in controlling vibration of buildings subjected to action of wind and earthquake loads.

Keywords: Buildings, Earthquake, Multi-Hazard, Tuned Vibration Absorbers (TVAs), Wind Loads.

1 INTRODUCTION

Wind response control of structures using passive tuned vibration absorbers (TVAs) were extensively investigated in last few decades. Commonly, it was reported by the researchers that the optimum devices achieved significant improvement in the performance to increase the response reduction as compared to the conventional design of the devices. Recently, a detailed review is presented by Elias and Matsagar [1] for development of the passive vibration control of structures. Lu et al. [2] reported that the particle TVAs are more effective than the optimal TVAs. The researchers presented the multi-mode response control of tall structure by different TVA schemes [3-10]. They concluded that the distribution of the multiple TVAs (d-MTVAs) as per modal properties of the structures caused maximum responses reduction. However, in all the studies the devices were designed for consideration of single hazard either wind or earthquake excitations. Only few studies are exist that the researchers checked the performance of the controllers for wind and earthquake excitations [11, 12]. Based on detailed literature survey conducted no such study is seen that the effect of multi-hazard on the performance of the tall building without control (NC) and controlled by different passive TVAs were taken into account. Therefore, it is deemed important to investigate the performance tall buildings equipped by TVAs subjected to wind and earthquake. In this study the proper TVA scheme is designed to be effective while subjected to wind and earthquakes. The device which designed for wind vibration control of tall building may not be as effective for seismic vibration mitigation. Therefore, a robust multi-mode response control of tall buildings is presented using multiple TVAs. Initially, based on modal properties of the NC building, the TVAs' optimal locations are anticipated. Then, the effects of the addition of masses are taken into consideration for selection of the optimal placement for multi-hazard assessment of tall buildings. The basic assumption is to design a device for one hazard to be effective for both hazards or at least not to amplify the responses of the building while subject to the second hazard.

2 GENERAL THEORY

In this study the benchmark building is considered which was reported by many researchers to be wind sensitive. However, Aly and Abburu, [11] concluded that the tall building subjected to earthquake excitation could exhibit large floor acceleration due to higher modal contribution and higher drift ratio while subjected to wind forces. They recommended proper device controller needs to be installed to control the responses of the building under both wind and earthquake excitations. Therefore, it is important to investigate the effectiveness of adding TVA schemes for mitigation of the responses of the benchmark building subjected to wind and or earthquake excitations. The benchmark building equipped with the single TVA (STVA) shown in Figure 1(a), with multiple TVAs all installed at top floor (MTVAs-all.top) is shown in Figure 1(b). MATLAB code is prepared to conduct the numerical simulation of the uncontrolled and controlled buildings subjected to wind or earthquake excitations. The complete information of the building can be seen in the study presented by Elias et al. [10]. The three TVA schemes designed for the wind sensitive building and then subjected to the earthquake excitations. Then, the schemes designed to control the seismic response of the building and then subjected to the wind forces. In this procedure the optimal scheme is identified to be robust under both wind and earthquake excitations. To be noted that the cross wind forces are applied on the N degrees of freedom (DOFs) of the structure with zero forces on n DOFs of the TVAs ($\{F_t\} = \begin{Bmatrix} \{F_t\}_{N\times 1} \\ \{0\}_{n\times 1} \end{Bmatrix}$). For the system under consideration, the governing equations of motion for the benchmark building installed with the TVA schemes are obtained by

considering the equilibrium of forces at the location of each degree of freedom during the wind or earthquake excitation as

$$[M_s]_{(N+n)\times(N+n)}\{\ddot{X}_s\}_{(N+1)\times1}+[C_s]_{(N+n)\times(N+n)}\{\dot{X}_s\}_{(N+1)\times1}+[K_s]_{(N+n)\times(N+n)}\{X_s\}_{(N+1)\times1}=\{F_t\}_{(N+n)\times1} \quad (1)$$

where $[M_s]$, $[C_s]$, and $[K_s]$ are the mass, damping, and stiffness matrices of the building, respectively; $\{X_s\}$, $\{\dot{X}_s\}$, and $\{\ddot{X}_s\}$ are the unknown relative floor displacement, velocity, and acceleration vectors, respectively; and $\{F_t\}$ is the load vector. In case of earthquake excitations, $\{F_t\}=-[M_s]\{I\}\ddot{x}_g$ where $\{I\}$ is the influence vector and $\ddot{x}_g$ is the earthquake ground acceleration.

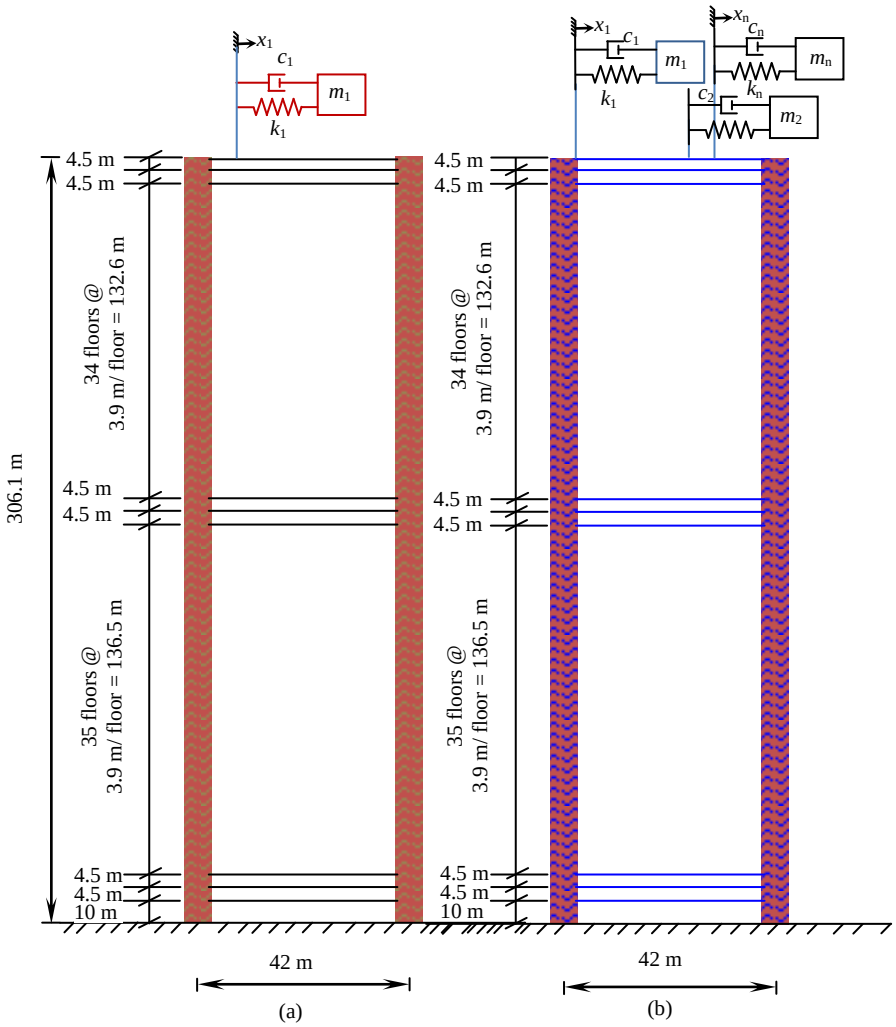

Figure 1: Model of benchmark building (a) installed with STMD, and (b) installed with MTVAs-all.top

3 NUMERICAL STUDY

The benchmark building is having height of more than 300 m and it is classified as a wind sensitive structure. However, if such structure is located at earthquake prone area, the question arises if the safety of the structure is underestimated. Similarly, different methodologies were proposed by the researchers to mitigate the wind response of the same building. Again it is not clear if those devices will be effective during the earthquakes. In this study the comparative analysis are conducted to find out a proper answer to the un-cleared questions. In Fig-

ures 2 and 3 show respectively the time variation of top floor displacement and acceleration for 76-storey benchmark building installed with the STVA, MTVAs-all.top under wind forces or Kobe, 1995 earthquake excitation. The figure shows that both the displacement and acceleration of the building are quite high while subjected to the earthquake ground excitation. Therefore, it is underestimated to design high-rise buildings only for a single hazard especially if the structure is located in seismic prone area. For such situation a multi-hazard scheme is required to design a robust structure to be safe under multiple hazards. The optimal STVA designed as per the parameters suggested by Patil and Jangid [13]. The optimal parameters of the STVA are 0.94, 0.06 respectively for frequency tuning ratio and damping ratio for total mass of 1250 ton.

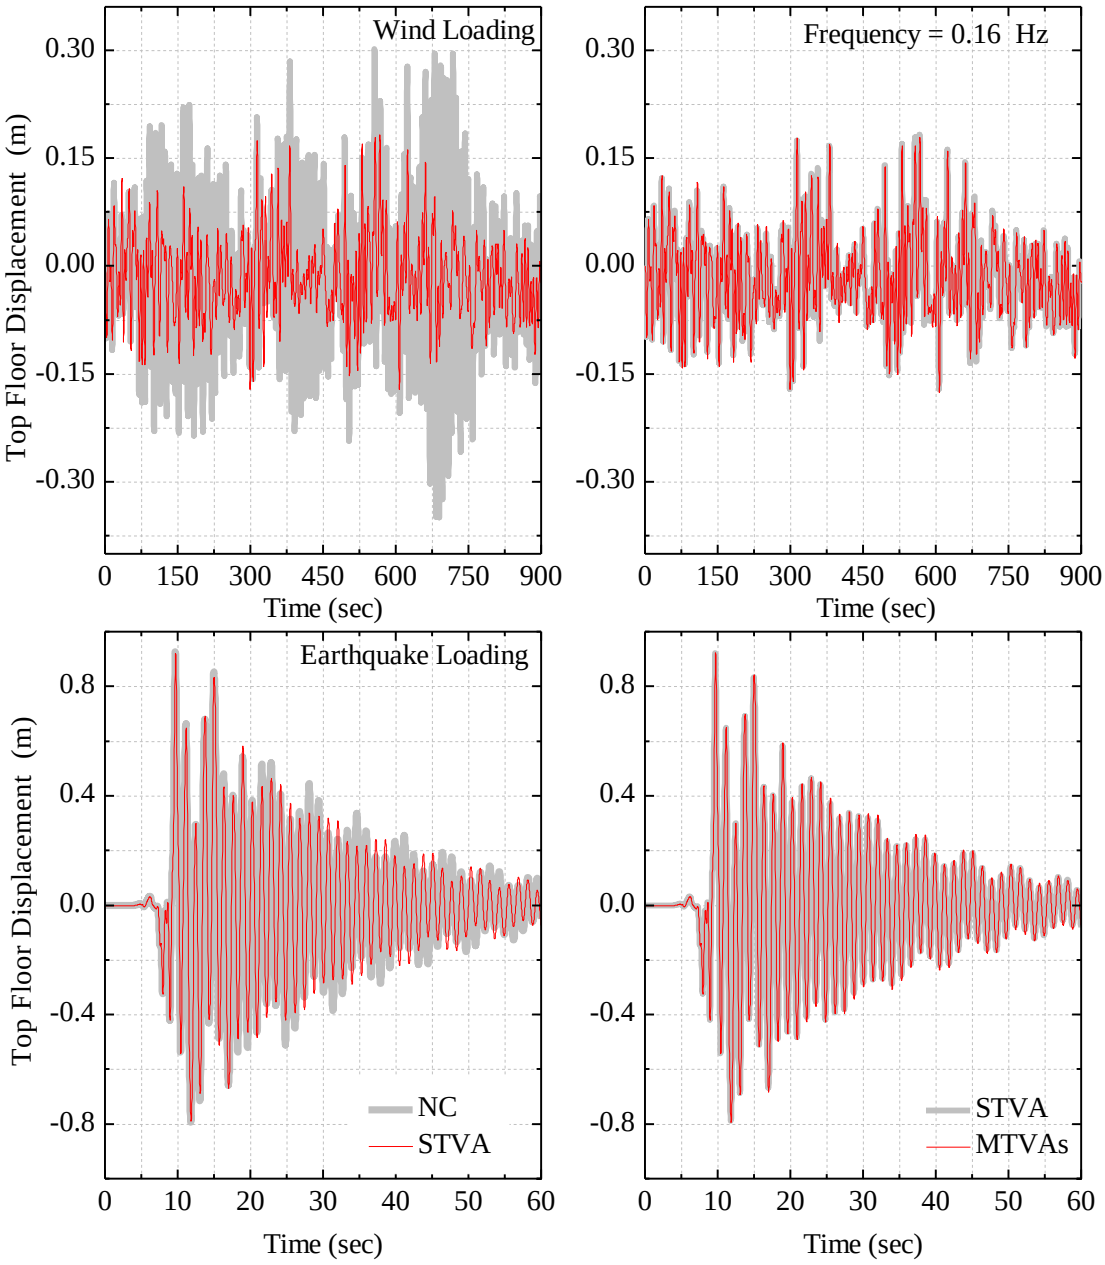

Figure 2: Time variation of top floor displacement for 76-storey benchmark building installed with the STVA, MTVAs-all.top under wind forces or Kobe, 1995 earthquake excitation.

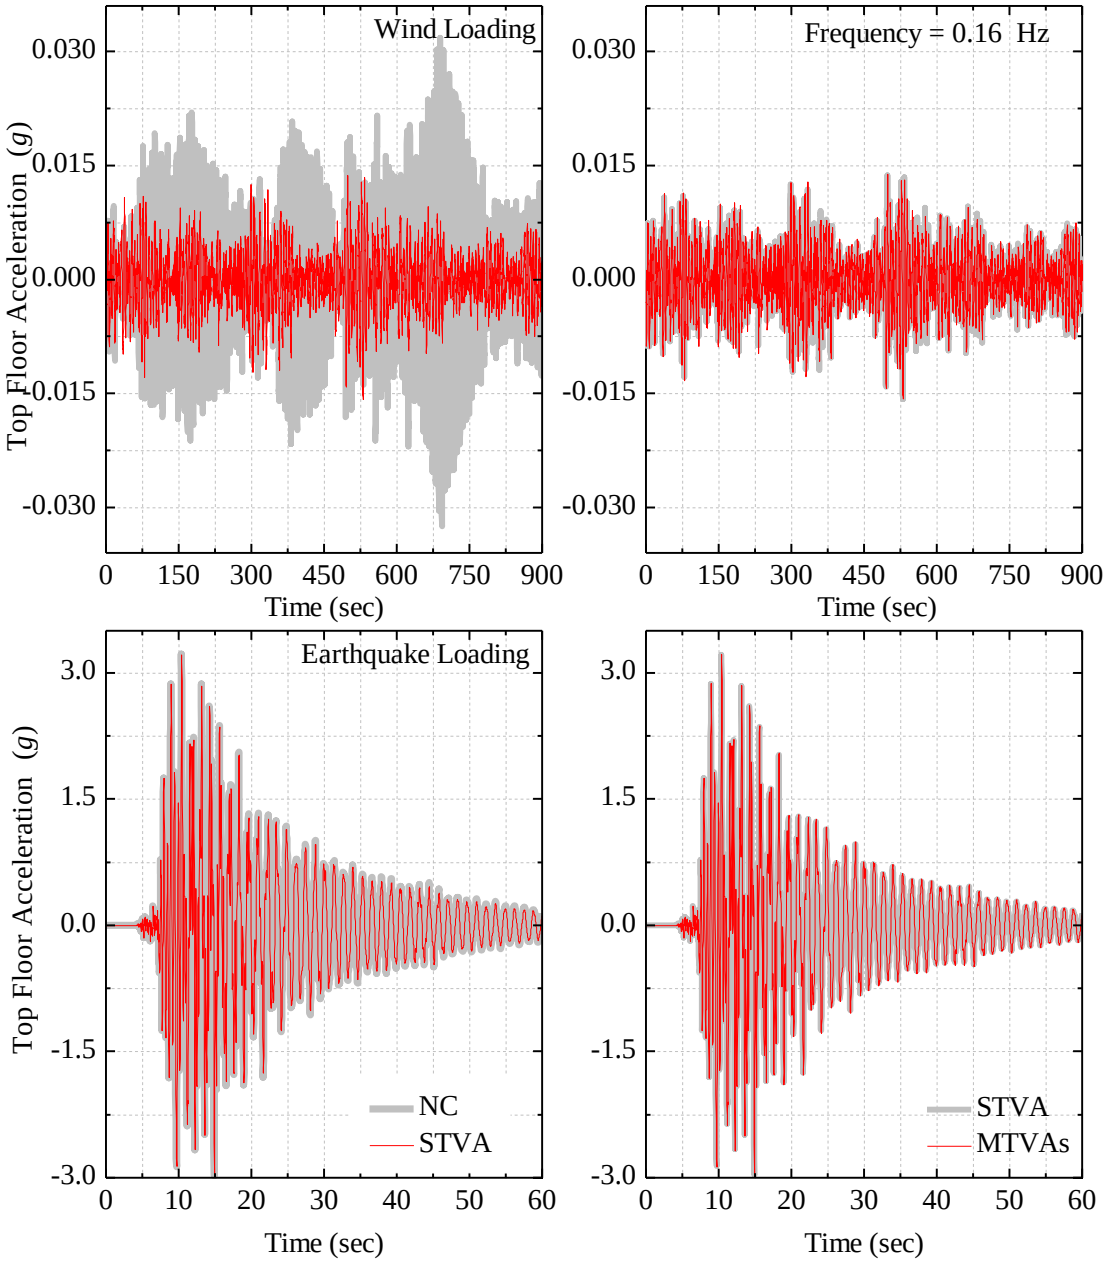

Figure 3: Time variation of top floor acceleration for 76-storey benchmark building installed with the STVA, MTVAs-all.top under wind forces or Kobe, 1995 earthquake excitation.

The STVA is designed for control of the building subjected to the wind forces. In the figure it is clearly shown that the STVA is quite effective for response reduction of the building while subjected to wind forces. However, it is noticed that the STVA designed for the reduction of wind response of the structure may not be as effective for earthquake response reduction. Even the scheme is not effective to reduce the peak displacement response of the benchmark building under Kobe earthquake. Having same mass (1250 ton) into consideration, the MTVAs are designed as per the optimal parameters suggested by Patil and Jangid [13]. The optimal parameters for MTVAs having five TVAs are 0.1, 0.94, and 0.05 for the frequency bandwidth, frequency tuning ratio, and damping ratio respectively. The MTVAs shows similar response reduction, which quite effective under wind forces but not much effective under earthquake ground excitation.

The STVA and MTVAs designed as per the closed formulation proposed by Sadeck et al. [14] for seismic response reduction of the buildings are presented in Figures 4 and 5. The system designed for earthquake response mitigation is subjected to wind forces. From the figures it is observed that the overall root mean square (RMS) of the responses are reduced significantly but not the peak responses while subjected to Kobe earthquake excitation.

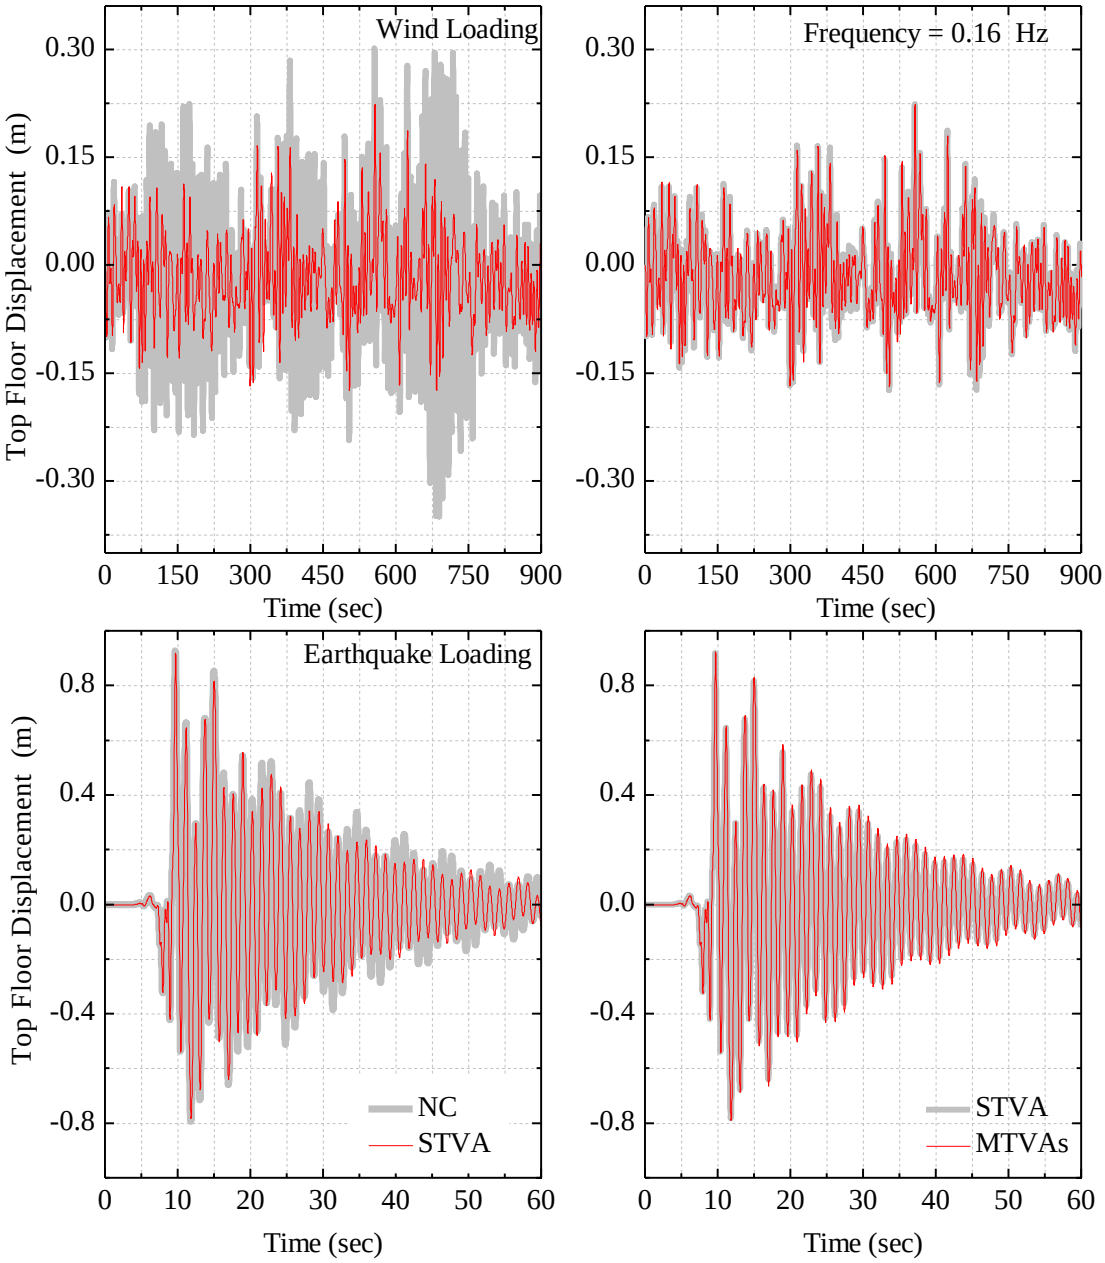

Figure 4: Time variation of top floor displacement for 76-storey benchmark building installed with the STVA, MTVAs-all.top under wind forces or Kobe, 1995 earthquake excitation.

The STVA and MTVAs perform good while the system subjected to wind forces. Although, the performances were not the same as the optimal devices designed for wind excitation. But the devices are not amplifying the responses of the benchmark building. Therefore, it is concluded that the optimal designed TVA schemes designed for wind sensitive situation would be vulnerable while subjected to the earthquakes, but the TVA schemes designed for

earthquake sensitive situation can still be effective for response reduction of structure subjected to wind forces.

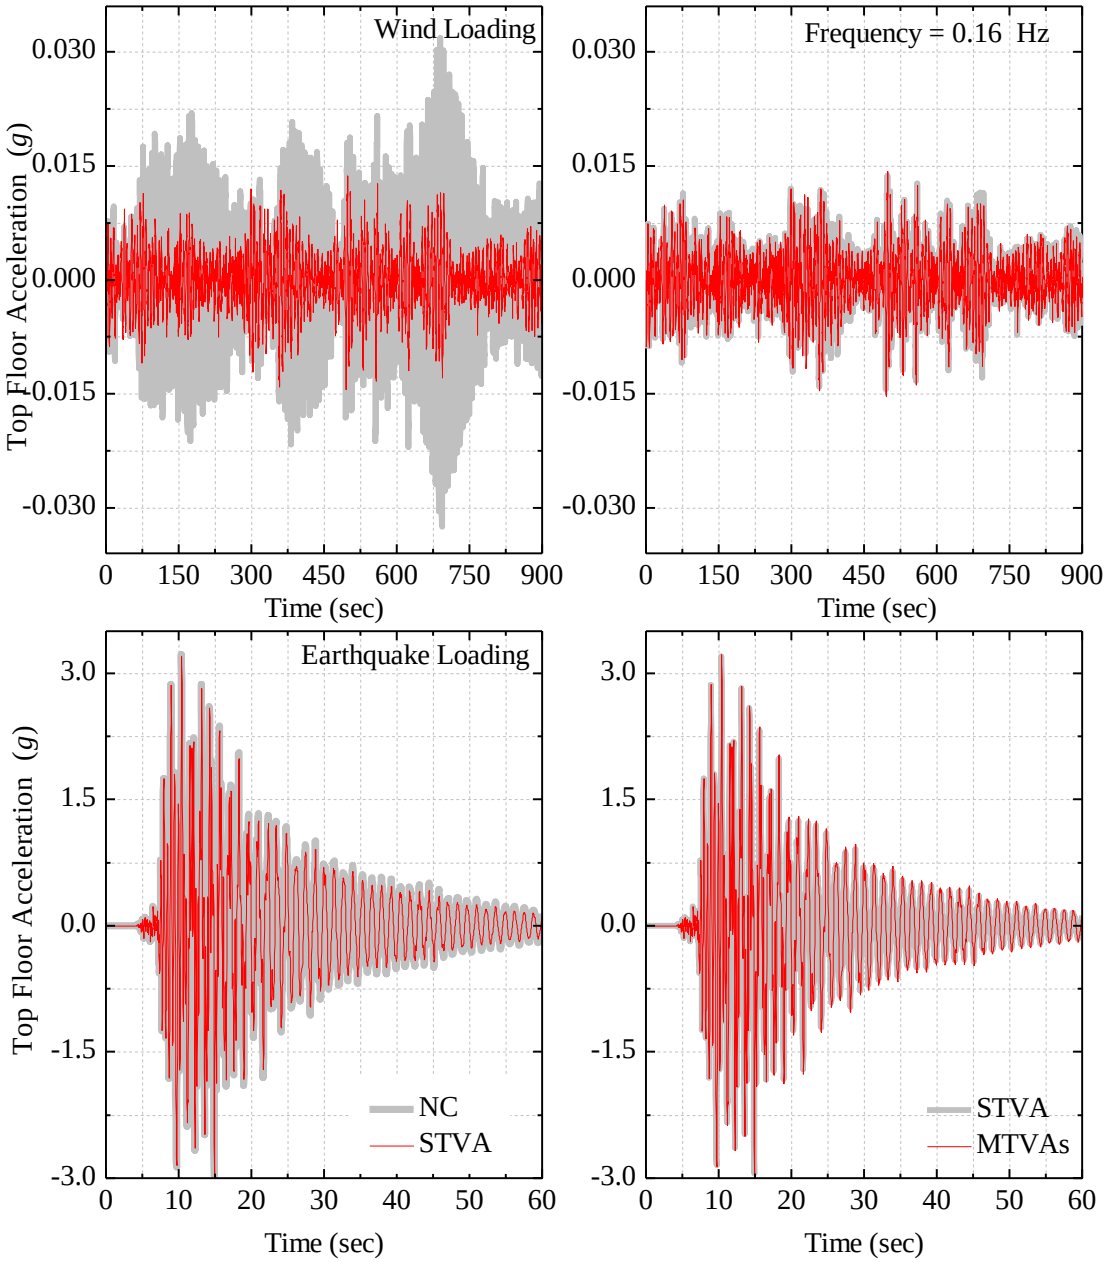

Figure 5: Time variation of top floor acceleration for 76-storey benchmark building installed with the STVA, MTVAs-all.top under wind forces or Kobe, 1995 earthquake excitation.

Multi-mode control is reported to be effective procedure for both wind and earthquake vibration mitigations. Elias et al. [7, 8] presented the detailed procedure for seismic response control of buildings considering multi-mode control. Very recently Elias et al. [9, 10] showed the effectiveness of the multi-mode control of the structures subjected to wind forces. In both methods the designed parameters showed to be quite different for earthquake vibration control the devices were designed having equal masses but for wind vibration control the devices designed considering equal stiffness. In this study for response mitigation of the benchmark building subjected to wind and earthquake excitations, both the designs applied to compare

the performance of the devices under multi-hazards. The MTVAs designed as per the procedure defined by Elias et al. [7, 8] named as e-MTVAs and the MTVAs designed as per the procedure defined by Elias et al. [9, 10] named as w-MTVAs. In Figures 6 and 7 the comparisons of the performances of the w-MTVAs and e-MTVAs for vibration control of benchmark structure are presented.

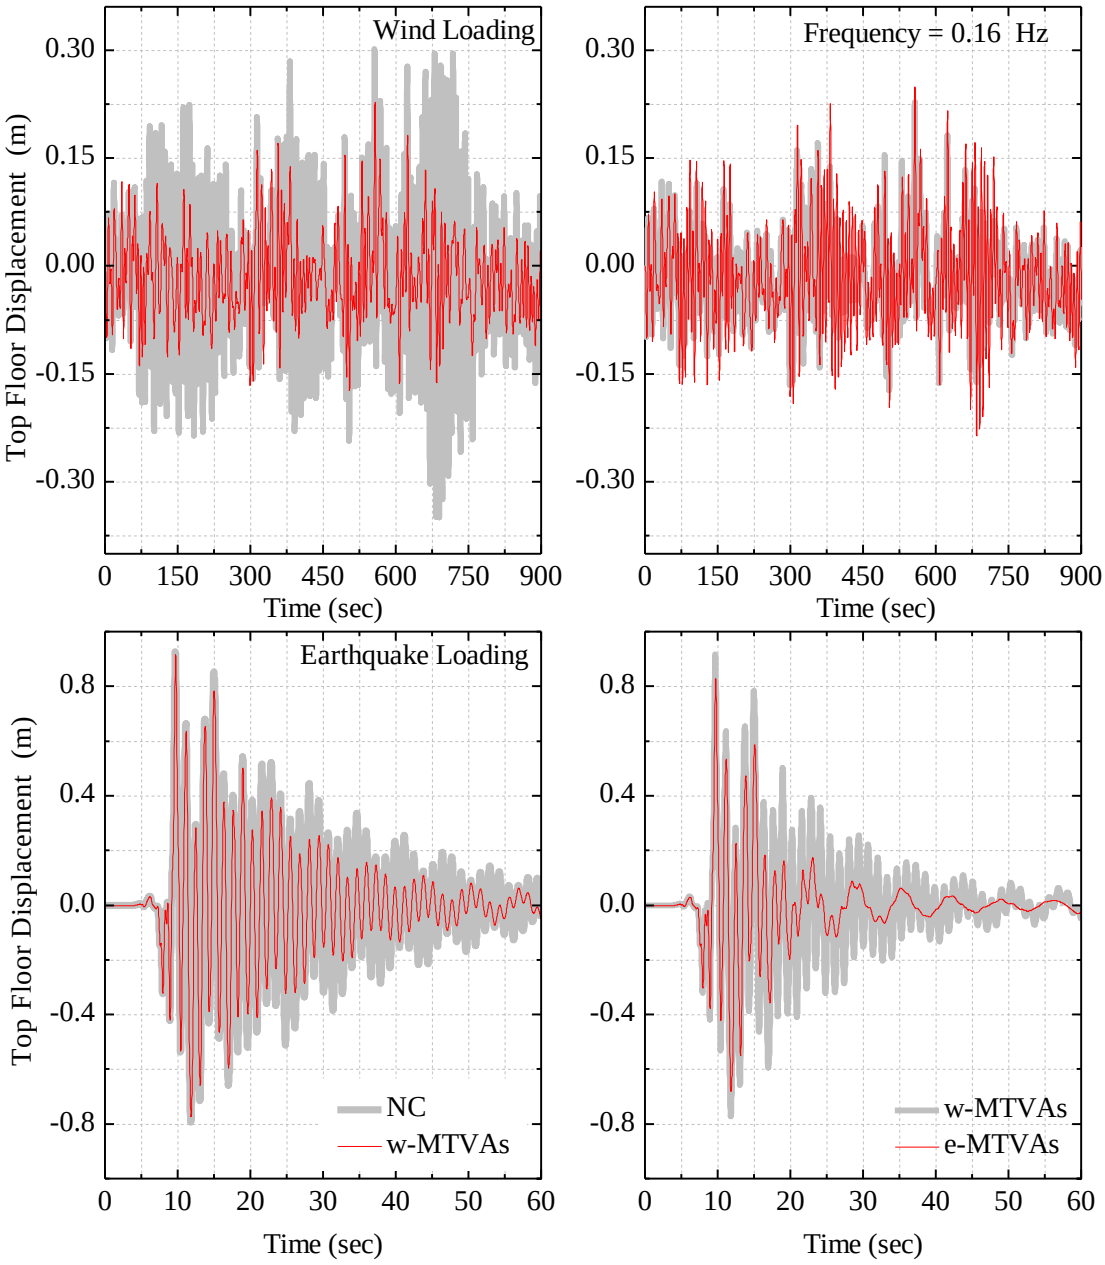

Figure 6: Time variation of top floor displacement for 76-storey benchmark building installed with the w-MTVAs, e-MTVAs under wind forces or Kobe, 1995 earthquake excitation.

It is observed that multi-mode control is quite effective procedure under both wind and earthquake excitations. The peak and RMS responses of the building are controlled significantly each subjected to earthquake or wind forces. It is to be noted that still the multi-mode control scheme designed for earth response mitigation is more effective as compared to the system designed for wind response mitigation (while subjected to Kobe earthquake). For wind

response mitigation still both the schemes are effective. It is found that the recent advancement proposed by Elias et al. [7-10] were the most effective solution for the benchmark building under multiple loading condition.

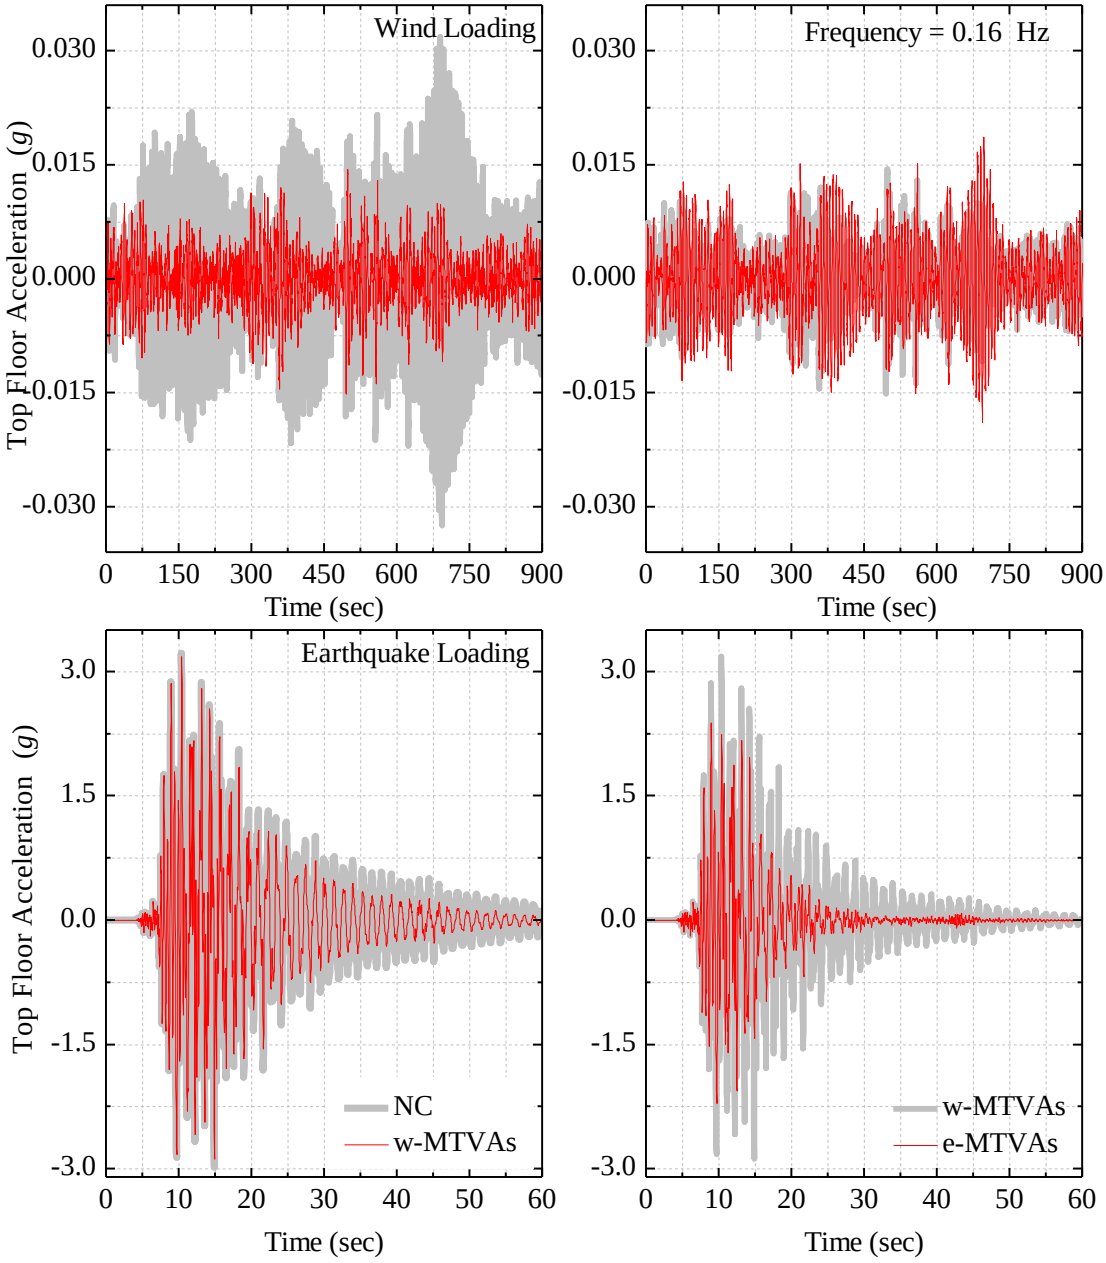

Figure 7: Time variation of top floor acceleration for 76-storey benchmark building installed with the w-MTVAs, e-MTVAs under wind forces or Kobe, 1995 earthquake excitation.

The effect of the mean wind speed at top of the building is also studied by having the speed of 40 m/sec, 50 m/sec, and 60 m/sec (see Table 1). It was found that by increasing the mean wind speed at the top of the building the responses increased by about 50%. But the increase the speed did not reduce the performance of the TVA schemes and same response reduction is achieved. The w-MTVAs reduced the top floor displacement by about 35% and e-MTVAs reduced about 30%. The top floor acceleration of the building is reduced by about 54% and 42% for w-MTVAs and e-MTVAS respectively while subjected to wind forces. While the

schemes subjected to different earthquake ground motion, still both performed. Generally for acceleration response reduction the e-MTVAs performed significantly better than the w-MTVAs while subjected to earthquakes. By accepting 12% less acceleration response reduction of the building while subjected to wind forces, therefore the e-MTVAs is the best solution among the schemes investigated in this study. However, for displacement response reduction there is not much difference in both devices while subjected to wind forces.

Scheme	Response	Wind Forces with Different Velocities at Top of the Building (m/sec)			Earthquakes		
		40	50	60	Imperial Valley 1940	Mexico City, 1995	Duzce, 1999
NC	Top Floor Displacement (m)	0.2507	0.3917	0.5640	0.9089	0.8784	0.2084
	Top Floor Acceleration (g)	0.0233	0.0364	0.0524	1.6523	0.6529	4.5354
w-MTVAs	Top Floor Displacement (m)	0.1629	0.2545	0.3664	0.4750	0.6421	0.2086
	Top Floor Acceleration (g)	0.0108	0.0169	0.0244	1.6504	0.6031	4.5164

4 CONCLUSIONS

Tuned vibration absorbers (TVAs) for control of tall buildings under wind and earthquake loads are investigated. The comparison of different TVA schemes such as single TVA (STVA), multiple TVAs (MTVAs) are presented. Based on the results presented the following conclusions can be drawn:

- The tall buildings designed for wind are not safe under strong earthquake loads. Nevertheless, it is important to mention that nonstructural systems may represent a high percentage of loss exposure of buildings to earthquakes due to high floor acceleration. Therefore, suitable vibration control techniques are recommended for response reduction of the buildings under wind and earthquake loads.
- The optimal devices designed only for wind sensitive structures may not be effective while subjected to earthquakes, but the device designed for earthquake sensitive structures may still be less effective under the wind forces.

- The multi-modal response control is a robust technique for vibration mitigation of the structures under multiple hazard situations.

Abstract

Contemporary seismic isolation systems for building structures provide drastic reduction to the structure's interstorey drifts and absolute accelerations. However, their major drawback is the large increase of the base displacement. Due to the high equivalent damping ratio, the novel KDamper passive vibration isolation and damping concept can provide an alternative approach for seismic protection. The KDamper is based on the optimal combination of appropriate stiffness elements, which include a negative stiffness element. The main advantage of the KDamper over other similar concepts including negative stiffness elements, is that no reduction in the overall stiffness of the system is required.

This paper considers the application of a KDamper system to 3 storey concrete building structure. A dynamic system consisting from a simplified flexible structure model and KDamper devices is considered and is subjected to artificial accelerograms designed to match the EC response spectra. The KDamper is designed to higher frequencies compared to the isolated system with seismic isolation bearings, exploiting the extraordinary damping properties it offers.

A comparison with a base isolated structure using Lead Rubber Bearings designed to greatly increase the fundamental period of the system (2.0-2.5 sec), confirms that KDamper base seismic absorption designs can provide great reduction to the interstorey drifts and absolute accelerations reducing at the same time the base displacement.

Keywords: Seismic isolation, negative stiffness, KDamper, damping.

1 INTRODUCTION

Throughout the last decades, the need for updated seismic design codes, incorporating advanced techniques and technologies, has been intensified, due to the damages of major earthquake events occurring in densely populated areas. Especially, considering structures whose functionality needs to be preserved even after a seismic event, such as hospitals, bridges etc., numerous novel methods have been developed, promising to improve each structure's dynamic behavior. Focusing on bridge structures, numerous devices have already been implemented, under the scope of seismic isolation, whose main principle is reducing the earthquake forces induced on a structure instead of increasing the structure's capacity. Devices of this kind enable the decoupling of the superstructure – in this case the bridge's deck – from the substructure – in this case the bridge's piers and abutments. As a result, the system gains in flexibility and lower forces are imposed to the superstructure (the isolated system's fundamental period leads to a design acceleration value that is obtained from the descending branch of the response spectrum).

Recently, scientific interest focuses on the use of innovative devices and configurations based on the introduction of an additional mass to the structure, namely the Tuned Mass Dampers (TMDs). Since their first application by Frahm [5], TMDs have been frequently used to absorb vibrations of skyscrapers under earthquake and/or wind loading (Luft [10]), (McNamara [11]), (Qin et al. [15]), with the Taipei 101 Tower (101 stories, 54 m) in Taiwan (Haskett et al. [6]) being one of the most characteristic examples. The implementation of TMDs on bridge structures, in order to mitigate the effects of seismic or other types of vibrations, has been, lately, included in many research studies (Debnath et al. [3]). The optimal design theory proposed by Den Hartog [4] is usually employed when designing a system with TMDs. Their salient performance feature is the tuning of the TMD's natural frequency in resonance with the fundamental frequency of the primary structure. This way, a large amount of the structural vibrating energy is transferred for the superstructure to the TMD and then dissipated through damping. Besides their effectiveness, TMDs demonstrate two basic drawbacks: a) their performance is vulnerable to even slight changes of external and environmental factors that cause detuning phenomena (Weber & Feltrin [20]) and b) a large oscillating mass is required in order for the device to be effective and the resulting isolated system to exhibit an improved dynamic behavior.

Furthermore, the use of negative stiffness elements as parts of vibration absorption configurations becomes more and more popular. True negative stiffness is defined as a force that assists motion instead of opposing it. The use of negative stiffness elements was first introduced in the pioneer publication of Molyneaux [12], as well as in the milestone developments of Platus [14]. Specifically, many researchers have demonstrated the effectiveness of "Quasi Zero Stiffness" (QZS) oscillators, aiming to reduce the system's stiffness and, by extent, its natural frequency to almost zero levels (Carella et al. [2]), regarding the seismic protection of structures through the alleviation of dynamic forces (Ibrahim [7]), (Nagarajaiah et al. [13]). Negative stiffness behavior is achieved by special mechanical designs involving conventional positive stiffness pre-stressed elastic mechanical elements (e.g. post-buckled beams, plates, shells and pre-compressed springs), arranged in appropriate geometric configurations (Winterflood et al. [21]), (Virgin et al. [19]). Interesting applications of QZS oscillators in seismic isolation are described in Iemura and Pradono [8] and Sarlis et al. [17]. However, the drastic reduction of the total structural stiffness to almost negligible levels, namely, the main feature of QZS oscillators, is, also, its fundamental drawback, as it is accompanied by a decrease of the structure's static load capacity.

Inspired by the two aforementioned technologies (TMDs and QZS oscillators), a novel passive vibration absorption and damping concept is proposed, the KDamper concept. A detailed presentation of this concept can be found in Antoniadis et al. [1]. The KDamper devices comprise of both negative and positive stiffness elements, as well as an additional mass and an artificial damper, properly arranged, in order to exhibit an extraordinary damping behavior. Even though negative stiffness elements usually demonstrate an unstable behavior, the KDamper is designed to be both statically and dynamically stable, presenting the same overall (static) stiffness as a traditional reference oscillator. Thus, the proposed concept overcomes the previously mentioned disadvantages of TMDs and QZS oscillators. The salient feature of the KDamper concept is the transfer of the vibrating structural energy from the primary structure to the additional mass, which is then dissipated through damping. The resulting isolated system exhibits an improved dynamic behavior. A first approach to the implementation of the KDamper concept for base isolation of structures can be found in Kapasakalis et al [9].

In this paper, the implementation of the KDamper concept to a 3 storey concrete building structure for base isolation, is considered. The Structure is subjected to 10 Artificial Accelerograms designed to match the EC8 response spectra. A comparison with a highly damped conventional seismic isolation system (Lead Rubber Bearings), designed to greatly increase the fundamental period of the structure (2.0 sec), confirms that KDamper base seismic absorption designs can provide great reduction to the interstorey drifts and absolute accelerations, reducing at the same time the base displacement, offering high damping properties.

2 OVERVIEW OF BASE ISOLATION AND THE KDAMPER CONCEPT

The principle on which seismic isolation is based on, is that increasing the structure's fundamental period leads to the transition branch of the response accelerations spectrum, as presented in Figure 1a. However, it should be mentioned here, that excessively high values of the fundamental period could result in an undesirable increase of the structure's displacements as it can be observed in Figure 1b. It is also observed, that further increase of the base's damping ratio ζ (*20%*) does not improve the dynamic behavior of the system.

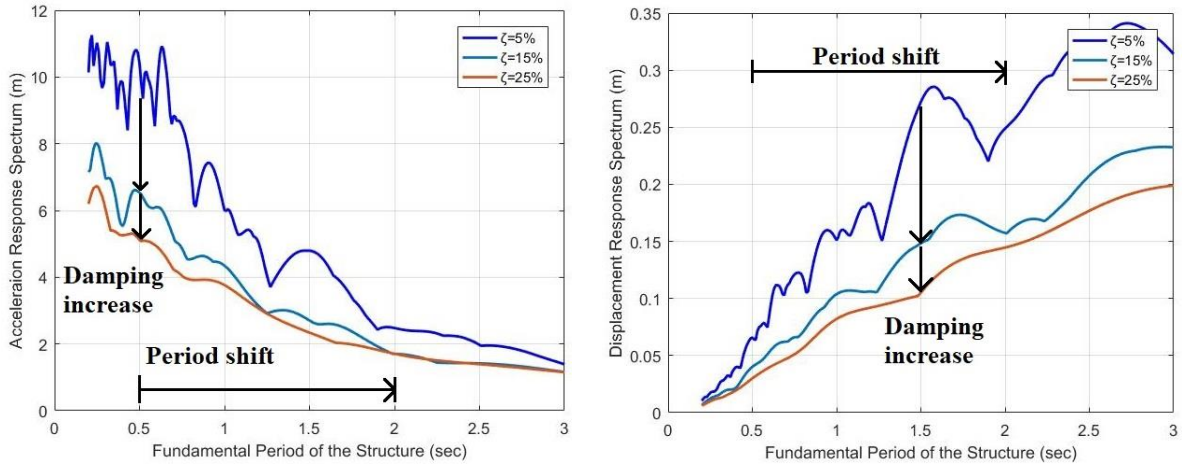

Figure 1. Indicative examples of response spectra of (a) accelerations and (b) displacements and their variation over damping.

Even though the implication of dampers seems a rather effective choice to overcome this problem, it is not always a feasible solution, because relatively high values of damping are usually required. An optimum compromise between accelerations and displacements, within

an acceptable range of structural fundamental periods, results in a region of feasible solutions. This region is referred to as design window and its lower and upper bounds are shown in Figure 2.

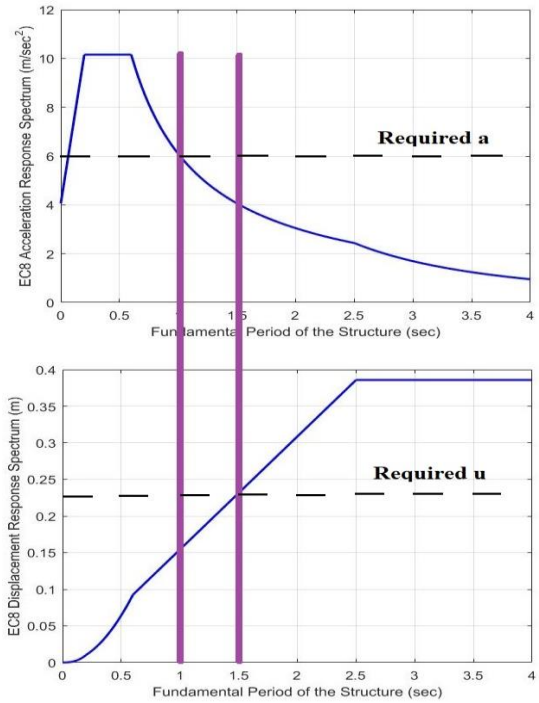

Figure 2. Conceptual illustration of the design window for isolation systems.

More specifically, the left boundary of the design window is imposed by the necessity to reduce accelerations. Its value generally depends on the soil of the structure's foundation (soil properties define the margin between the branch of constant accelerations and the descending one) and it is roughly estimated to be equal to 2 seconds. On the contrary, the right boundary cannot be defined as easily as the left one, as it is relevant to the displacement performance requirements of each structure. Consequently, the upper limit of the design window depends on each structure's functionality, security and implementation demands. In light of the above, the need to employ an optimization procedure, in order to efficiently design a seismic isolation system, is inherently apparent.

Figure 3 presents the basic layout of the proposed vibration isolation and damping concept, the KDamper concept, where k_N denotes the algebraic value of the negative stiffness element. An initial SDoF system is considered (Figure 3.a), consisting of a mass m_S and static stiffness *ko*, which may be undamped or have a low damping ratio. As it can be observed from Figure 3.b, the additional mass, m_D inside the device creates a second degree of freedom. Thus, the resulting isolated system is a 2-DoF system.

The device's performance is controlled by three parameters, μ, κ and ζ_D designated by the following equations:

$$\mu = \frac{m_D}{m_s},\ \kappa = -\frac{k_N}{k_e + k_N},\ \zeta_D = \frac{c_D}{2\sqrt{(k_e + k_N)m_D}} \tag{1}$$

Where ζ_D represents the equivalent damping ratio of the additional artificial damper with constant c_D.

Further information including a detailed description of the proposed device's optimized performance, the equations of motion of the isolated system, the realization and treatment of

the negative stiffness element and a possible implementation of such a device can be found in Antoniadis et al. [1].

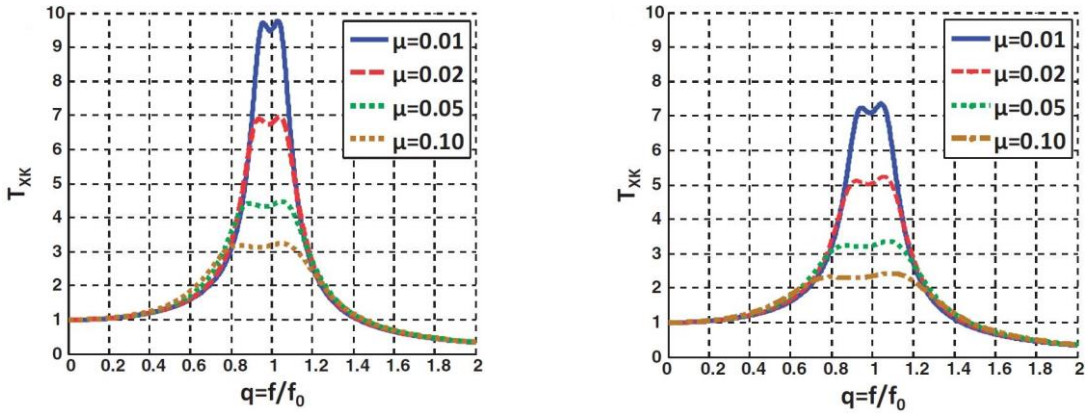
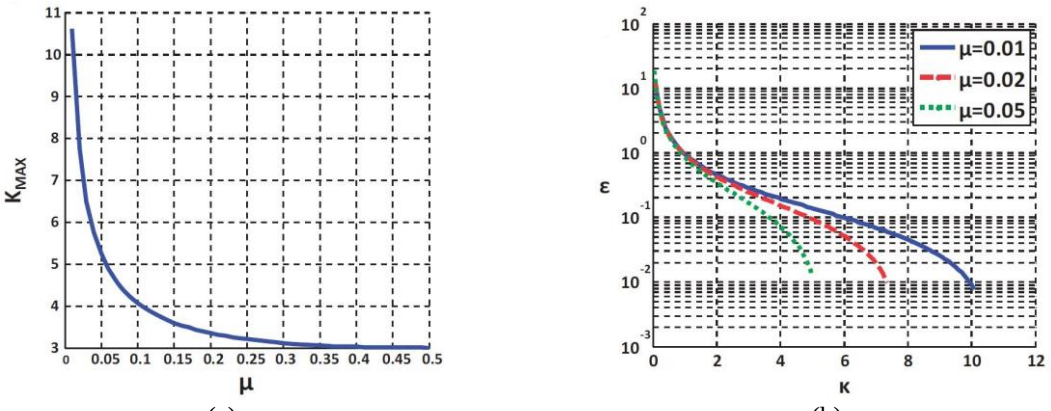
Figure 3. (a) Undamped SDoF system and (b) schematic representation of the considered vibration absorption and damping concept, the KDamper.

The effect of the mass ratio on the Transfer Function of the system is presented in Figure 4 and the variation of the KDamper basic parameters are presented in Figure 5.



(a) (b)

Figure 4. Effect of the mass ratio μ on the Transfer Function T_{XK} of the KDamper for (a) $\kappa=0.5$ and (b) $\kappa=1.0$.



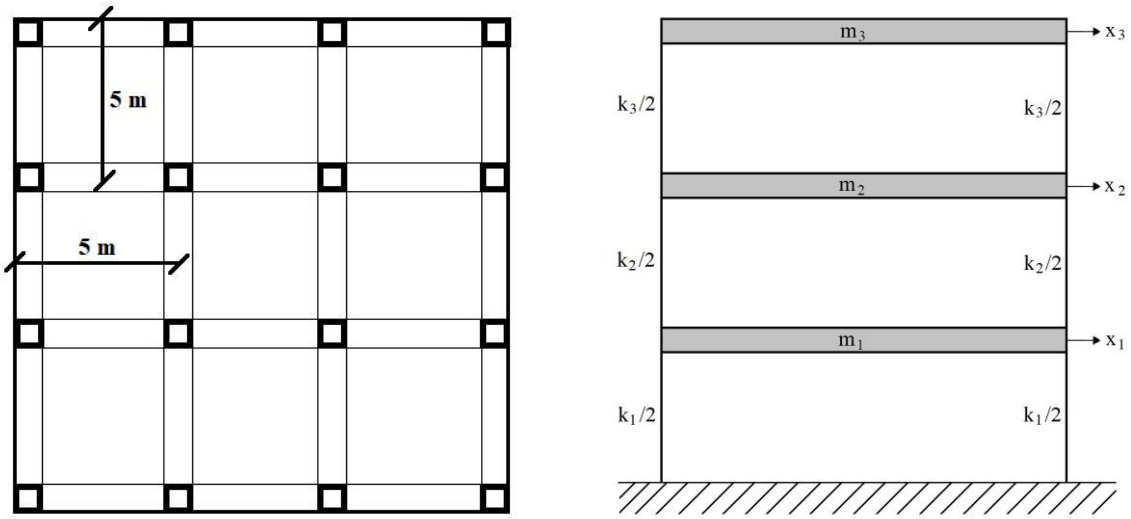
(a) (b)

Figure 5. Variation of KDamper parameters. (a) Effect of the mass ratio μ on the maximum value κ_{MAX} of κ and (b) effect of κ and μ over the static stability margin ε.

Based on these three parameters (Eq.1), all the other constants (regarding either stiffness or damping) of the KDamper elements are defined. Certain limitations are imposed to the values of the three parameters in order for the device to be economical and easy to place, regarding each structure's safety and functionality requirements and demands. Restrictions concerning the maximum allowable displacement (stroke) of both DoFs (internal and external) have to be also taken into consideration. More specifically, the maximum allowable value of the internal DoF depends on the mechanical equipment used to realize the negative stiffness element at each specific case/structure. For all these reasons, proposing an accurate optimization procedure is of paramount importance to facilitate the selection of the device's basic parameters and, by extent, the implementation of the KDamper concept.

3 IMPLEMENTATION ON 3-STOREY CONCRETE BUILDING STRUCTURE

A 3-storey concrete building structure as shown in Figure 6 (*C20/25, H_{floor}=3.1 m, g_{tot}=3.5 kN/m^2, q=2.5 kN/m^2*), is examined. The structure is idealized as a three storey shear type building as shown in Figure 6.b. The building is modeled as a 3-DoF system for fixed base, as a 4-DoF system for base isolated condition, using Lead Rubber Bearings, and as a 5-DoF system for base isolation using KDamper devices. The structure is modeled using one lateral degree of freedom at each floor. The damping of the superstructure is assumed as Rayleigh's mass and stiffness proportional damping, for that critical damping is considered as ξ=5% in all modes.



(a) (b)

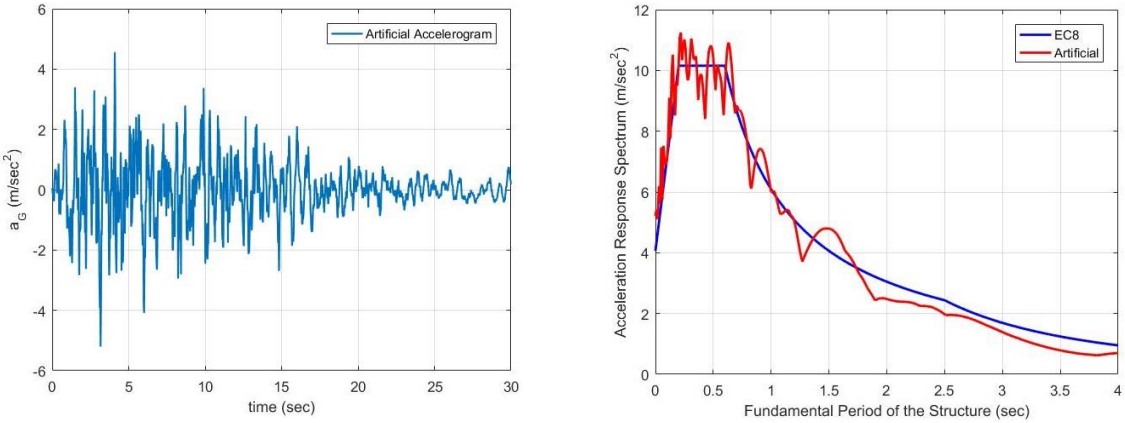
Figure 6. (a) Ground floor plan of a typical floor of the structure and (b) schematic presentation of a 3-Dof system mounted on a fixed base.

The various assumptions made for the modeling of the structure are:

a) The system is subjected to a single horizontal component of the earthquake ground motion.
b) The total mass of the structure is concentrated at the levels of the floors.
c) The slabs ad grinders on the floors are rigid as compared to the columns.
d) The columns are inextensible and weightless providing the lateral stiffness.
e) The effect of soil-structure-interaction is not taken into consideration.

In addition to this for base isolated buildings we assume that the superstructure is considered to remain within the elastic limit during the seismic excitation. This is a reasonable assumption as the isolation attempts to reduce the earthquake response in such a way that the structure remains within the elastic range.

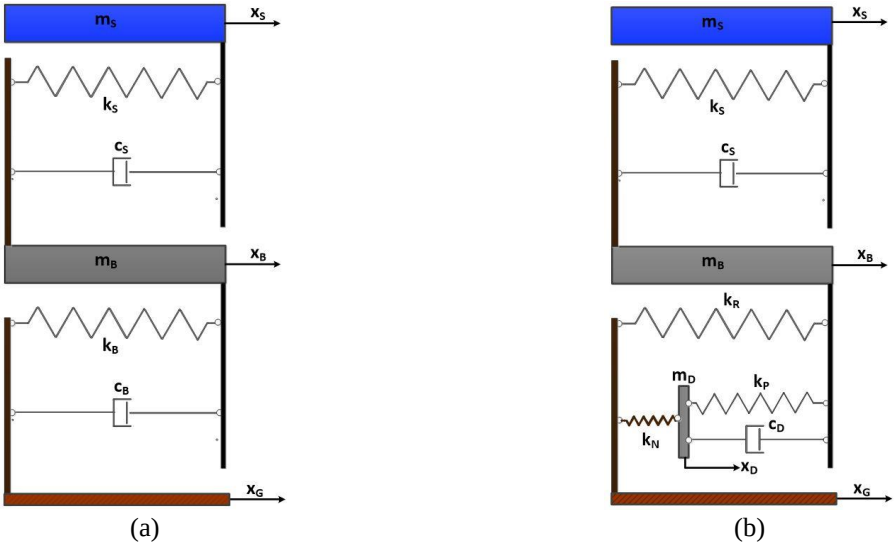
The system is subjected to Artificial Accelerograms designed to match the EC8 response spectra, as in Figure 7. The Artificial Accelerograms are generated using the SeismoArtif Software [18], for spectral acceleration *0.36 g*, ground type C, spectrum type I, importance class II, calculation method Artificial Accelerogram Generation and Adjustment using an envelope shape by Saragoni & Hart [16]. In Figure 7b, it is observed that the acceleration response spectrum of an Artificial Acclerogram, calculated as described above, is matched very accurately with the EC8 response spectrum, with characteristics: spectral acceleration *0.36 g*, ground type C, spectrum type I, importance class II.



(a) (b)

Figure 7. (a) Artificial ground excitation and (b) Artificial Acceleration response spectra vs EC8 response spectra.

Figure 8 presents the seismic isolation concepts considered in this paper. The SDoF system with mass m_S, stiffness k_S and damping coefficient c_S represents the superstructure, which in this case is the 3 storey building structure. It must be noted here that the presentation of the structure as a superstructure, in Figure 8, is made only for comprehensibility reasons.



(a) (b)

Figure 8. (a) Flexible structure on a conventional seismic isolation base and (b) possible implementation of the KDamper concept on a seismic isolation base.

The base isolated system with Lead Rubber Bearings (Figure 8.a) is designed to provide an increased fundamental period of the structure of *T=2.0 sec* and an equivalent base's damping

ratio *20%* of critical. The hysteresis loop is modelled as bilinear, as presented in Figure 9. The parameters d_1, F_1, d_2 and F_2 define the bilinear curve and are given for a standard LRB.

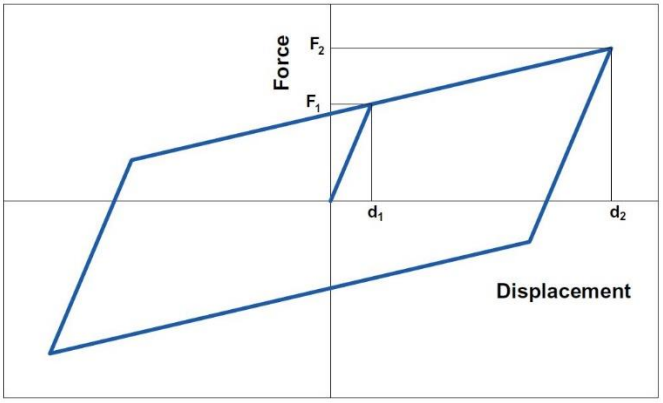


Figure 9. Bilinear hysteresis loop of an LRB.

The hysteretic behavior of an LRB can also be modelled as linear, by means of the effective stiffness K_e and the equivalent viscous damping coefficient ξ_e, which depend on the maximum displacement d_2, and on the corresponding force F_2 to which they refer:

$$K_e = F_2 / d_2 \,,\ \xi_e = \frac{2}{\pi}\left[\frac{F_1}{F_2} - \frac{d_1}{d_2}\right] \tag{2}$$

The system controlled with KDamper devices (Figure 8.b) is designed to increase the fundamental period of the structure to *1 sec*. The additional mass ratio μ_D is *5%* of the total superstructures mass. The stiffness elements are obtained through an optimization procedure with an objective function the base's displacement and proper constraints concerning the floor's accelerations and displacements. The KDamper elements are presented in Table1.

m_D (*tn*)	k_N (*kN/m*)	k_P (*kN/m*)	k_R (*kN/m*)	c_D (*kNs/m*)

4 RESULTS

Fig.10 presents the Transfer Functions of the main system responses. As it can be observed, the effect of the conventional seismic isolation system is to shift the natural period of the structure from *0.45 sec* to *2.0 sec*, well below the main frequency content of the earthquakes.

The effect of the KDamper, implemented to the base isolation system, leads to a significant reduction of the initial Transfer Function H_{US} of the Structure's displacement. However, the Transfer Function H_{AS} of the Structure's acceleration retains a significant frequency content.

The Transfer Function of the base's displacement is dramatically improved with the KDamper compared with the conventional seismic isolation base, in all the frequency range, except very high frequencies (5-6 *Hz or 0.15-0.2 sec*).

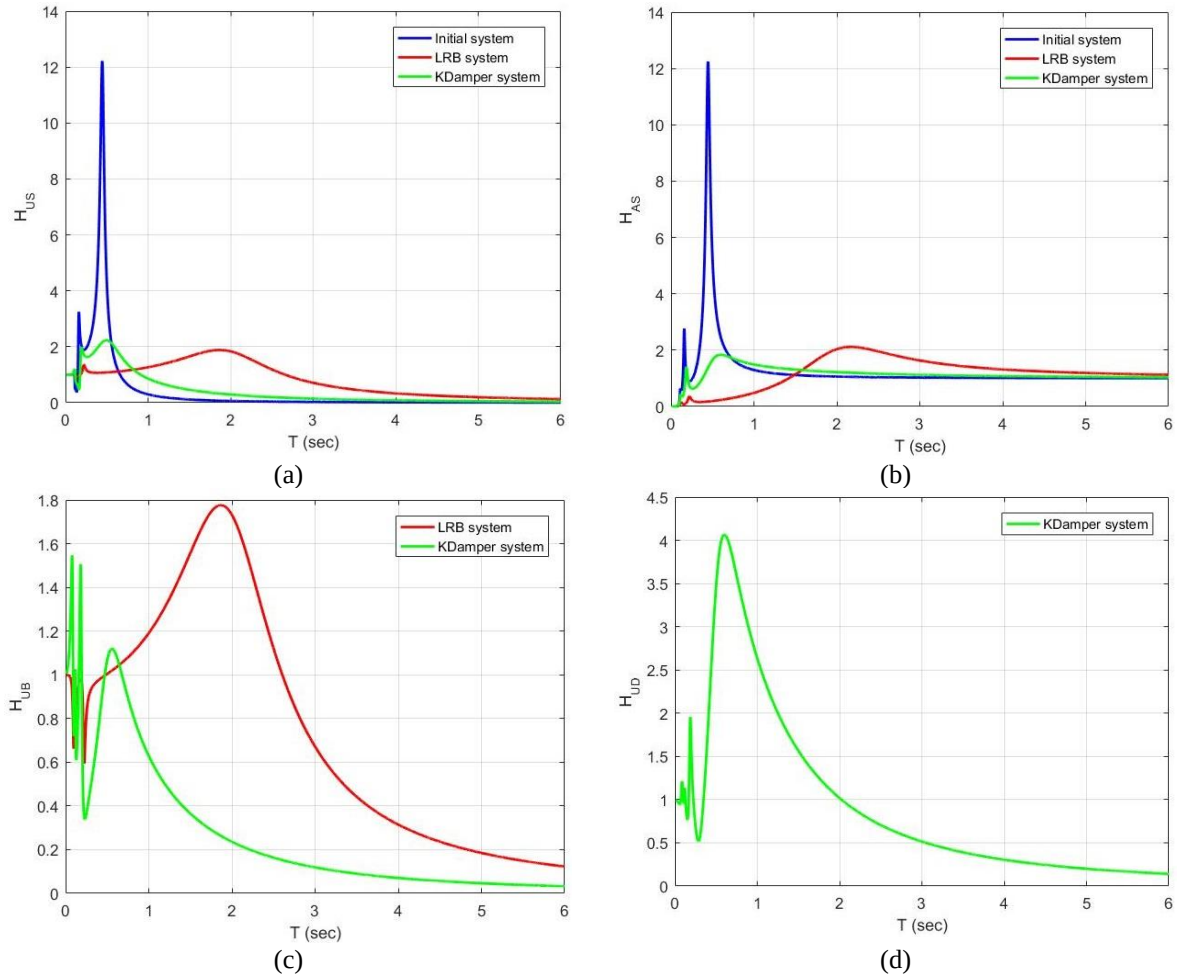

Figure 10. Transfer Functions of the initial system and the isolated system with a conventional seismic isolation base and with a KDamper (a) structure's relative displacement, (b) structure's absolute acceleration, (c) base's displacement and (d) KDamper's displacement.

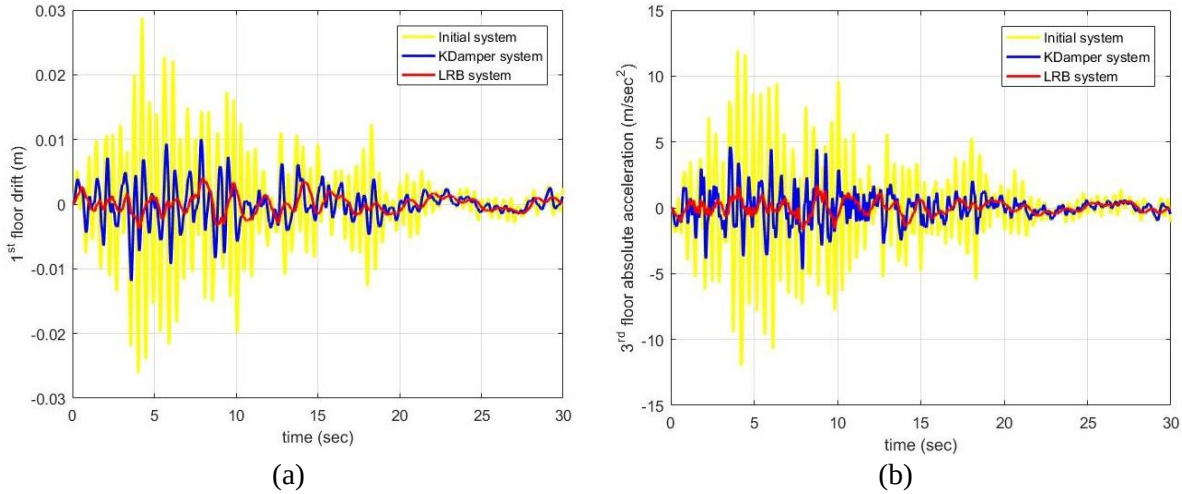

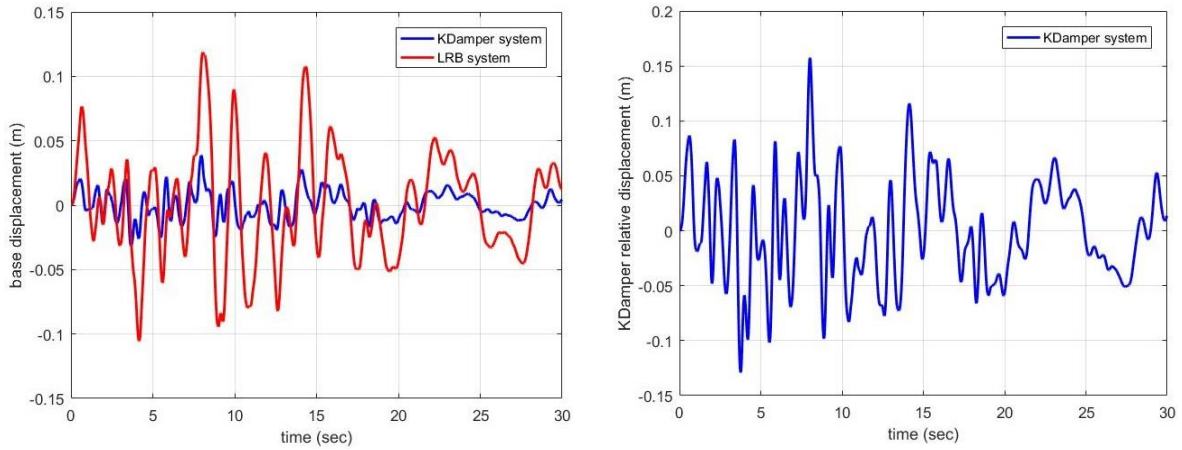

(c) (d)

Figure 11. Dynamic response of the structure under the base isolation concepts considered (a) Structure relative displacements, (b) Structure absolute accelerations, (c) Base relative displacements and (d) KDamper relative displacement

The system is solved using the Newmark-β method with linear acceleration. The responses of the structure to an Artificial Acceleration (Art. Acc. No1), are presented in Figure 11. Figure 11a and 11b confirms that the proposed implementation of the KDamper to the base isolation system, results to a drastic reduction of the structure's dynamic response in both terms of relative displacement and absolute acceleration, at acceptable levels compared to the highly damped conventional base isolation system (LRB). The base's displacement is dramatically improved with the KDamper system than the LRB system *(~70%* reduction), as presented in Figure 11.c.

The responses of the structure are presented in Table2 and 3, for 10 Artificial Accelerograms for the initial system as well as the base isolated system using conventional seismic isolation bearings (LRB) and KDamper.

5 CONCLUSIONS

The implementation of the KDamper concept for base isolation of a 3 storey concrete building structure subjected to Artificial Accelerogramms designed to match the EC8 response spectra for ground type C, reveals that the KDamper concept can provide a realistic alternative approach to the existing base isolation schemes.

The application of the KDamper leads to reductions of more than *50%* for the structure's maximum relative displacements and absolute accelerations, while retaining the base's relative displacement to acceptable levels more that *70%* lower than that of the high damped conventional seismic isolation systems (LRB), designed to shift the natural period of the structure to *2.0 sec*.

Provided that efficient technological realizations of the negative stiffness element can result, the KDamper can offer further advantages in terms of complexity and reliability, compared to a conventional highly damped base isolation system. Moreover, the inherit non-linear nature of the negative stiffness force can be exploited to offer further advantages of the KDamper concept, such as robustness, broadband response and energy sinks.

Keywords: Multistory buildings, Floor isolation system, Passive damper, Shape-memory alloy, Non-structural elements, Hospitals.

Abstract. *Healthcare facilities symbolize the principal lifeline activity whose operability should be assured after a natural calamity. However, hospital post-disaster functionality is closely related to both structural and nonstructural response, highlighting how facilities can lose their operability just for medium intensity earthquakes. Accordingly, this work aims to focus on a novel pseudoelastic isolation prototype when adopted to damp floor systems, therefore potentially relevant to isolate and retrofit, respectively, new and existing hospitals.*

Initially, based on tests accomplished at the Italian National Research Council (CNR), dedicated numerical simulations are performed to interpret the tensile response of the proposed shape-memory alloy (SMA) passive damper. In this regard, static and dynamic, as well as hint of coupled thermo-mechanic analyses are performed to clarify and predict the physical phenomena underpinning the complex SMA-based damper response.

Finally, focusing on the concept of hospital resilience, the paper demonstrates and updates reasons behind floor isolation systems, underlining structural and non-structural enhanced capabilities when applied to multistory moment resisting frame (MRF) healthcare facilities.

1 INTRODUCTION

In seismic areas a higher level of structural performance is desired for hospital systems than for residential buildings: on one hand, working continuity of such systems depend on the proper functioning of technical installations; on the other hand, medical facilities need to sustain life-line activities in post-emergency healthcare [1].

Although it is generally possible to make medical structures able to remain in function, even after severe seismic events, conspicuous financial losses are related to poorly planned hospital evacuation procedures and lack in operability [2]. Moreover, California is the only country having a specific code for hospital seismic retrofitting [3]. However, according to [4], meet these code requirements approximately consists in retrofit an equivalent 50% of medical facilities (or close them over the next 28 years), and therefore renovate 75% of non-structural components over the same period, for a total cost of $41.7 billion. Numerous guidelines on the hospital seismic assessment have been developed by the World Health Organization (WHO) within the 'Safe Hospitals' campaign, better known as the Hyogo Framework [5]; nonetheless, it is recognized that these guidelines are more practical policies than ad-hoc technical standards.

Resilience is described as the capacity of the system to reduce chances, to absorb and recover after a shock [6]. Especially, hospital resilience intimately depends both on structural and non-structural components, as well as on strategical vulnerabilities (such as emergency planning) toward a performance key indicator that describes the serviceability state of the system [7, 8, 9]. For instance, to prevent and minimize medical record losses, modern complementary techniques implement strategies that protect data in a double perspective, i.e., safeguarding non-structural hardware contents and formulating both Business Continuity (BCP) and Disaster Recovery plans (DRP) [10, 11].

As a result, our study pursues three main goals: (i) numerically model innovative dampers to be adopted as floor isolation systems (indicated as 'FIS', according to [12]) in a novel retrofitting perspective; (ii) highlight local and global isolation performance when dampers are equipped in multistory hospitals; (iii) face main non-structural vulnerabilities, protecting delicate human processes as ones conducted in laboratories, computer and operating rooms.

Therefore, the work is organized as follows: in Section 2 we discuss the novel passive damper developed by Nespoli et al. [13], composed by a parallel system of shape-memory alloy wires (indicated as 'SMA device'). Initially, we focus on the device dynamics, both empirically (through experimental tests performed by Nespoli et al. [14]) and numerically (by means of 3D finite element models developed using the software Abaqus [15], in Section 2.1). Afterwards, we display the effectiveness of the SMA device both in modifying the hospital structural dynamics and in reducing the non-structural vulnerability, when floor passive dampers are considered as a retrofitting procedure (Section 3). In detail, most relevant structural modeling stages (Section 3.1) and the device equivalent 1D model reduction (Section 3.2) are presented. Subsequently, local and global effects of FIS in structural response are discussed, highlighting attenuation in non-structural response and safeguarding human sensitive healthcare procedures (Section 4). Concluding remarks are presented in Section 5.

2 MATERIAL AND METHODS

The main stages fulfilled in this section can be outlined as follows:

- to summarize experimental tests previously performed by Nespoli et al. [14];
- to numerically reproduce the experimental tests;

- to establish the physical and mechanical effects on the response of the SMA damper;
- to re-design the device for floor isolation system applications;

To describe these stages, the consistency of modeling assumptions is discussed.

2.1 Shape-memory alloy (SMA) device

The scope is to study the mechanical response of the damper described in [14], investigating on shape-memory alloy physical peculiarities such as high strain recovery (known as shape memory effect) and recentering capabilities (due to pseudoelasticity) [16, 17]. In detail, pseudoelasticity is a recoverable deformative process induced by a thermo-elastic transformation between two different solid phases, martensite and austenite. This process is the base mechanism for the damper behavior, of which we concisely recapitulate the functioning in the following.

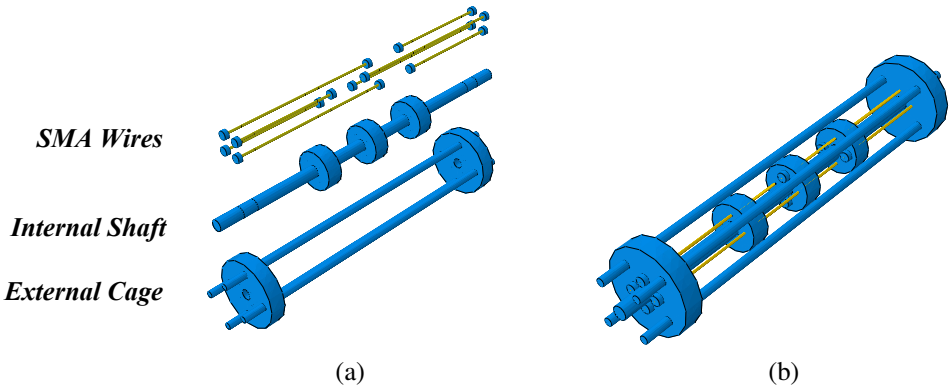

Figure 1: Shape-memory alloy device, components (a) & assembly (b).

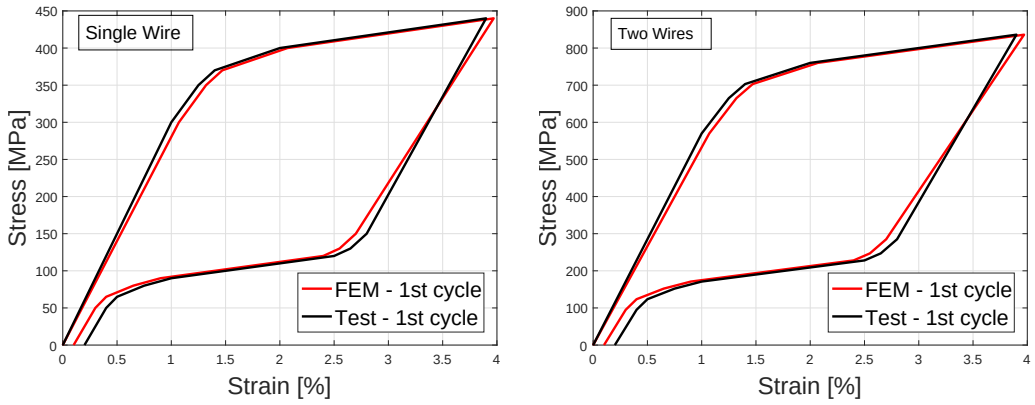
The device is constituted by two groups of SMA wires with the same diameter (1.2 mm) and different length (210 and 132 mm), organized in a specular parallel disposition (Figs. 1(a), yellow). According to Indirli et al [18] and Ren et al [19], this wire disposition tunes the stress-strain response of different length wire groups, composing multi-plateau force levels and improving the overall damping capacity. Externally, a steel cage protects the wires and support an internal steel sliding shaft: the shaft puts in tension the SMA wires through three fixed disks (Fig. 1(a), blue), providing bi-directionality to the damper.

Quasi-static and dynamic cyclic tests have been performed by Nespoli et al. [13, 14] to assess the mechanical behavior, initially on single SMA wires, subsequently on pseudoelastic systems (composed by groups of two wires), and finally on the global device (Fig. 1(b)). Tests have been fulfilled by means of a servo-hydraulic thermo-mechanical MTS equipment and temperatures have been measured by thin thermocouples. Quasi-static tests have been executed at controlled deformation rate (1% min^{-1}), while dynamic tests have been performed at 0.5-1 Hz for 1000 working cycles, stretching wires up to 6.4% strain.

Therefore, we develop 3D finite element (FE) models by means of the software ABAQUS [15], employing 8-node brick-based models in an isoparametric framework, in accordance with [20]. Geometrical and material non-linearities are considered. In order to reduce numerical analyses, we model the external cage rigidly, while we assume the rate-independent Von Mises yielding principle to reproduce the metal plasticity of shaft components [21]. The shape-memory alloy constitutive model is derived by Auricchio et al. [16].



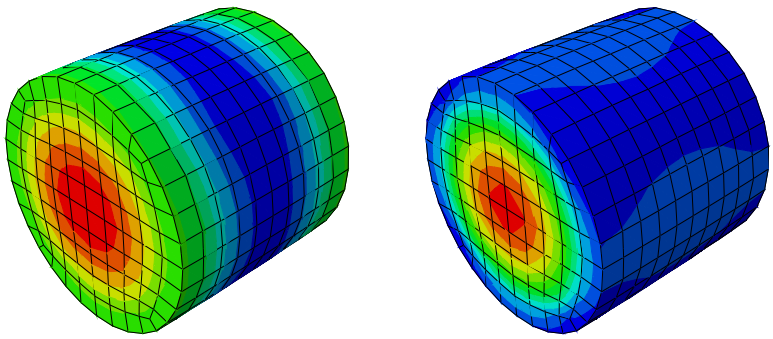
(a) (b)

Figure 2: Model calibration, tests on one- (a) & two-wire (b) pseudoelastic system.

At first, based on quasi-static experimental tests, we calibrate a single wire model capable to reproduce the one- and the two-wire experimental system, stretching such system up to 4% strain. Fig. 2 display the correlation between experimental and numerical results.

Afterwards, to numerically interpret the dynamic behavior of the whole damper, and therefore to characterize material property variations due to the exothermic transition from austenite to stress-induced martensite, single wire dynamic stress-strain response is expressed by functions of temperature in a coupled thermo-mechanical problem. Even if the simulated problem has an uniaxial nature, the response is explored in a three-dimensional domain. Specifically, dynamic analyses are performed in ABAQUS [15] by means of full-scale coupled temperature-displacement models, accounting for transient heat transfer: the external stagnant air is simulated applying a convective film coefficient to each free surface, while conduction is considered negligible. According to [22], although it is known that the expansion coefficient and the thermal conductivity may depend on the solid phase of SMA (whether alloy is austenite or martensite), these coefficients are considered to be independent from strain or temperature, as well as the specific heat and the film coefficient [15].

As a result, numerical tests are performed in a tensile/compressive fashion loading the wires for 1000 working cycles toward a 6.4% strain for the short wire (132 mm) and 4% strain for the long one (210 mm). Fig. 3 displays the heat radiation, moving from the center to the external surface in short- and long-wire sections.



(a) (b)

Figure 3: Model calibration, thermo-mechanical tests on short- (a) & long-wire (b) sections.

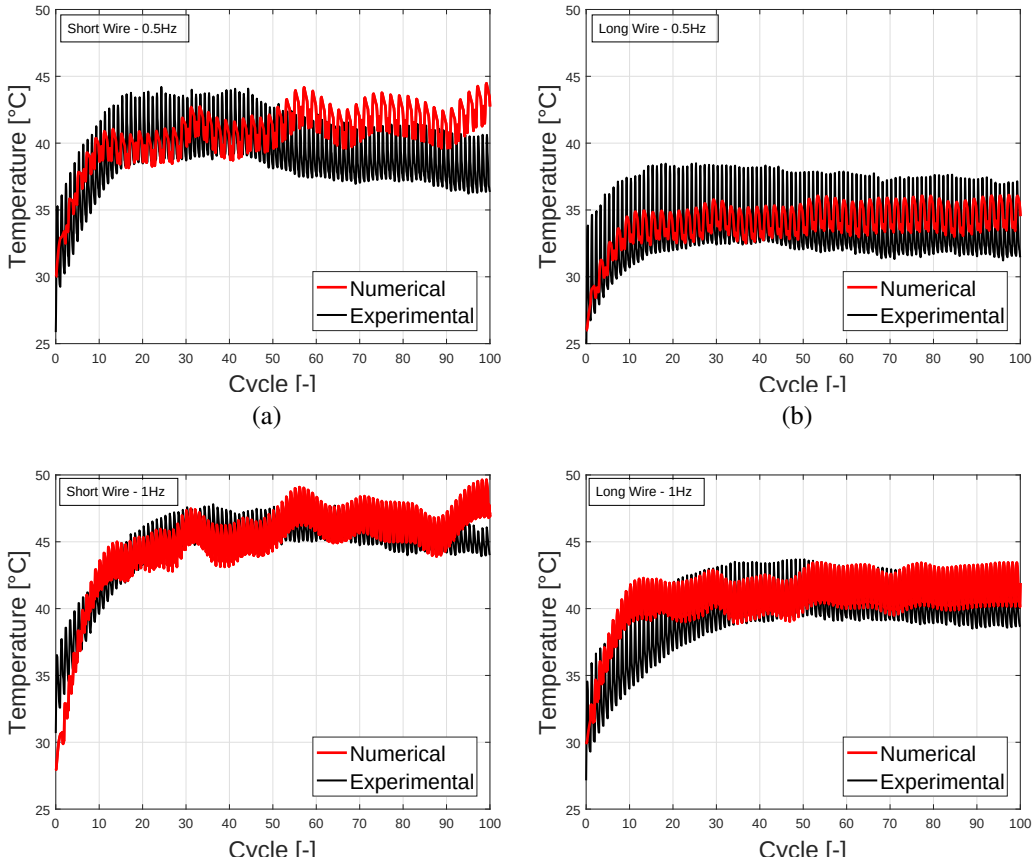


Figure 4: Coupled thermo-mechanical simulation, 0.5Hz - short wire (a) & 0.5Hz - long wire (b) & 1Hz - short wire (c) & 1Hz - long wire (d), numerical and experimental results.

Fig. 4 compares the experimental [14] and numerical temperature variation for the short and the long wire during the first 100 working cycles. The sinusoidal trend is due to the exothermic phase transition. Finally, we assemble the damper global model with tested wires: Fig. 5 depicts force-displacement diagrams during the first working cycle, registered at 0.5 and 1Hz.

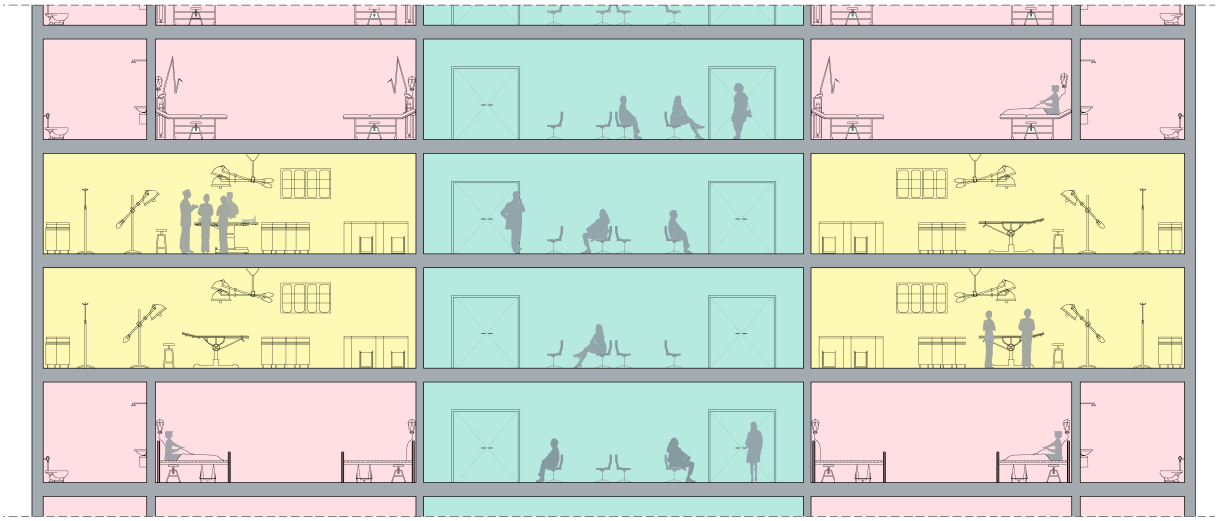

Figure 6: Model of hospital facility, the hazard color code.

2.2 SMA devices for hospital floor isolation systems

As illustrated in Fig. 6, several key activities are daily performed in hospitals: these activities can be conceptually gather according to an hazard color code. As a sample, in yellow we highlight delicate procedures, such as procedures executed in laboratories or operating rooms; in pink we depict recovery rooms and in green the waiting rooms. Interruption of yellow activities may affect life-saving operations or result in safety and economic losses. As a result, we decide to adopt floor isolation techniques to seismically protect non-structural elements, equipment and fragile building contents of yellow areas. Particularly, the isolation is achieved by decoupling secondary floor systems form the motion of structural frame by means of horizontally flexible links called isolators (Fig. 7(a)). However, despite preserving the content of critical facilities might produce the greatest cost-benefit ratio, floor isolation systems have not been codified yet; additionally, distinctions from conventional base isolation systems arise on the supported weight and on the seismic input, generally making floor isolation technique laborious. By contrast, thanks to SMA devices we propose an intuitive floor isolation scheme (Fig. 7(b)).

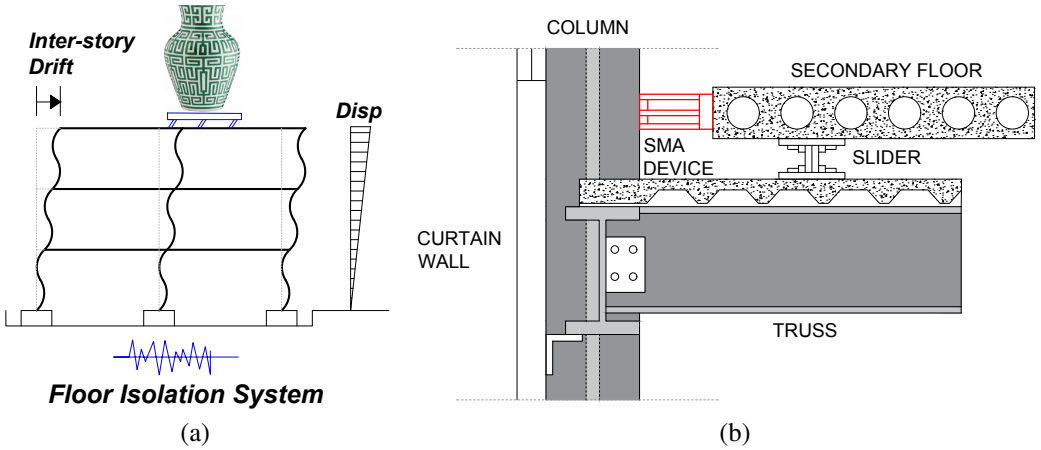

Figure 7: Floor isolation system, conceptual model (a) & application scheme (b).

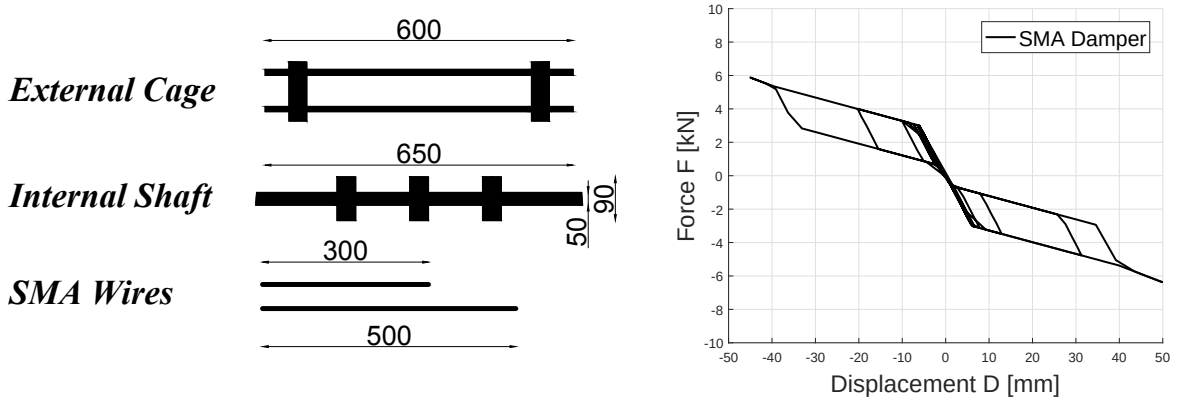
In this scheme, the secondary floor system is supported by a low friction slider, while laterally the motion is damped by SMA devices. Successively, we perform a parametric numerical campaign, iterating numerical simulations presented in Section 2.1 in order to re-design a SMA-based damper, capable to support a 50mm inter-story drift in displacement and a 6kN lateral load in force. In Fig. 8 we depict the new damper geometries (8(a)) and the force-displacement dynamic response (8(b)).



(a) (b)

3 NONLINEAR TIME HISTORY ANALYSES

The main objective of this work is to highlight the potentiality of SMA devices as a retrofitting tool, in order to isolate hospital floors safeguarding lifeline activities during extreme events, throughout these main stages:

- to reproduce, by means of fiber-based models, the seismic response of four multistory hospital facilities introduced in Section 3.1;
- to reduce 3D device numerical simulations (introduced in Section 2.1) in equivalent 1D fiber-based link elements;
- to assess the potential impact obtained by implementing SMA-based floor isolation techniques, correlating structural and non-structural seismic response attenuation demonstrated by means of nonlinear time history analyses.

In this regard, the main conceptual simplifications will be discussed.

3.1 Description of the case-study buildings

We design four hospital prototypes (Fig. 9) according to Eurocode 8 [23], consisting in 6 x 6-bay buildings extrapolated from reference 5-,10-,15- and 30-storey three-dimensional structures. We consider high seismicity areas (i.e. PGA = 0.40 g) with soil class C (180 m/s $\leq$ Vs $\leq$ 360 m/s) and a medium ductility class (DCM). Fig. 9 displays the lateral force resisting system (LFRS): internally, a braced core redistributes vertical loads and guarantee stability against horizontal forces; externally, outriggers arranged every 15 floors impede lateral displacements

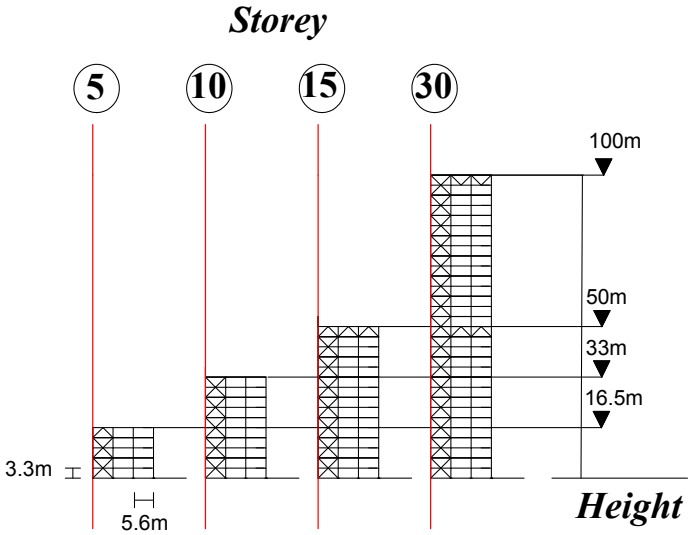

Figure 9: Reference hospital structures.

and inter-story drifts. As specified in 6.3 of EC8, we conservatively assume the behaviour factor (q) equal to 2, considering V bracing systems. Moreover, we hypothesize 2 and 4 kN/m^2, respectively, for dead and live loads; additional 3.5 kN/m^2 are assumed to consider medical equipment and permanent non-structural weights in laboratories and operating rooms (yellow areas according to the hazard color code introduced in Fig.6), 2 kN/m^2 otherwise. Furthermore, in areas susceptible to overcrowding (green code according to Fig.6) we combine vertical permanents with 60% of live loads. In order to explore the dynamic response of reference hospital prototypes, we perform nonlinear time history analyses (NLTHAs), symbolizing an efficient technique to evaluate global and local seismic performances. In detail, we develop inelastic force-based fiber element models through the open source platform OpenSees [24], efficient in predict distributed plasticity and geometric nonlinearities in a classical corotational transformation framework: the plastic propagation in key structural elements is simulated through the bilinear stress-strain relationship by Menegotto-Pinto [25]. Gusset plate connection is specified in Fig. 10, along with the main modeling assumptions. Structures are subjected to a set of 10 natural records [26], scaled in displacement to match the design response spectrum defined by EC8. For additional information on the fiber-based modeling the reader may refer to [27].

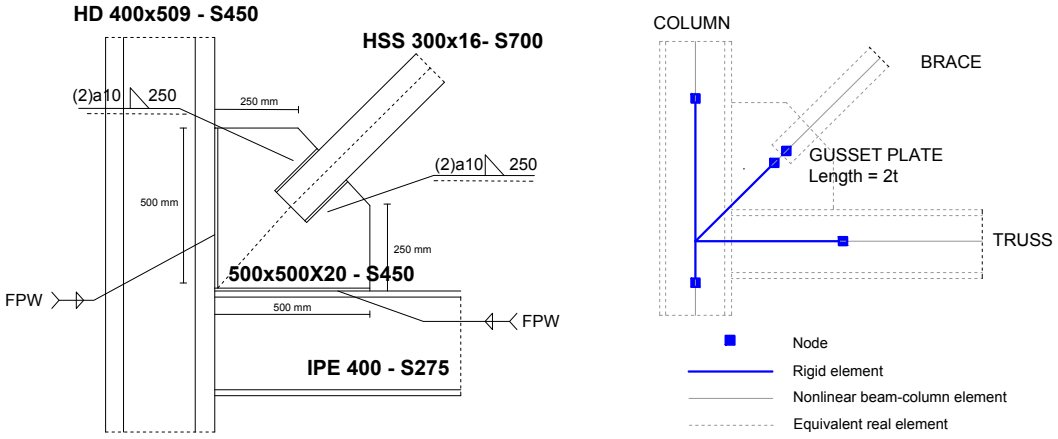

Figure 10: Designed gusset-plate connection with modeling assumptions.

3.2 SMA device equivalent 1D model reduction

Finite element approaches acquire efficiency when the computational cost decreases; however, model veracity tends to be deeply sensitive to the numerical simplifications [28]. By contrast, particularized three-dimensional simulations may become excessively onerous in terms of computational time [29]. According to [30], we calibrate equivalent mono-dimensional links capable to extensively describe the dynamic response of the SMA damper, legitimized by the need in developing predictive models that reduce the demand of expensive experimental tests. Fig. 11 depicts the 3D global model and the schematic of the mono-dimensional spring model, achieved by calibrating and combining non-linear links that individually represent one out of six lumped plasticity constitutive curve.

The proposed scheme is flexible and adaptable to secondary floor system geometry changes and mass variability. As a result, input parameters are deduced by means of iterative numerical calibration of Section 2.2.

4 RESULTS AND COMPARISONS

This work explores the employment of shape-memory alloy dampers in original floor isolation applications: specifically, we wish to study modifications in hospital structural dynamics associated to reductions in non-structural vulnerability. Therefore, in this section we highlight main results, provided in terms of global and local performance of four reference medical structures. Accordingly, each diagram display the comparison between NLTHA average response achieved by the retrofitted structure (SMA) and the correspondent bare moment resisting frame (MRF), along with individual earthquake (MRF EQs) acceleration result.

4.1 Global performance

We equip floor isolation systems in hospital frames in order to limit absolute displacement and acceleration demands on sensitive medical equipment. Thereafter, we wish to highlight the dual effect of FIS in limiting the maximum instantaneous seismic demand on such equipment: on one hand, reducing the structural response; on the other hand, decoupling non-structural elements.

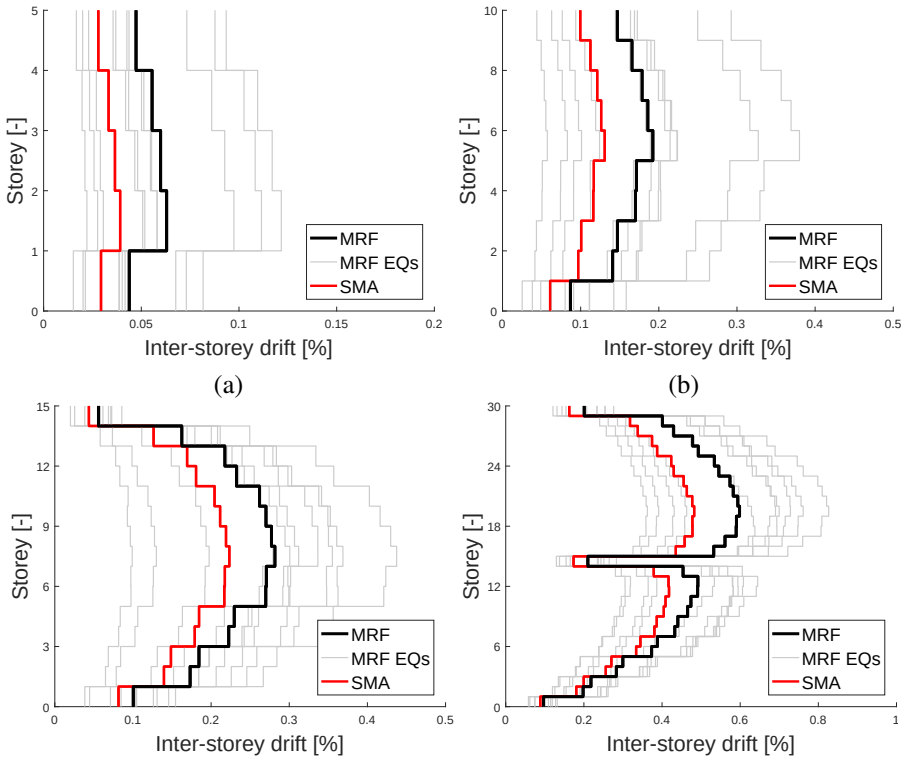

Figure 12: NLTHA Avg peak values for SMA & MRF, inter-storey drift.

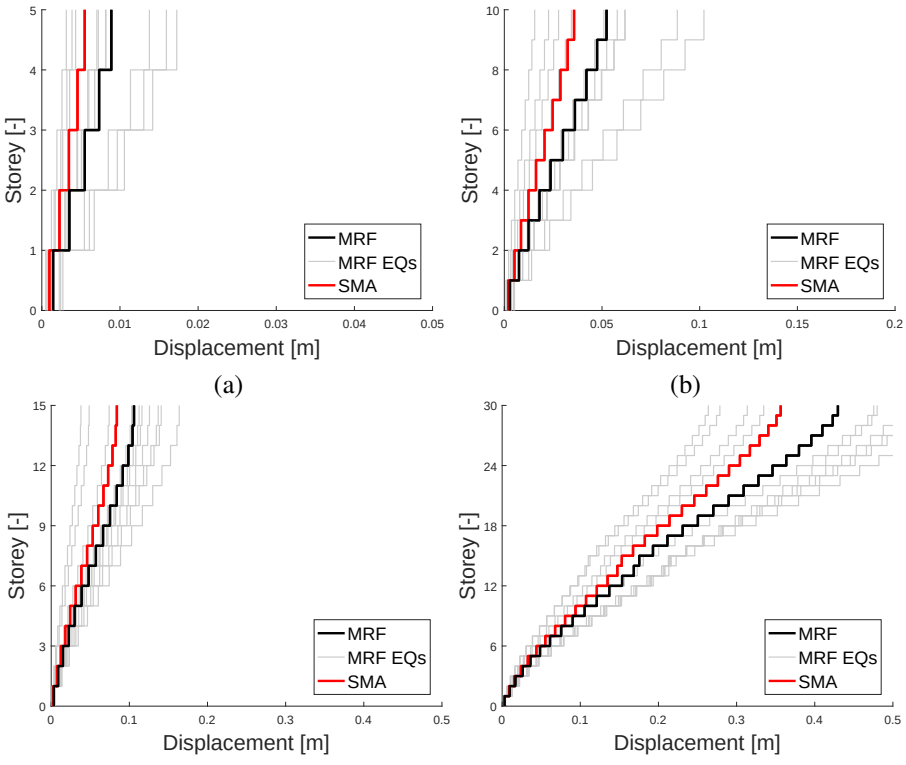

Figure 13: NLTHA Avg peak values for SMA & MRF, displacement.

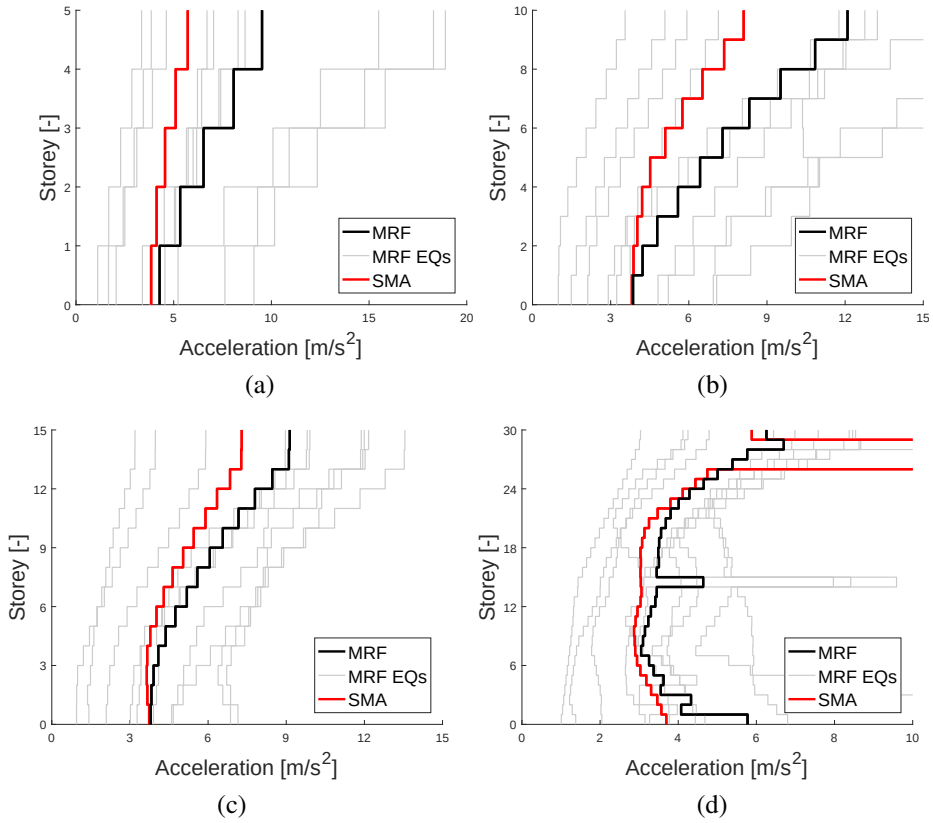

Figure 14: NLTHA Avg peak values for SMA & MRF, acceleration.

Accordingly, a series of nonlinear time history analyses are performed to validate the damper design: we analyze the global performance of four hospital frames (introduced in Section 3.1) in terms of maximum inter-storey drift, peak displacement and acceleration peak profiles, together with their average values. Specifically, Fig. 12 compares inter-storey drifts in bare moment resisting frames and in SMA-based isolated structures. SMA-based results deviate from MRF average at approximately mid-height: the drift appears clearly reduced when the floor isolation system is considered, up to an attenuation of 37.77%, 31.84%, 20.70%, 18.23%, showing a inversely proportional trend along the height. These values remain under the threshold of 0.5% for deformation sensitive equipment [31, 32].

In Fig. 13 we summarize peak displacements: the response assumes a rough cantilevered shape with maximum values on top. The percentage attenuation is respectively 38.28%, 31.79%,

Performance	**5 Storey**		**10 Storey**		**15 Storey**		**30 Storey**	
	SMA	**MRF**	**SMA**	**MRF**	**SMA**	**MRF**	**SMA**	**MRF**
Inter-storey Drift [%]	0.039	0.054	0.13	0.17	0.22	0.27	0.42	0.50
Displacement [mm]	5.5	7.6	35.7	47.1	84.2	101.6	356.4	417.1
Acceleration [m/s^2]	5.72	8.00	8.10	11.77	7.29	8.76	5.54	5.88
Drift Attenuation [%]	**37.77**	-	31.84	-	20.70	-	18.23	-
Disp. Attenuation [%]	**38.28**	-	31.79	-	20.69	-	17.04	-
Accel. Attenuation [%]	**39.94**	-	32.98	-	20.20	-	6.09	-

Table 1: NLTHA Avg peak values for SMA & MRF, global performance.

20.69% and 17.04%, once again displaying more pronounced percentage attenuation in low-rise respect to medium-rise structures. Significant top accelerations are experienced in dynamic simulations, i.e. 0.82g, 1.10g, 0.89g and 0.60g, underlining the stiffest behavior of lower structures. Moreover, the performance survey suggest that floor isolation efficiently reduces absolute structural acceleration demands recorded at the base of acceleration sensitive equipment: results are illustrated in Fig. 14, where peak percentage attenuation of 39.94%, 32.98%, 20.20% and 6.09% are reached.

We wish to recall that global performance values (inter-storey drift, displacement and acceleration summarized in Tab. 1) are recorded at structural level. Therefore, these results suggest that the use of FIS is an efficient technique for protecting sensitive equipment, reducing the overall structural response. However, in a control strategy perspective, either passive or semi-active, non-structural demand can be limited even modulating the decoupling effects provided by FIS. In detail, equipment displacements and accelerations might be effectively damped by the isolation system, establishing a response modification factor that scales the structural global performance, obtaining the corresponding non-structural local demand [33, 34]. Qualitatively, in Fig. 15 we represent the isolation scheme with the correlated stress-strain response: accordingly, from such response it is possible to specify the stiffness and damping properties of the floor isolation system, evaluating the transmissible primary floor level demand.

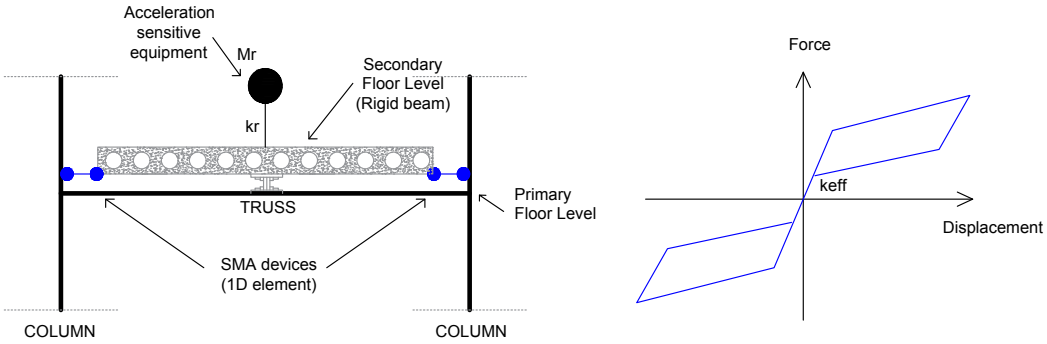

Figure 15: Secondary floor isolation scheme.

4.2 Local performance

According to Casagrande et al. [27], key components that support the seismic action in MRFs are internal core columns: the reader may refer to Fig. 16 where we display the extent of seismic overburden in such columns. Thereafter, the response in terms of axial load, bending and shear peak profiles in critical members is displayed. In addition, the percentage attenuation between MRF and SMA-based isolated structure results is illustrated.

Specifically, in Fig. 17 compressive peak forces of most critical columns are depicted, along with their average. The obtained peaks reach a maximum in 30-storey frame with 19823kN, reduced up to 9.33% with the SMA-based isolation. A proportional demand is obtained in 5, 10 and 15 storey buildings, as a consequence of the structural weight increment, where is demonstrated that modeling the structure without FIS conduce to overestimate NLTHAs results up to 32.22%. In Figs. 18-19 we summarize the seismic peak bending moments and shear forces in columns: diagrams depict a comparison between forces observed considering the moment resisting frame with the external floor isolation and the supporting structure alone: values are almost stable along the height, reaching a maximum at the base.

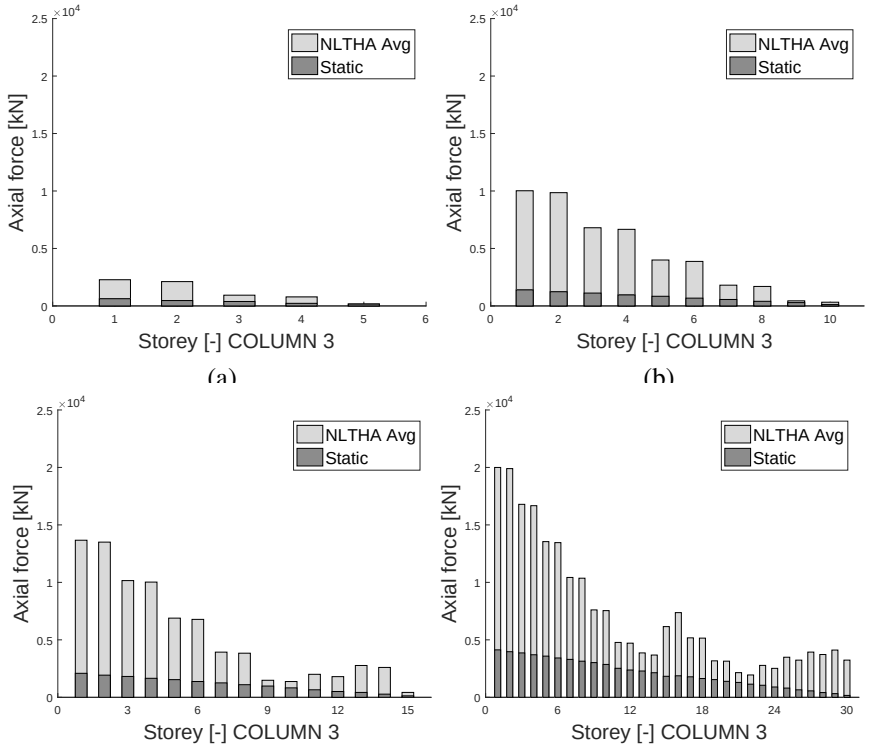

Figure 16: NLTHA Avg peak values and static loads, axial forces.

Table 2: NLTHA Avg peak values for SMA & MRF, local performance.

Even if similar percentage attenuation are achieved between bending moments and shear forces, a larger mismatch is determined for the 5-storey structure, up to approximately 32%. This discrepancy reflects that particular care has to be paid in evaluating the earthquake-induced demand, expressly during the design phase of low rise structures with FIS. Results are summarized in Tab.2, where peak responses are collected together with their percentage attenuation.

5 CONCLUSIONS

The work presented investigates on some critical challenges of interest for the seismic isolation of hospitals. Initially, shape-memory alloy devices have been explored, experimentally and numerically, to be adopted as a novel isolation device. Afterwards, we have focused on the advantageous features related to floor isolation systems (FISs) when equipped in multistory medical structures exposed to nonlinear time history analyses. Finally, analogies and contrasts between SMA-based floor isolated structures and traditional moment resisting frames have been discussed. The main conclusions may be summarized as follows.

Shape-memory alloy floor isolation systems:

- suggest attenuation in inter-storey drifts, displacements and accelerations, up to 40%, 38% and 37%, respectively. As a result, SMA-based dampers globally decrease seismic demand on non-structural contents;
- reveal a beneficial increment in energy dissipation capacity, resulting in local force attenuation (up to 32% in columns, the most seismically overloaded element);
- may be designed to remain elastic, locally decoupling accelerations and displacements directed to non-structural elements;
- result to be more effective in low-rise frames (5-storey). Dampers also decrease the structural period when increasing the structural eight.
- reasonably boost the reliability of sensitive equipment located in secondary floor systems;
- may be adopted in existing buildings as a retrofitting technique.

Additional applications under assessment, compatible with this results, regard either extending the survey to other damper typologies or deeply investigating the thermo-mechanically coupled SMA device response.

Abstract

The seismic monitoring of buildings is important for two fundamental reasons:
- evaluate the possible dynamic behavior of these structures during earthquakes;
- gain experience on the general seismic behavior of the structures so that the experience and the database can be used in the future for design and analysis.
The results of previous efforts in seismic monitoring of the structures have facilitated the development of a database, which in turn was used in the creation of new formulas and reference values for the estimation of the fundamental periods of the structures and the percentage of critical damping from use during dynamic analyzes. The database is very well supplied with data on traditional buildings, but there is still not enough data for buildings isolated at the base. Some different structures with seismic base isolation have been monitored during recent strong earthquakes in Italy, namely Amatrice earthquake (2016/08/24, M_w=6.0) and Norcia earthquake (2016/10/30, M_w=6.5).
For the structure under examination, amplification phenomena have been noticed, up to about twice the accelerations on the superstructure, for very low energy value inputs. In these cases, however, it is noted that the amplified accelerations are extremely small, and very far from being able to damage the structure. Records from the ENEA permanent accelerometric network, installed on the structure under examination, and the tests carried out on the same isolators used for the qualification tests of the devices mounted below the analyzed structure, permit to describe the behavior of the isolators in terms of force and displacement defining two non-linear laws, derived from experimental data.

Keywords: Seismic isolation, monitoring.

1 INTRODUCTION

It's well known that seismic isolation of a structure in order to uncouple the ground motion from the one of the super-structure represents the better solution to prevent seismic damage to buildings, by introducing a disconnection in the structure which is then divided into two parts: the substructure, rigidly connected to the ground, and the superstructure.

Seismic isolation, instead of increasing the capacity of the structure, use RID's strategy, drastically reducing the energy transmitted from the ground to the building. The substructure, generally very rigid, has roughly the same acceleration of the ground and must be designed in elastic field, while the superstructure benefits from the increased deformability resulting from the introduction of isolating devices.

Typically, response spectra in terms of accelerations of most earthquakes have a strong amplification in the range 0.1÷ 0.8 sec, where the main vibration period of many traditional buildings stands. Assuming, for simplicity's sake, that the isolators have an elastic or comparable behaviour, the increase of deformability consequent to their installation brings the own period of the structural system (Substructure-isolating system-superstructure) in a zone of spectral lower acceleration. As a result, the earthquake-generated accelerations on the isolated structure are drastically lower than those produced in the fixed-base configuration, to such an extent that the structure can be easily designed to withstand violent earthquakes without suffering damage both in structural and in non-structural components. Of course, increase in period also produces an increase in displacement, but they are concentrated in the devices, where most of the energy of the earthquake is low-pass filtered and also, in part, dissipated.

From analysis of experimental data on isolated structures, performed in the present study, however, it has been noticed that for low acceleration values the system has vibration periods not suited to those of an isolated structure but closer to the ones of a fixed base traditional structure, as can be observed from recordings of low energy seismic events carried out by the authors in the structure under examination.

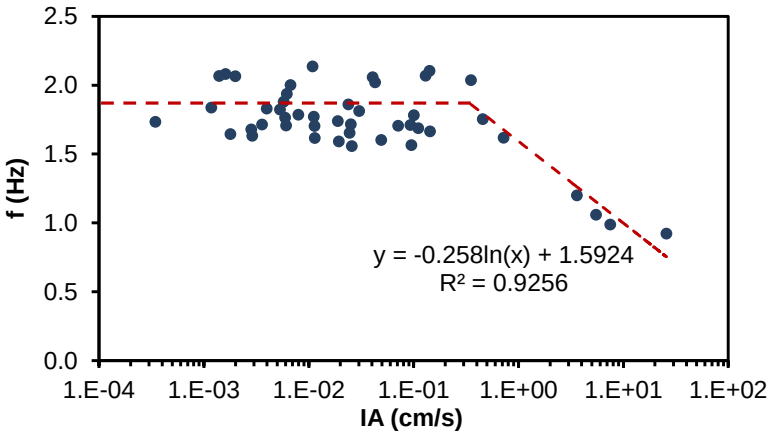

Figure 1 Base energy/frequencies

In figure 1 Arias intensity versus frequency of the system is shown. The Arias intensity (1) is an integral parameter, obtained as cumulative measure of seismic motion during its duration, and it represents the energy at the base of the structure.

$$\mathrm{IA} = \frac{\pi}{2g} \cdot \int_0^t a_x^2 + a_y^2 + a_z^2 \; dt \tag{1}$$

Corresponding to low input energies at the base of the structure the frequency of the structure itself leads to frequency values different from those for which it was designed (< 0.5 Hz). The reduction of the vibration period increases the acceleration more than the case of higher period.

These accelerations are higher than those evaluated in the design with consequent possible damage to the superstructure. In figure you can see the accelerations recorded on the structure at levels 0 (structure solidary to the ground), 1 (at the first level) and 2 (in correspondence of the cover).

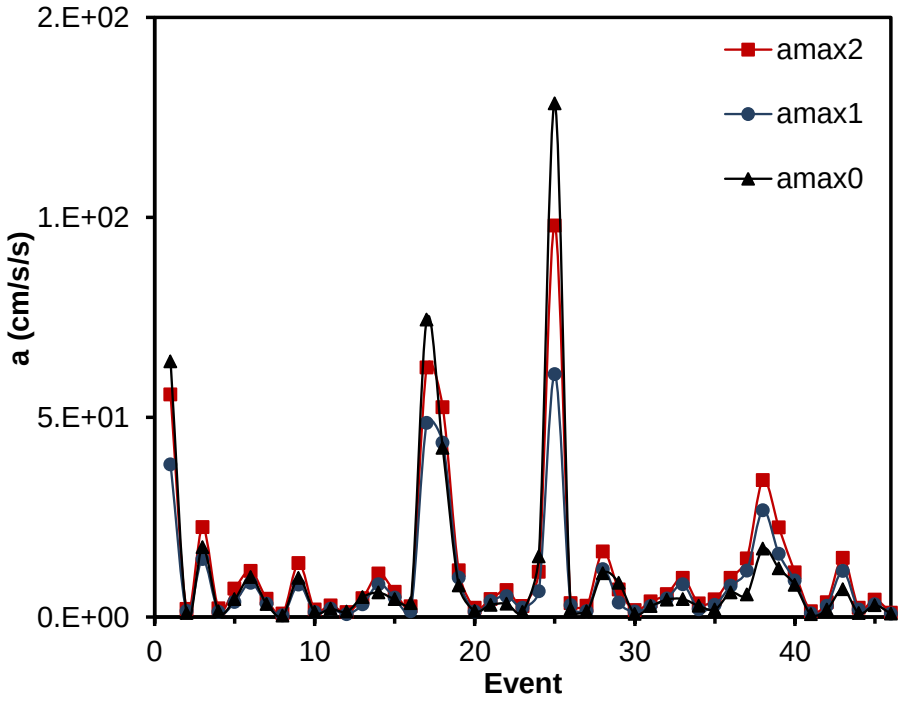

Figure 2 Base acceleration/number of events

For events characterized by small base acceleration there is an amplification of the acceleration from the bottom upwards. The two accelerations peaks are related respectively to the earthquake of Amatrice (2016/24/08, M_w 6.0) and Norcia (2016/30/10, M_w 6.5).

2 THE MONITORED STRUCTURE: REGIONAL CIVIL PROTECTION CENTER (UMBRIA REGION, ITALY)

The regional civil Protection center of the Umbria region (highlighted in red in the following figure), is located in Foligno. The Regional Center is composed by a building (operative room, analyzed in detail in the present work), a regional building (emergency and training) where the Special Office for Reconstruction (Umbria Region) is currently located and a third building (Amphitheatre – Plants building). The first two buildings are seismically isolated and the third is a traditional one.

The structure under consideration has three floors above ground and a basement for a total area of about 1532.25 m^2 above ground, and a volume equal to 8,630.00 m^3; it has built with reinforced concrete and it is seismically isolated by ten high damping elastomeric isolators, located externally on the ground floor. The isolated superstructure has a dome supported by ten half arches with cross section 40 x 120 cm, converging towards a single ring from which two concentric cylinders of 16 cm thickness are suspended, with a prestressed reinforced concrete. The size of the dome is 22 meters in height and 31 meters in diameter base.

Figure 3 Monitored isolated building location

Figure 4 Operation Room

The two concentric cylinders have inside a spiral staircase and an elevator placed inside the innermost cylinder. The outermost cylinder stops at the height of the first floor while the innermost cylinder continues to the basement, at a height of -4.00 m.

The foundation system consists of plinths based on four piles each, linked together by a reinforced concrete beam with cross section 80 x 80 cm, and by radial beams converging in a ring beam with cross section 50 x 140 cm and diameter, measured on the longitudinal axis, equal to 7.20 m inside which descends, until the basement, the elevator core. There is no

connection between the elevator core and the ring beam above.

Above the beams connecting the plinths there is a 20 cm thick slab which is also the base of the dome. The pedestrian access to the structure is possible by means of a slab (18 cm thick) that extends as a cantilever from the core elevator suspended on the base of the dome. There is no connection between the slab for pedestrian access and the base of the structure. Above the foundation plinths, there are 10 concrete supports on which the elastomeric isolation devices are fixed. The floors, with a radial dimension descending from the bottom towards the top of the structure, are supported by circular and radial beams that connect the half arches to the outer vertical cylinder.

Figure 5 base for pedestrian access

Figure 6 Support of an isolator during the construction and after its completion

In the innermost cylinder are also contained the plants of the various levels down to the basement level which remains separate, and therefore suspended, by the foundations.

The two upper floors are used as offices for the Civil protection operative room and more precisely:

- The first floor consists of 14 offices, in addition to the services and organized through furniture-equipped walls;

- The second floor is divided into a meeting room of about 145.50 m^2, a direction hall of about 60.00 m^2, a meeting hall of about 136.60 m^2 and services.
- The third floor contains other offices and a room for air conditioning systems.

3 SEISMIC ISOLATOR USED IN STRUCTURE

The isolators are elastomeric one with soft-type rubber, namely SI-S 1000/240. Their mechanical characteristics are shown in table 1.

.

Figure 7 SI-S 1000/240 elastomeric isolator installed

External diameter	D_g	1000	mm
Total high without anchorage plates	H	392	mm
Total high with anchorage plate	H	472	mm
Volume of the nucleus	Vol	307.88	dm^3
Total weight without anchorage	W	1834	kg
Maximum horizontal force with maximum seismic displacement	F_{xy}	497	kN
Maximum seismic uniform pression = V / A'	$\sigma_{v\,s,max}$	**3.98**	Mpa
Mimimun sesismic uniform pressure = V_{min} / A'	$\sigma_{v\,s,min}$	**0.00**	Mpa
Vertical stiffness = $E_c \cdot A' / t_e$	K_v	**2310**	kN/mm
Horizontal equivalent stiffness = $G_{din} \cdot A \cdot t_e$	K_e	**1.31**	kN/mm
Stiffness ratio	K_v/K_e	**1764**	

Table 1 – Mechanical properties of seismic isolators

Type test were performed for the determination and control of the isolator characteristics. In this case was evidenced an increasing cyclical stress at constant frequency and the corresponding strength of resistance of the isolator.
Being the test carried out on isolators of dimensions equal to half of the installed ones, their mechanical properties are then related to the real dimension of installed isolators.
The results reported the following values for the shear resistance module and damping:
the devices have an increase in the damping and in the shear stiffness modulus with the decrease in the deformation.
In particular, for a deformation values from 30% to 5%, there is a sharp increase in stiffness and damping values.

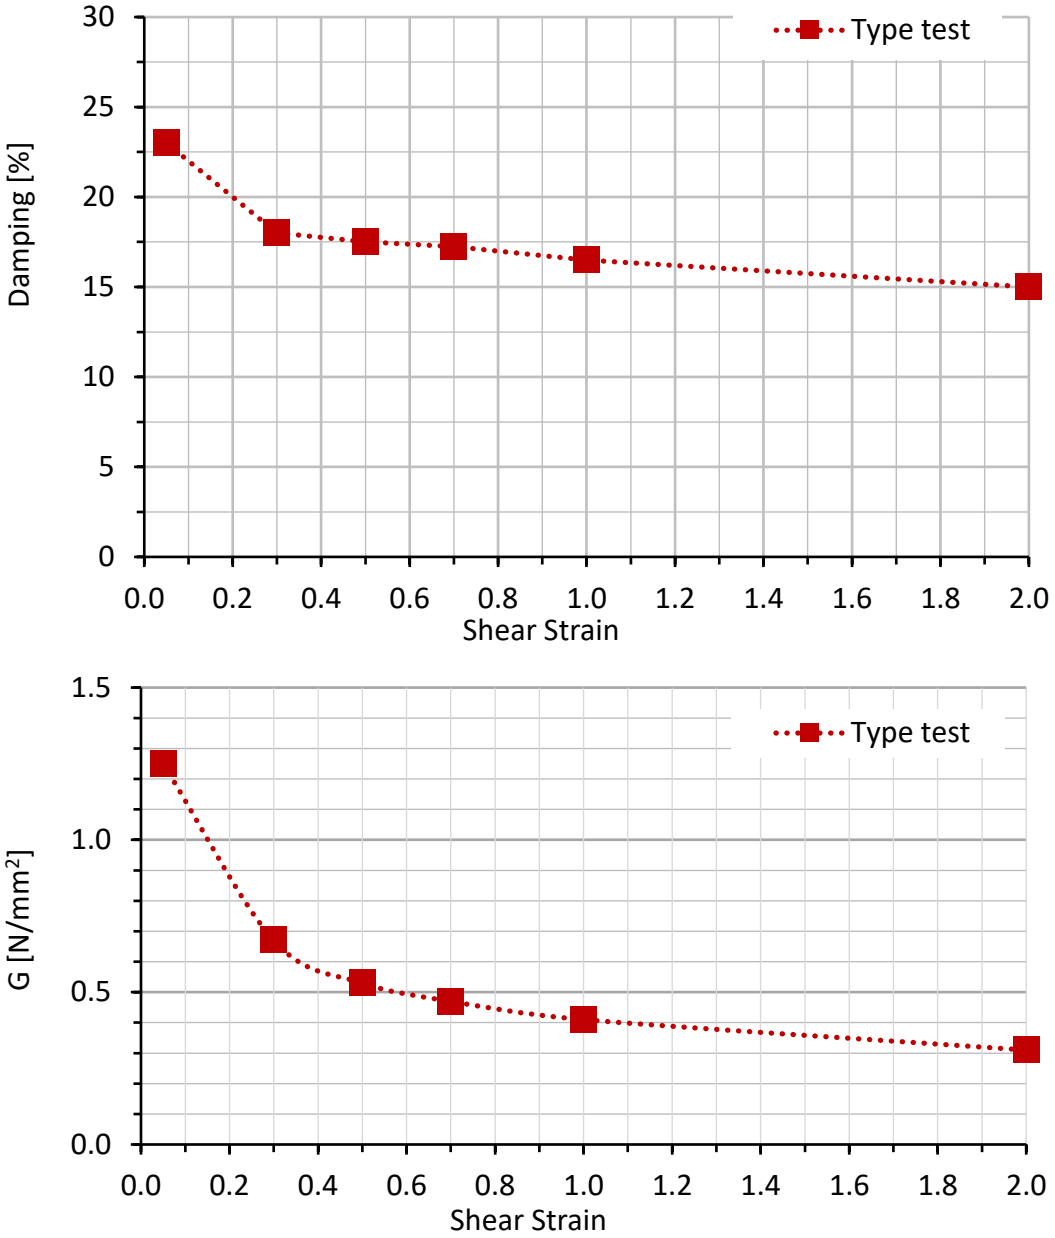

Figure 8 Increase in damping and shear modulus as strain varies.

4 MONITORING SYSTEM INSTALLED ON THE STRUCTURE

In order to monitor the structure a control equipment was installed in August 2014, with:
- Acquirer Kinemetrics K2, absolute timing using GPS, equipped with 24-bit A/D converter (digital analogue), 12 acquisition channels, 3 of which are connected to the sensor triad inside the acquirer and 9 connected to the external sensors;
- 12 Sensors Kinemetrics Type Force Balance with dynamic > 120 DB and full scale 2 G, three of which, orthogonal each other, are contained in the acquirer; the remaining 9 are arranged at the level of the first deck, below the floating floor (also used for cable passage).

The instrumentation is arranged on the structure according to the diagram shown in the following figure, where the arrows indicate direction and positive sensors and the point corresponds to the arrowhead, so the sensors for the channels A02, A04, A05 and A06 are vertical.

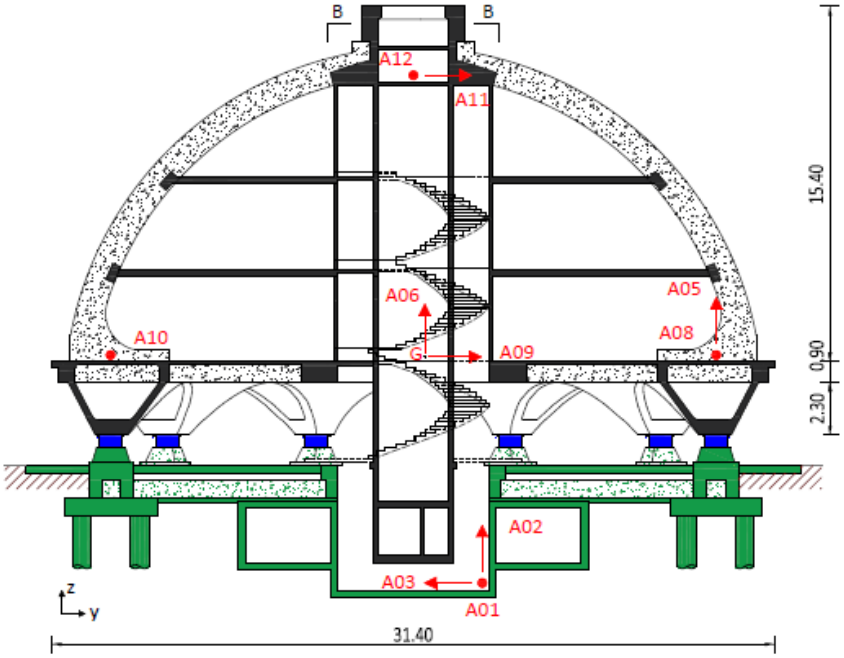

Figure 9 Provision in section of the instrument and fixes installed

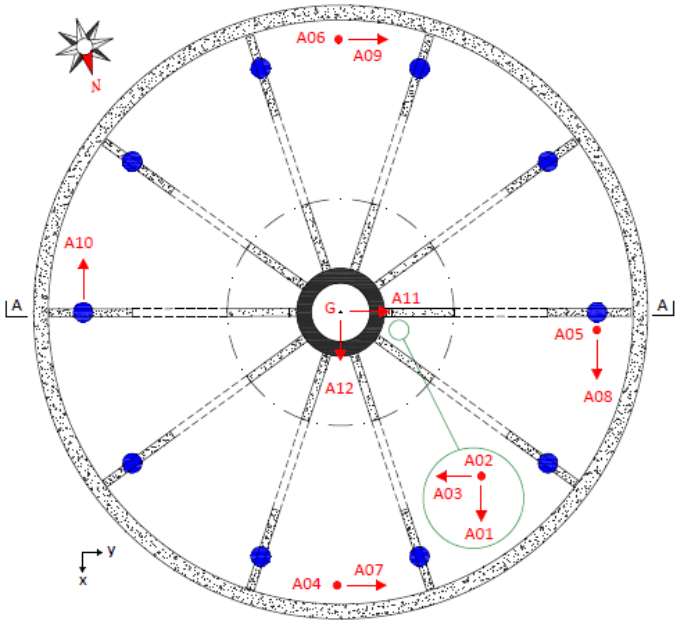

Figure 10 Plant arrangement of installed equipment

The sensor group inside the acquirer, A01, A02 and A03, is positioned below the isolating plane, in the lowest attainable position, near the terminal part of the Elevator Core. The positioning of sensors on the structure, the accelerometers relative to the channels from A04 to A10 are located to the share of the first deck, immediately above the isolating plane, while the sensors related to channels A11 and A12 are positioned at the top of the inner core.

The recognition of seismic events is carried out in STA/LTA logic (Short Term Average/Long Term average), i.e. by comparing the mean signal measured by each sensor, filtered pass 0.1-10 Hz band, in a short time interval, in this case 0.6 s, (STA) and the mean signal rate

detected by the same sensor, band pass filtered 0.1-10 Hz, in a long time interval, in this case 60 s, (LTA).

If the STA/LTA value exceeds a preset value, in this case equal to 4, the signal from the channel generates a trigger command.

Figure 11 GPS antenna and accelerometers (A04 and A07) below the floating floor.

Figure 12 Accelerometers A11 and A12 (internal core top)

To reduce the amount of recorded spurian signals, the trigger condition for a single channel is not sufficient to initiate the recording. To start the recording a determined number of sensors must exceed simultaneously trigger conditions. In this case were delegated to this task the sensors at the base and the two sensors at the top, clearly less affected by local disturbances. If 2 Sensors exceeds at the same time the trigger condition starts recording on a card of memory PCMCIA internal to the acquirer.

To record the entire signal the acquirer adds to the head of the recording the portion of the signal prior to the trigger for a preset duration, in this case 30 s. The detected event is considered terminated when the selected sensors check the condition of detrigger, i.e. the signal amplitudes fall below a preset value, in this case the 40% of the trigger conditions. Starting from the time of detrigger, the acquirer still continues the recording for a preset time, post event, in this case 30 s

5 EVENTS RECORDED BY THE ACCELEROMETRIC NETWORK

In table 2 are reported all the seismic event recordings with M_W or $M_L \geq 4.0$ relative to the seismic sequence started on August 24, 2016 (with an event of magnitude M_W= 6.0) until 31 December 2017. The table lists the events defined from time source, localization (latitude, longitude, depth), the source of the data (Seismic Bulletin INGV), the name of the registration (ENEA internal code for the archiving of events), the epicentral distance and eventual notes.

Table 2 – Recorded events

The process of processing the recorded data requires that the following processing be carried out for each registration:

- Transformation of data from acquirer units, Volt, into CM/s/s units.
- Calculation and graphical representation of Fourier transforms to select the filtering frequencies.
- Instrumental correction for the characteristics of each sensor, natural frequency and damping, with a change of direction for sensors related to ch03 and ch10, frequency filtering and dual integration to obtain the temporal histories corrected in terms of acceleration, speed and displacement.
- For magnitude ≥ 5.0, the calculation of the Accelerometric Group response spectra at the base was also carried out.
- For all recordings, the maximum, in acceleration and displacement, for each channel was

calculated, the maximum for each recording and the channel on which that value was obtained. The following table shows the maximum acceleration values expressed in cm/s^2.

Table 4 – Maximum displacement values of recorded events

The event which gave the major values had magnitude $M_w = 6.5$, registered under the name TP151 (Norcia earthquake PG of 30/10/2016). This event is discussed in more detail.
To test the finite element model implemented and the isolator characteristics, the event recordings were also used with the name TN015, relative to the effects of the event of 24/08/2016 with magnitude $M_w = 6.0$ with epicentral zone near Amatrice (RI).

5.1 RECORDING ANALYSIS TP151

The comparison between the temporal histories of the accelerations at the three monitored levels and for the two directions, shown below, shows that seismic actions are different in both directions.
Moving from the ground motion to the motion above the isolator plane, there is a decrease in the amplitude of the accelerations and a noticeable lowering of the frequency content.
Moving from the level above the isolator plane there is an increase in accelerations, which are still lower than those of the ground.
The dominant frequency appears to be still the same but it is evident, more in the direction of CH11, the presence of higher frequencies.

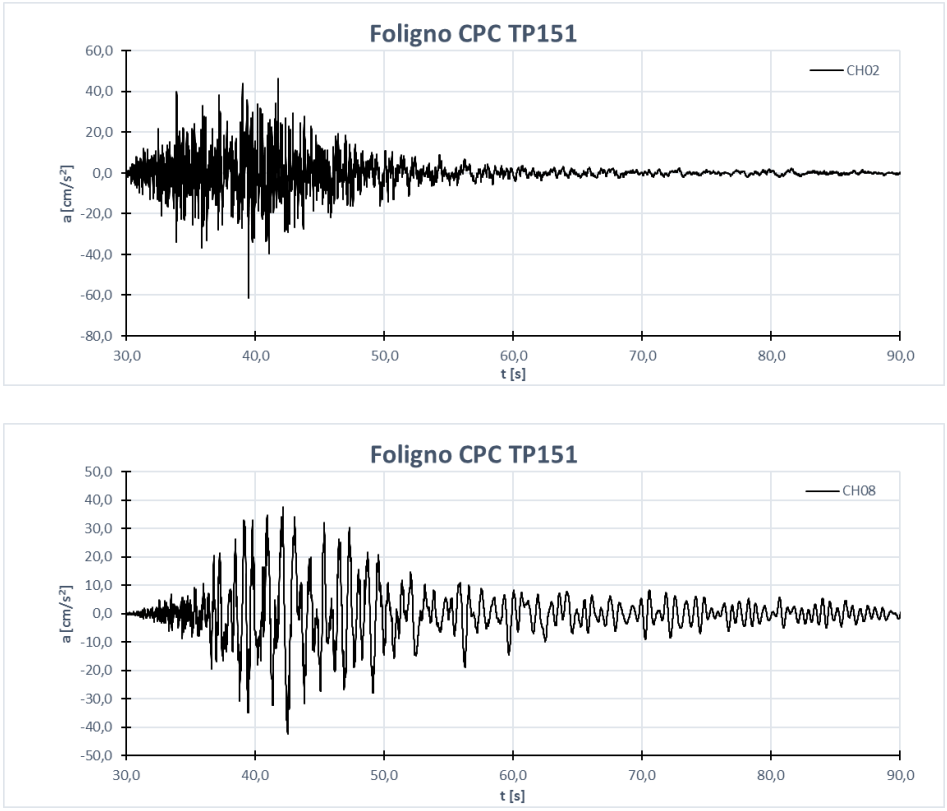

Figure 13 TP151 comparison of the time history signals

The analogous comparison between the Fourier spectra, shown below, shows that the frequency content in the two measuring points above the isolator plane, CH08 and CH12 in one Direction and CH07 and CH11 in the other direction, is substantially identical, for each direction, below 2 Hz. In the direction of Ch07 and Ch11 A significant frequency content is manifested between 7 and 9 Hz, even dominant for Ch11. Such frequency content is not justified in a structure with seismic isolation at the base.

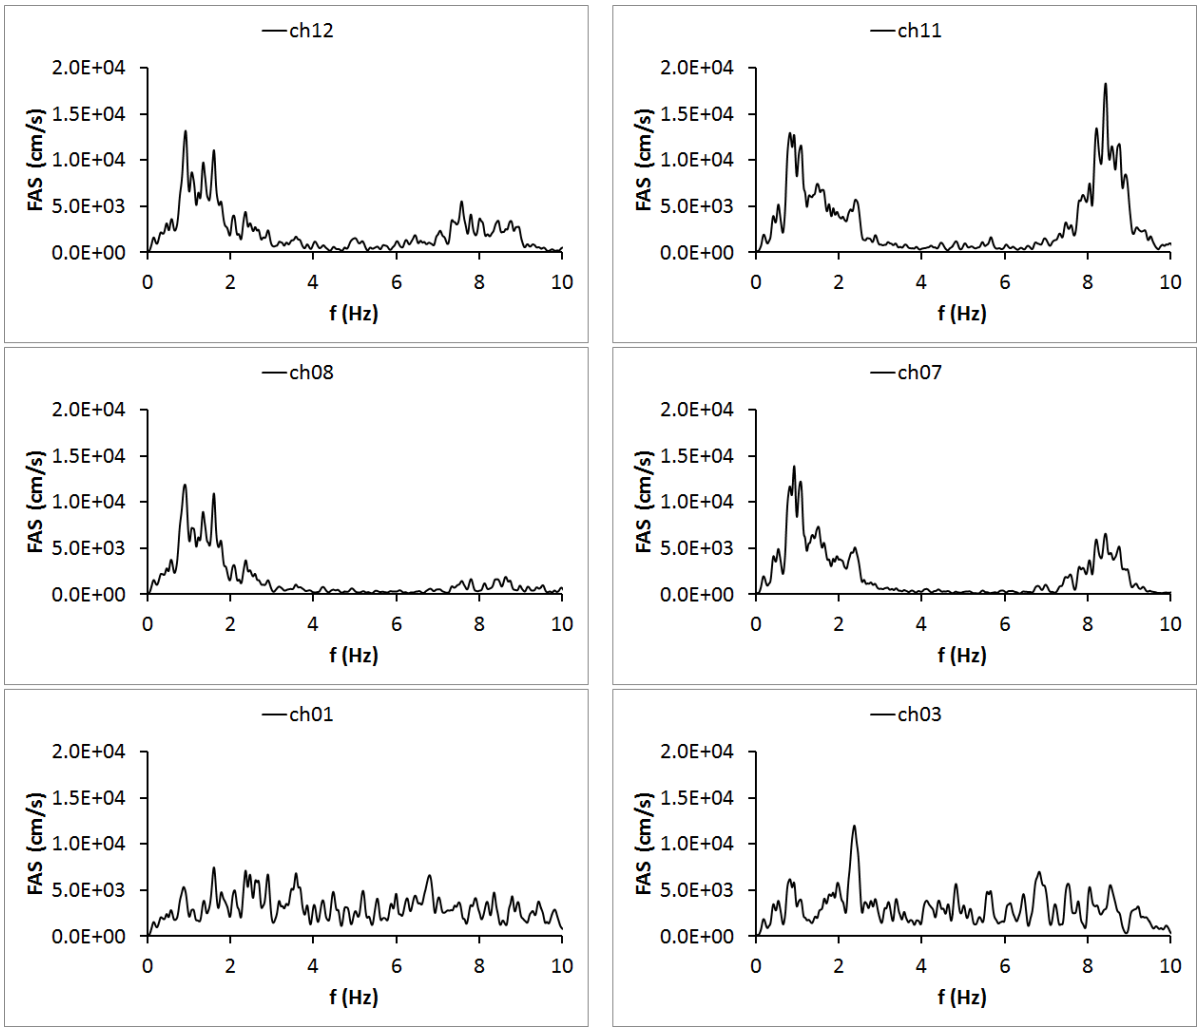

Figure 14 TP151 comparison of the Fourier spectra of accelerations

Cross-spectral analysis, Ch08 Ch12 and Ch07 Ch11, stresses that the motion of the structure above the isolator plane increases very little by proceeding upwards in the range in frequency less than 2 Hz, and it is also consistent and in phase.
This frequency range can be considered representative of the motion of the isolated structure.
The frequency content between 7 and 9 Hz has much greater amplitudes on the top of the structure and in the direction of Ch11, which decrease by going downwards; Consistency is high and the motion of the two points of measurement is in opposition to phase. It can be stressed that the motion at these frequencies is originated within the isolated superstructure.
To explain the presence of several frequency peaks in the recordings examined, a time-frequency analysis was carried out for the CH11 and CH12 channels. From these it is evident that the dominant frequency varies during the seismic action as it is expected for a structure with seismic isolation at the base [Bongiovanni et al, 2017].

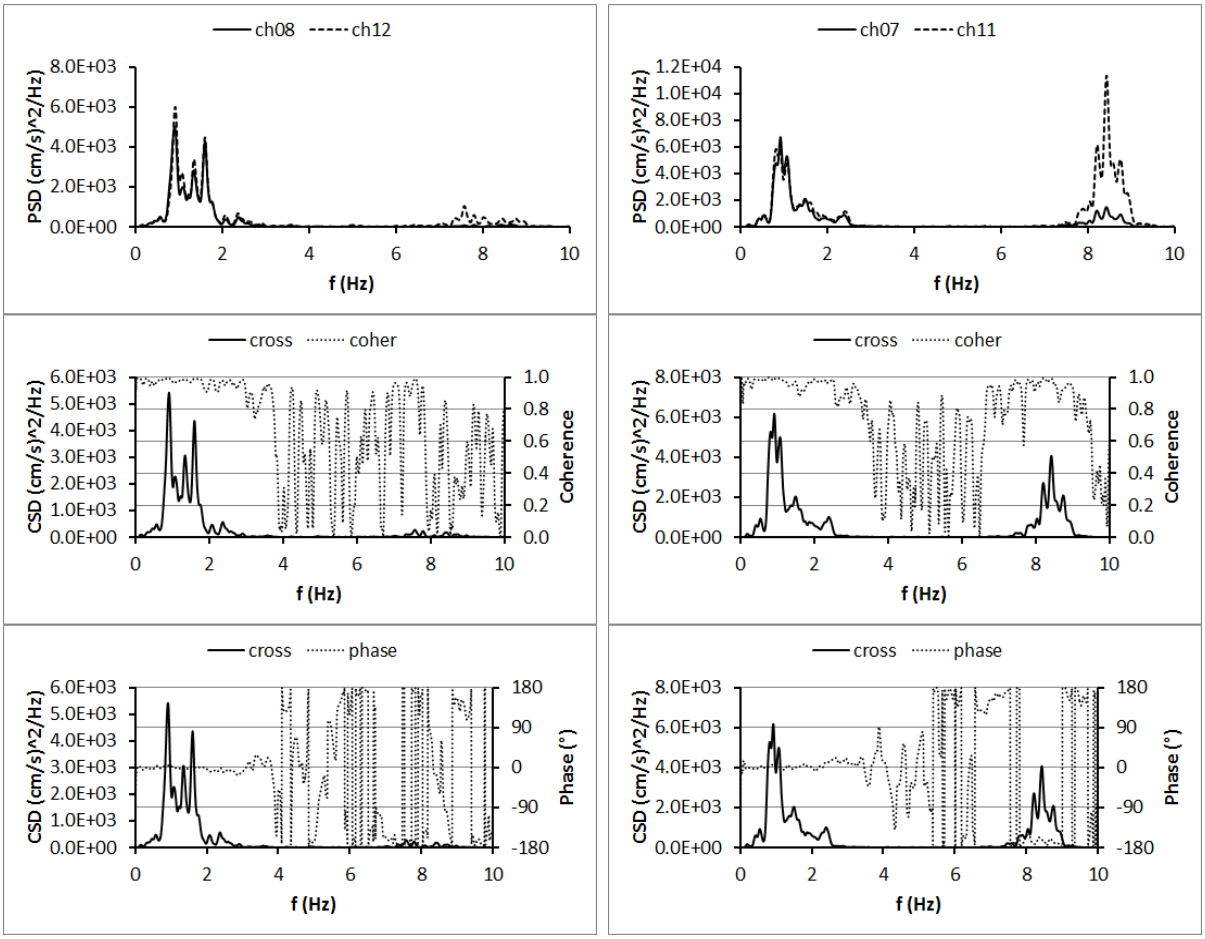

Figure 15 Cross-Spectral analysis

6 EXPERIMENTAL TEST ON SEISMIC ISOLATOR

In order to know the actual characteristics of the isolator for deformations less than 5% was performed a test on the same isolators used for the Type Test of the isolators mounted on the structure under examination using as input data the relative displacements between the isolated structure and the ground, deriving from the double integration of the accelerations recorded by the "CH03" accelerometer located at the base of structure under examination and integral to the ground and the barycentric displacement of the structure, calculated by mediating the movements deriving from the recordings of the accelerometers "CH07" and "CH09" placed in correspondence of the first scaffold, in diametrically position Opposite, just above the elastomeric isolators.

The registrations for the TP151 event were used for the test. The event TP151 is the recording, of the accelerometers installed on the structure, of the event of the day 30/10/2016 06:40:17 of magnitude Moment (M_w) of 6.5, with an epicenter at a distance of about 36 Km, near Norcia (PG).

The deformation of the test is below 5% deformation of the isolator, the height of the isolator is equal to 240 mm. The results obtained from the test are shown in the following shift-force graph: in blue are shown the curves related to the test with the time history obtained from the data of the event TP151 while the curves in red are those related to a test of type Type-Test for a 5% deformation performed at constant frequency.

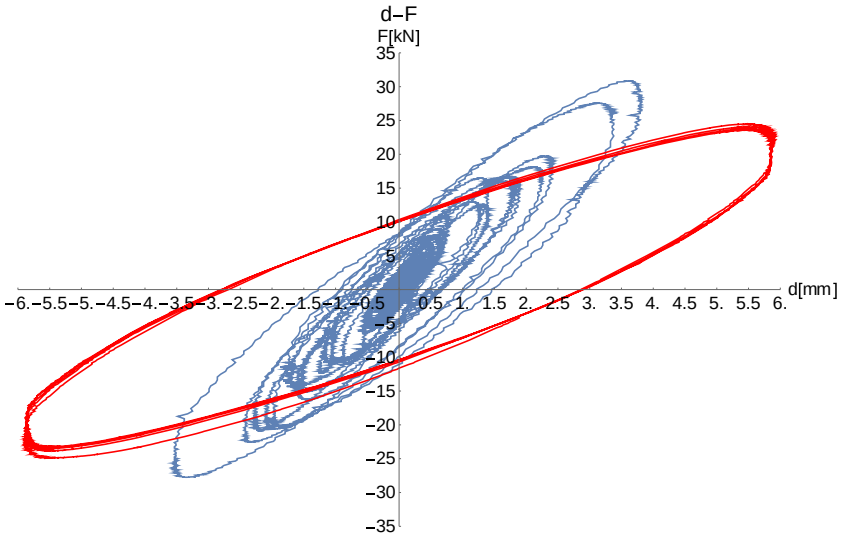

Figure 16 curves related to the test with the time history obtained from the data of the event TP151

7 NON LINEAR ANALYSIS WITH TIME HISTORIES AND NON LINEAR ISOLATOR'S LAW

To verify the validity of the law and analyze the structure's behaviour, a finite element model of the structure was analyzed. The definition of a model that is correct and adherent to that which is the real situation is a very delicate operation, also through the model you have to recreate, in the most likely way possible, the condition of load present on the structure at the time when you are verified recorded events.

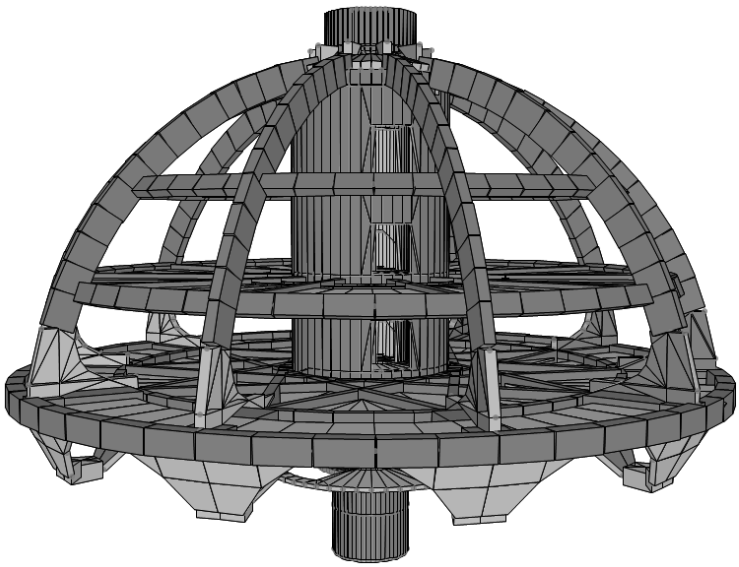

Figure 17 Set view of the Realized calculation model

On the model a nonlinear dynamic modal analysis was conducted, (considering the first 50 modes of vibration of the structure), using as input the time histories in terms of acceleration recorded directly on the structure, optimizing the model by inserting the nonlinear behavior of the elastomeric isolator by using the laws obtained from the results of the test, performed on the isolator based on the displacement recordings of the TP151 event.

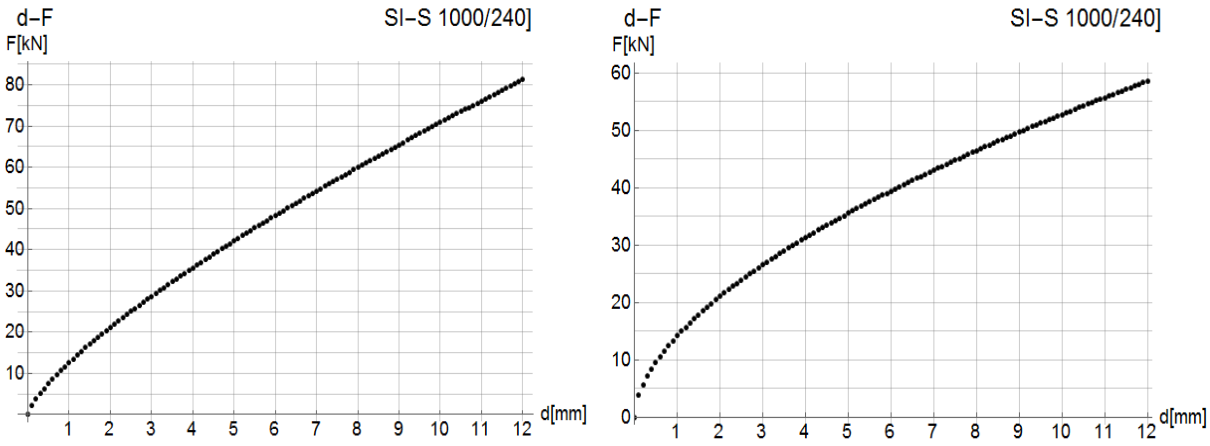

Figure 18 Local and global isolator non linear curves

The laws have been appropriately discretized in a number of points with step 1 mm and have been inserted inside the model. The results were then extrapolated in terms of displacement and acceleration of the same points where the accelerometers used in the monitoring are compared with the actual recordings of accelerations and displacement recorded during the analyzed events.

It is known that the orientation of the accelerometers with respect to the structure is the same even within the model and in particular:

- The CH03 is oriented in the model according to the X-axis
- The CH01 is oriented in the model according to the Y-axis
- The CH02 is oriented in the model according to the Z-axis

The results of the various analyses carried out below are shown below. It was inserted into the finite element model, as input data, the time history of the recording at the base, in terms of acceleration, of the event named TP151.

The input accelerations are as follows:

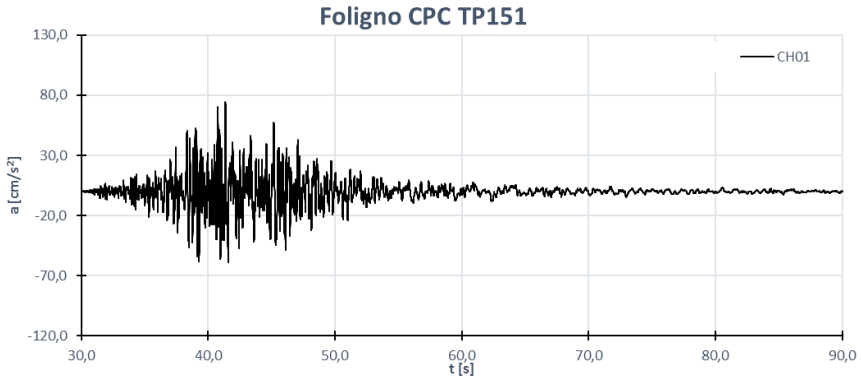

Figure 19 Nonlinear input acceleration TP151 CH01

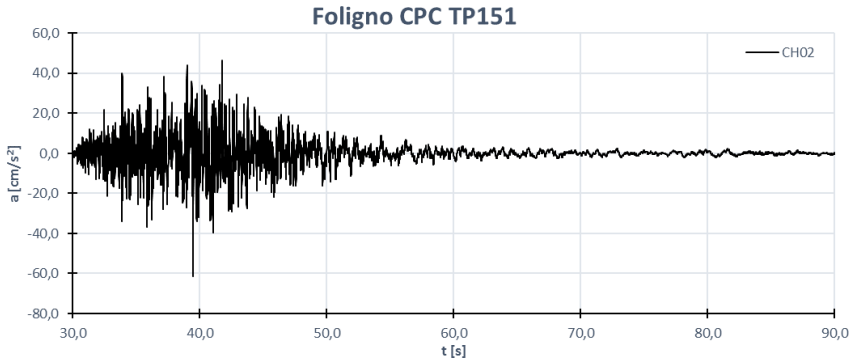

Figure 20 Nonlinear input acceleration TP151 CH02

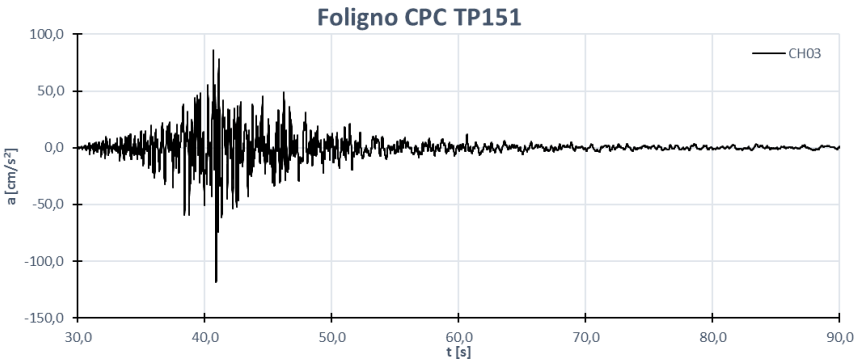

Figure 21 Nonlinear input acceleration TP151 CH03

Some of the results obtained for displacement, compared with the recordings made on the structure, are shown below:

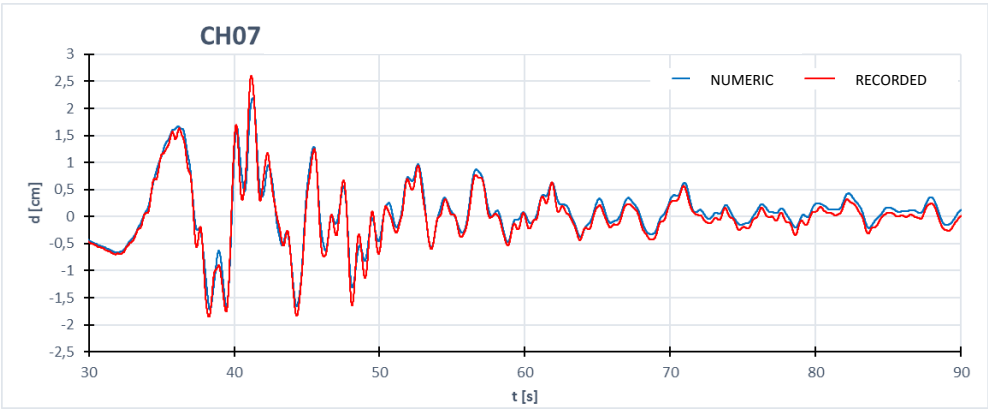

Figure 22 Comparison of recorded displacement with numeric ones

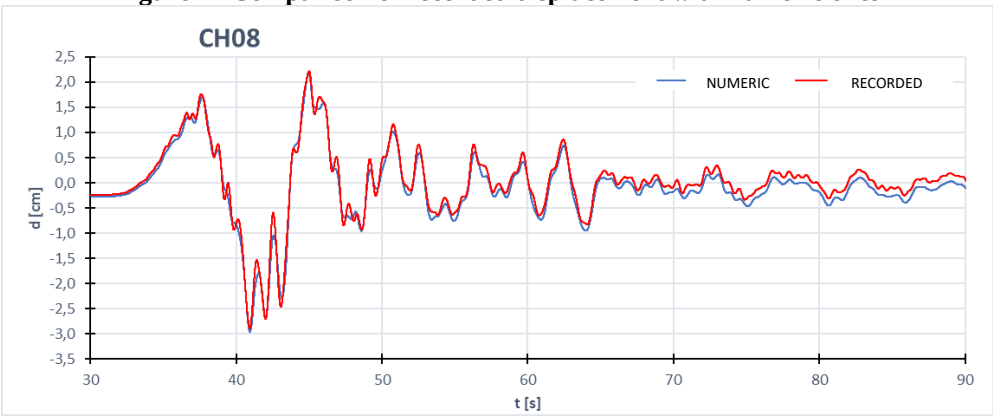

Figure 23 Comparison of recorded displacement with numeric ones

Below are the results in terms of acceleration compared, as in the previous case, with the recordings made on the structure:

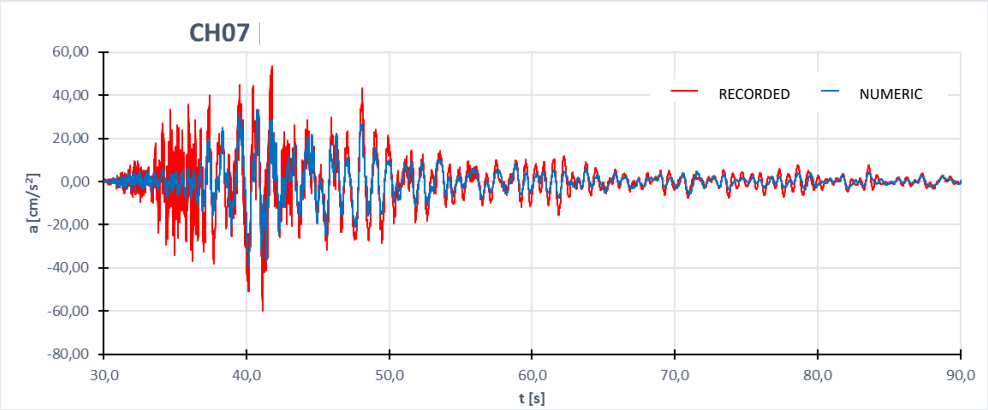

Figure 24 Comparison of recorded acceleration with numeric ones

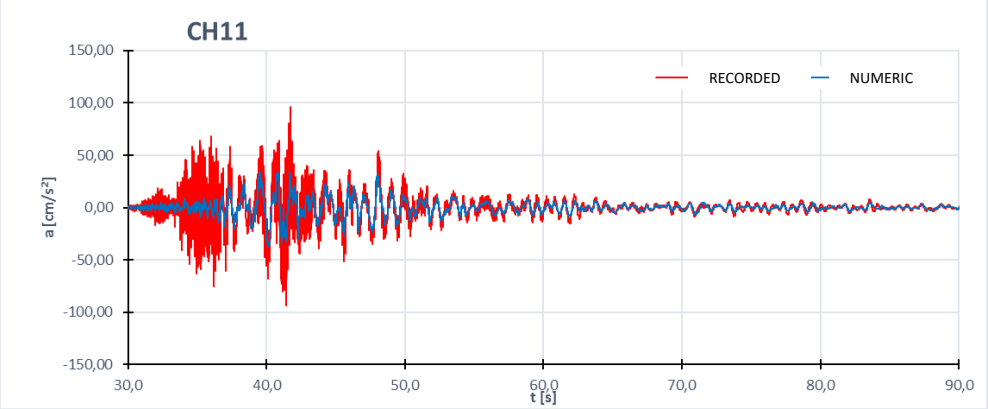

Figure 25 Comparison of recorded acceleration with numeric ones

It can be seen that the model, equipped with the non-linear law of the isolator, has an excellent correspondence with the recorded data. Note above all how, in acceleration terms, present a frequency, in most cases, almost equal to the one recorded, but with slightly lower values. As in the previous case, even the model implemented with the global law turns out to have a good correspondence with the recordings.

It is worthwhile to point out the effectiveness of the model and the implementation of the latter with the non-linear characteristics of the isolator, to conduct a linear analysis using the equivalent horizontal stiffness of isolators K_e = 1.31 KN/mm, by using acceleration recordings of the TP151 event in the three main directions as input data.

The results on two channels at the level of the first deck, one in the X-direction (CH09) and another in the Y-direction (CH08) are shown below, both as displacement and as acceleration.

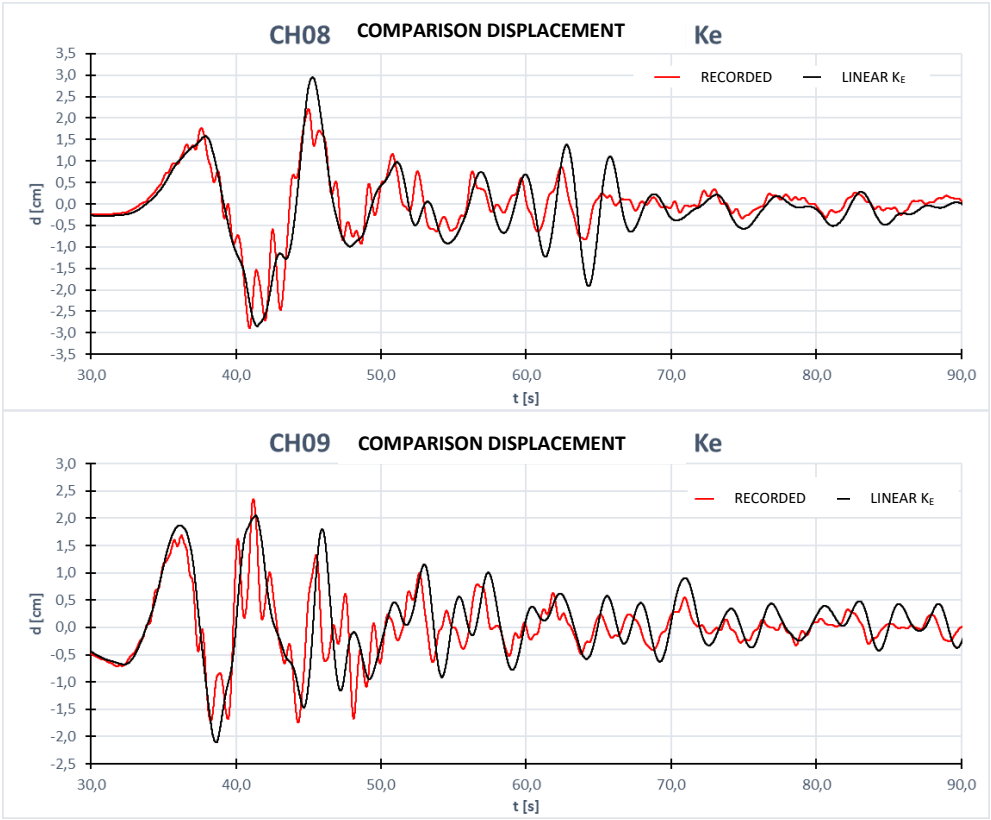

Figure 26 Comparison of displacement between linear analysis and recorded data

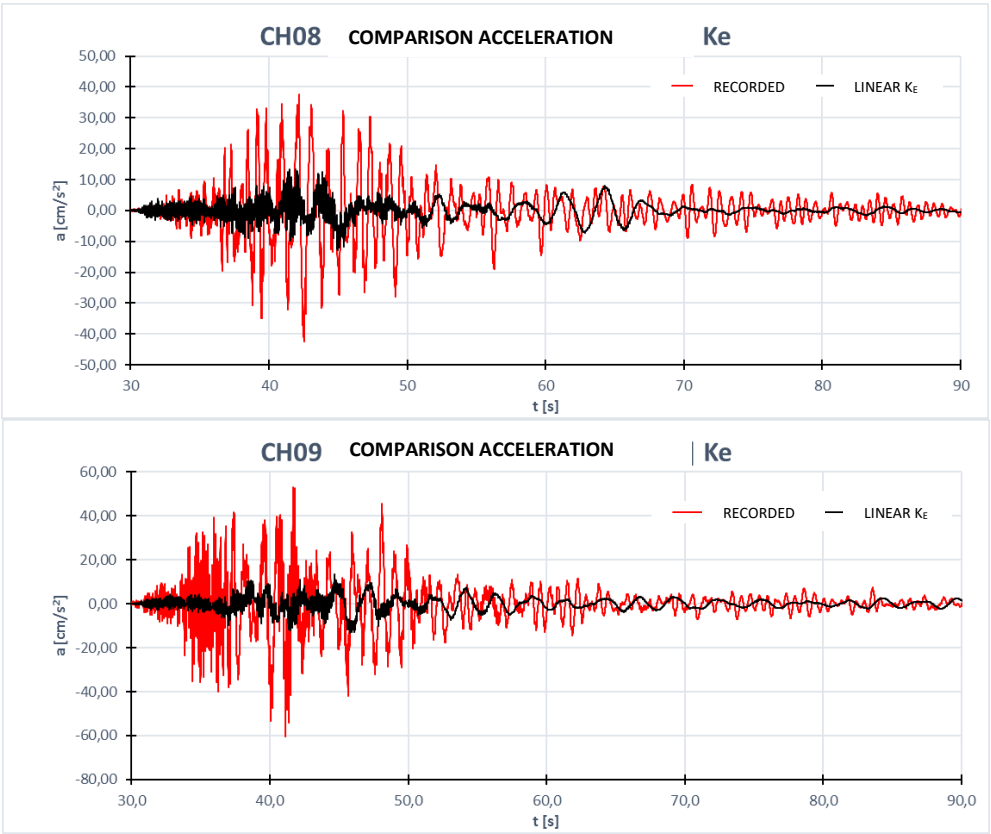

Figure 27 Comparison of acceleration between linear analysis and recorded data

The differences between linear analysis with K_e and the analysis with the non-linear characteristics of the isolator are very pronounced. As for displacement, the highest recorded peak is more or less reached, but the trend does not align with the movements recorded. As for acceleration, however, it is noticed that the numerical solution obtained by conducting the linear analysis heavily underestimates the acceleration of the structure, and the time sequence of the accelerations does not respect the recorded law.
There is also a preponderant frequency within the accelerations of the model, certainly different from that recorded on the actual structure.

8 CONCLUSIONS

For the structure under examination, amplification phenomena have been noticed, up to about twice the acceleration on the superstructure, for very low input energy values. In these cases, however, it is noticed that the amplified accelerations are extremely small entities, and very far from damaging the structure. This is because, as seen, isolation systems with high-damping elastomeric isolators have a stiffness that increases as the deformation decreases (as required to avoid disturbing vibrations even under weak horizontal loads such as wind, etc.), with nonlinear performance; in the case of low-energy seismic input, the insulation system is more rigid even than the equivalent horizontal stiffness K_e.
However, the isolation devices have been shown to function also in low stress conditions, with frequencies higher than those for which they were designed, but still carrying out a filter function, in fact, less than extremely low acceleration, there is no upward acceleration amplification.
It can be observed, from the recordings, the presence of a content in frequency different from that of the fixed-base structure. At the same time, it was also verified that the stresses on the structure were less than those of design.
Thanks to the recordings of ENEA permanent accelerometric network, installed on the test structure, and to the tests carried out on the same isolators used for the qualification, it was possible to describe the behavior of isolators in terms of force and displacement by defining two non-linear laws, derived from experimental data. Obviously, while the first local law seems more suitable to describe the behavior of the isolator for deformations below 5%, the global law is also suitable for uses that for which the isolator is deformed even beyond that value.
The developed finite element model is very faithful to what is the actual behavior of the structure and, accompanied by the non-linear laws of the isolator, has a very good feedback with the experimental measurements of seismic events. Consider however that we cannot expect that the results of the numerical model match exactly to the recording ones, because, of course, there are many other variables to consider in a calculation model.
By performing linear analyses using the equivalent horizontal stiffness modulus and comparing the results with the recordings of low energy seismic events, there are major differences, especially in terms of accelerations that are considerably undervalued (75% less than about).
The differences between the two analyses decrease in the case of higher-entity input accelerations, as could be seen by repeating the linear analysis in the case of the Norcia earthquake, considering the structure in the epicentral zone. The structure also lends itself very well to this type of analysis, both for a geometric factor being essentially a half sphere, and because it appears to have an extremely rigid superstructure.

Abstract

This paper describes a preliminary experimental study aimed at investigating the force-displacement behavior of Variable Friction base isolation Systems (VFSs). Full-scale VFS prototypes were tested under cyclic loading conditions. A series of dynamic hybrid tests simulating the response of a full-scale single-story structure isolated with VFS devices and subjected to ground motions with different intensities, was also performed.
The results of the experiments are presented and used to provide some preliminary validation of a previously developed numerical model. Overall, the results of the experiments were in good agreement with the predictions provided by the numerical analyses.

Keywords: Friction Pendulum bearing, variable friction, bearing testing, dynamic hybrid testing.

1 INTRODUCTION

In the context of developing innovative, high-performance seismic isolation devices, Variable Friction base isolation Systems (VFSs) were recently proposed [1, 2]. Preliminary numerical studies have indicated that VFSs may represent promising solutions because of their capability of providing adaptive response for increasing displacement demands [3].

This paper summarizes some recent experimental results achieved as part of an ongoing international research project focused on the development of VFSs. Two full-scale Variable Friction prototypes were tested under cyclic loading conditions, considering realistic values of vertical load and peak horizontal velocities. Numerical simulations were run alongside the experiments to verify the reliability of a recently proposed numerical model [4] implemented in *OpenSees* [5].

A series of dynamic hybrid tests of a full-scale single-story structure isolated with a VFS prototype was also performed. A natural ground motion time history was used as the acceleration input and different acceleration scale factors were implemented throughout the tests. Horizontal displacement, forces, velocities, and accelerations of the base isolation system and of the numerical superstructure were evaluated throughout the tests.

The results of the bearing tests were generally in good agreement with the numerical predictions. However, during the experiments some technological limitations emerged pertaining to the properties of the low friction materials employed to fabricate the Variable Friction prototypes that were addressed over the course of the project. The first refurbished VFS prototype (tested in the context of the dynamic hybrid simulations) showed improved force-displacement behavior, and its response matched well with the numerical predictions.

2 EXPERIMENTAL SETUP AND OVERVIEW

Full-scale experiments were conducted on a total of three VFS prototypes at the experimental facilities of EUCENTRE (European Centre for Training and Research in Earthquake Engineering) in Pavia (Italy) using the Bearing Tester System (BTS) shown in Figure 1. The Bearing Tester System, consists of a prestressed reinforced concrete frame equipped with a series of servohydraulic actuators providing five degrees of freedom to the testing device: vertical load, horizontal load and rotation about three axes (roll, pitch and jaw). Both horizontal and vertical actuators can be used to apply static and dynamic loads, with a peak velocity of 2,200 mm/s in the horizontal direction and 250mm/s in the vertical direction. The Vertical load capacity of the Bearing Testing System is 50,000 kN (40,000 kN static and ± 10,000 kN dynamic) with displacement capacity of ±60 mm, and the Horizontal load capacity is 2,100 kN, with ±580 mm of displacement. The BTS controller is a real-time, digital controller that provides PID closed loop control with a delta-p feedback signal, which enables the BTS to perform real-time dynamic hybrid testing. More details can be found in [6].

2.1 Test specimens

Each prototype bearing consisted of a conventional single friction pendulum system with rigid slider, but the concave stainless steel sliding surface was treated using different polishing techniques to achieve spatially varying frictional properties. Namely, two areas with different surface roughness were obtained: an inner circular area of radius r_1 with smooth surface finish ("low friction area"), and an outer ring area of external radius r_2 with rough finish ("high friction area"). A schematic drawing and a plan view of the full-scale prototype VFS bearing are shown in Figure 2.

(a) (b)

Figure 1. (a) The EUCENTRE BTS; (b) Elevation view of the bearing test setup.

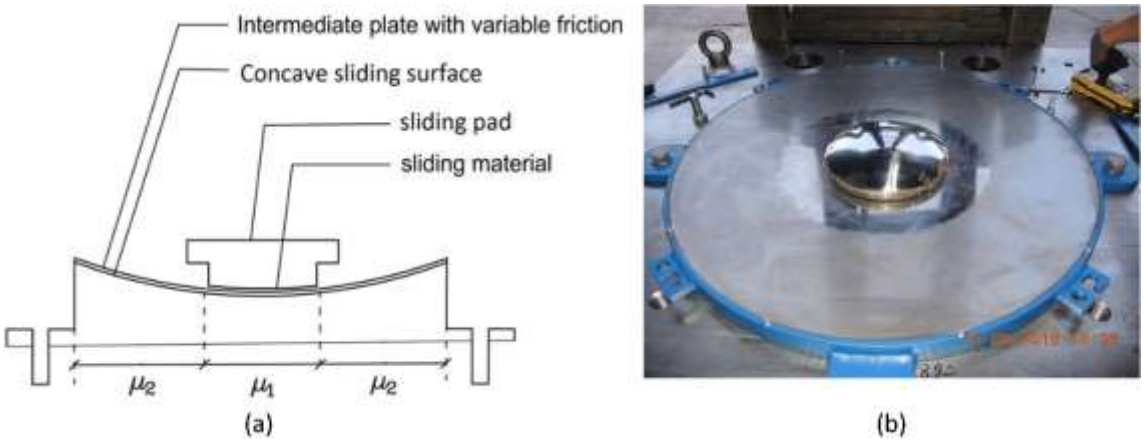

Figure 2. (a) Schematic drawing of a two-ring VFS bearing; (b) Plan view of the concave sliding surface and the slider of the prototype VFS bearing.

The main properties of the tested VFS prototypes are summarized in Table 1. The parameters reported in the table represent the radius of the sliding pad (r_0), the radius of the low friction area (r_1), the external radius of the high friction area (r_2), the coefficient of friction between the sliding pad and the low friction area (μ_1), the coefficient of friction between the sliding pad and the high friction area (μ_2), and the radius of curvature of the sliding surface (R).

Group #	Prototype #	r_0 (m)	r_1 (m)	r_2 (m)	μ_1 (%)	μ_2 (%)	R
1	1	0.125	0.150	0.450	7.0	9.2	4.5
	2	0.125	0.225	0.450	7.0	9.2	4.5
2	1	0.100	0.150	0.450	7.0	9.2	4.5

Table 1. Properties of the tested VFS prototypes

The dynamic coefficients of friction between the sliding pad and the sliding surface were equal to 7.0% and 9.2% for the smooth and the rough areas, respectively. These values were

provided by the bearing manufacturer and were confirmed through friction characterization tests performed in the laboratory.

2.2 Testing program

Following the friction characterization tests, the Group 1 VFS prototypes were subjected to the testing program recommended by the European standard EN 15129 [7]. The program comprised a series of unidirectional harmonic displacement histories, with different displacement amplitudes and frequencies. A list of the tests conducted is summarized in Table 2. For brevity, only the results pertaining to one test for each prototype are presented in this paper. For the presented tests, the displacement amplitude of the harmonic motion was 0.3 m, and the peak velocities were 500 mm/sec and 200 mm/sec, for prototype 1 and prototype 2, respectively.

Test name	Ampl. [m]	Max.vel. [m/s]	load shape	Vert.load [kN]	cycles
Frictional resistance	±0.006	0.0001	triangle	2000	1
Service	±0.060	0.005	sine	2000	20
Benchmark	±0.300	0.050	sine	2000	3
Dynamic 1	±0.075	0.500	sine	2000	3
Dynamic 2	±0.150	0.500	sine	2000	3
Dynamic 3	±0.300	0.500	sine	2000	3
Seismic	±0.300	0.500	sine	1000	3
Seismic	±0.300	0.500	sine	2500	3
Bidirectional	±0.300	0.500	sine	2000	3
Property verification	±0.300	0.500	sine	2000	3

Table 2. Testing program on Group 1 VFS prototypes

The Group 2 prototype was subjected to hybrid tests, simulating the response of a single-story structure isolated with VFS devices. The stiffness of the superstructure (treated as a linear-elastic single-degree of freedom system) was selected to achieve a natural period of vibration of 0.4 seconds, considering a seismic weight of 785 kN. A 785 kN vertical load was also adopted in the hybrid simulations, which resulted in an average pressure on the sliding pad of 25 MPa. The tests were performed under the application of recorded ground motions with different intensities. The peak velocity recorded during these tests reported was approximately 950 mm/sec.

3 PRELIMINARY RESULTS AND NUMERICAL COMPARISON

3.1 Bearing testing

The horizontal force-displacement response characterizing the Group 1 VFS prototypes [8] is reported in Figure 3. The black lines represent the first-cycle response, while the grey lines refer to the second and third loading cycles. It can be seen that the first-cycle response differs quite significantly from that of the subsequent cycles [9]. In particular, the effects of the variable friction are clearly visible in the first cycle, but they tend to disappear in later loops. This undesirable discrepancy was ascribed to the creation of a transfer film of the sliding material on the mating surface, which smoothed the surface and made the sliding behavior more uniform over the two areas with different roughness [10]. At the current stage, this still represents a major challenge and one of the main constraints limiting the possible frictional properties that

can be selected for a VFS. Additionally, μ_1 and μ_2 are only marginally different in their initial values, thus the variability of the friction coefficient is low.

However, Figure 3 shows that the numerical predictions based on the VFS model developed by [4] and briefly described in Section 3.3, successfully predicts the first-cycle experimental response of the systems tested.

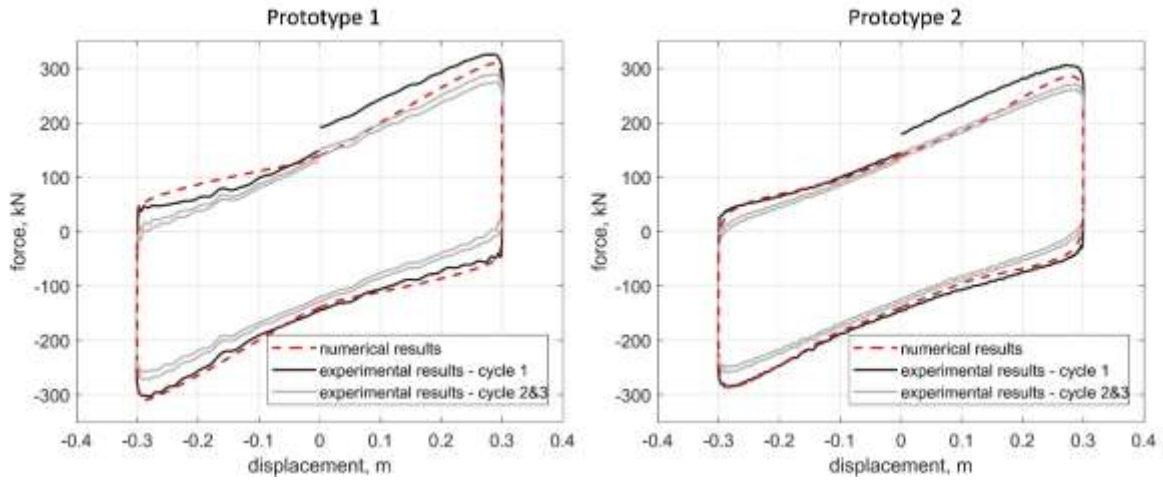

Figure 3. Comparison between the hysteretic curves from numerical model and experimental data for Group 1 VFS prototypes

3.2 Dynamic hybrid testing

The horizontal force-displacement responses characterizing the Group 2 VFS prototype undergoing a realistic ground motion in the context of hybrid testing is shown in Figure 4. The black dashed lines represent the experimental results, while the grey solid lines represent the numerical predictions. The numerical predictions are in good agreement with the experimental results. These preliminary results are very promising and suggest that the numerical element developed by the Authors [4] can adequately capture the mechanics of the VFSs tested, in the context of time history analyses. However, more experimental evidence is needed (including 3-D testing) before definitive conclusions can be drawn.

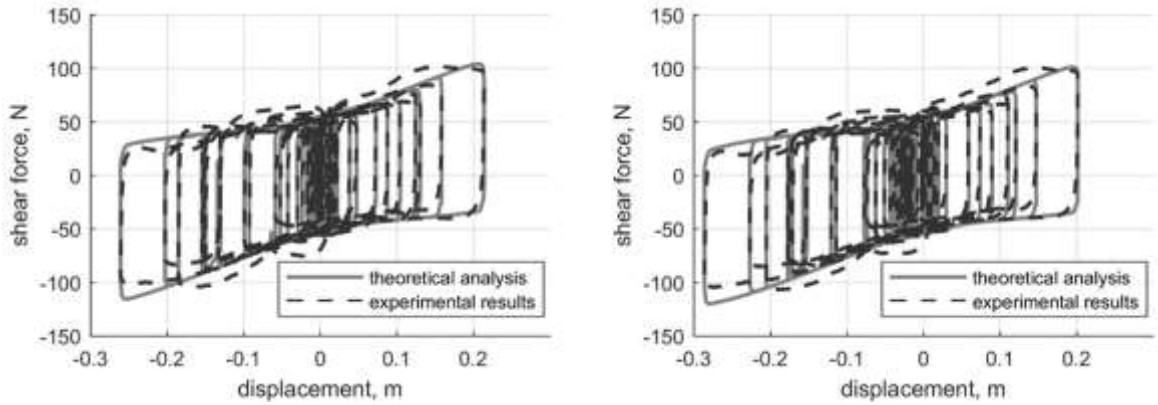

Figure 4. Comparison between the hysteretic curves from numerical model and experimental data for Group 2 VFS prototype.

3.3 Numerical modeling

The response predictions outlined in Figure 3 and Figure 4 were obtained using a newly developed numerical model that was recently implemented in *OpenSees* [4]. The numerical model was developed based on the bi-directional plasticity model proposed by [11]. The model accounts for complex aspects of the bearing response, such as simultaneous influence of velocity and axial force on the coefficient of friction, and vertical-horizontal coupling effect due to the geometric radius of curvature.

For this project, a velocity-dependent friction model was used while pressure-dependency was neglected because the axial force remained approximately constant throughout the tests. The relationship between the sliding velocity and the coefficient of friction can be described by the exponential function proposed in [12], shown in Equation 1:

$$\mu(v) = \mu_{max} \times (1 - (1 - \tilde{\mu}_v)e^{-av}) \quad (1)$$

where μ(v) represents the coefficient of friction as a function of sliding velocity, μ_{max} is the coefficient of friction at high sliding velocity, $\tilde{\mu}_v$ is the ratio between the coefficient of friction at slow sliding velocity and μ_{max}, and a is a constant describing the transition rate from low to high sliding velocity regimes. Past studies suggest that the value of the coefficient a can range from 20 sec/m to over 100 sec/m depending on the sliding material utilized [13]. In the present work, it was found that setting a equal to 20 sec/m provided the best match between the experimental results and the numerical predictions. The parameter $\tilde{\mu}_v$ was set equal to 0.5, which is consistent with past studies [14].

4 CONCLUSIONS AND FUTURE WORK

Preliminary experimental evaluation of three VFS prototypes are presented in this paper. The experimental results from both the bearing testing and the dynamic hybrid testing were in good agreement with the analytical results obtained using the numerical model presented in [4].

The results of the dynamic hybrid testing collected with respect to the behavior of the superstructure will be analyzed and discussed as part of future work. Further 2-D and 3-D bearing tests will also be performed in the future to further validate and improve the numerical model.

In addition, the development of more suitable sliding materials to be used in the context of implementing high-performance VFSs, persists as one of the key objectives of the ongoing research investigation.

Abstract

The usage of seismic protective devices in the electric power industry for improving seismic resiliency of high-voltage substation equipment is increasing worldwide. Friction or viscous dampers represent the most common devices used by the industry to reduce the seismic demand by incorporating supplemental damping and thus increasing the equivalent viscous damping of the system. Although viscous dampers are quite common in the building industry, an application of friction dampers is gaining traction as an efficient alternative for seismic protection of high-voltage equipment. To study the performance, friction dampers of a typical design were selected and studied. This paper summarizes the results of a research program that includes full-scale component testing and numerical modelling. A special test setup was created for component testing of the damper. A numerical model of a substation high-voltage equipment protected by friction dampers was developed. A numerical model of the damper was calibrated based on the results of component tests. A newly developed time history matched to the IEEE693 spectrum for use in seismic qualification of substation equipment by analysis/testing were used as excitation input motion. In the research program, the performance of the well-calibrated numerical model of the seismically protected high-voltage equipment was analyzed. The conclusions of the study demonstrate the benefits of using dampers for improving seismic resiliency of the electric power grid.

1 INTRODUCTION

The usage of seismic protective devices in the electric power industry for improving seismic resiliency of high-voltage substation equipment is increasing worldwide. Friction or viscous dampers represent the most common devices used by the industry to reduce the seismic demand by incorporating supplemental damping and thus increasing the equivalent viscous damping of the system. Although viscous dampers are quite common in the building industry, an application of friction dampers is gaining traction as an efficient alternative for seismic protection of high-voltage equipment. To study the performance, friction dampers of a typical design were selected and studied. This paper summarizes the results of a research program that includes full-scale component testing and numerical modelling.

2 COMPONENT TESTING OF FRICTION DAMPERS

A special test setup was created for component testing of the dampers. It is presented in Figure 1 and it simulates loading of the friction damper in a typical installation when the damper is installed as a stiffness and damping component of the anchoring system. Friction dampers from Ringfeder [1] were used in this study. Since the friction dampers work in compression only, there are several ways of using friction dampers as seismic protection devices. For example, if only one friction damper is used in the so-called single-acting configuration, the force will be developed in compression only as presented in the left side image of Figure 2. In this case, another spring or friction damper needs to be used on the tension side that corresponds to positive force and displacement to resist tension forces. When there is one damper on each side of the loading point, they create the so-called double-acting configuration. The force versus displacement curve is more symmetric in this case as presented in the right image of Figure 2.

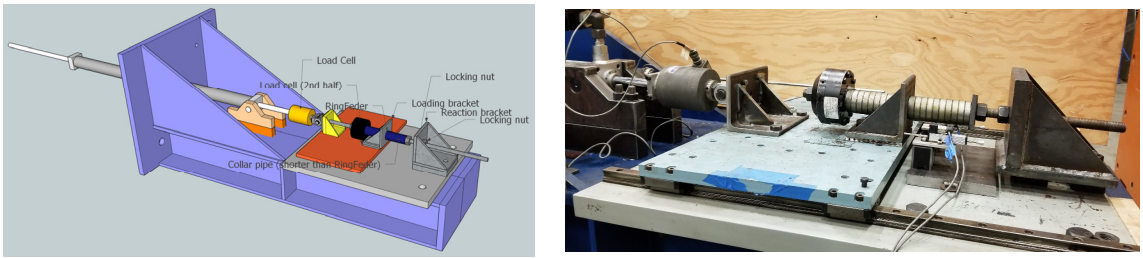

Figure 1: Component testing setup for Ringfeder friction dampers: sketch (left) and photo (right).

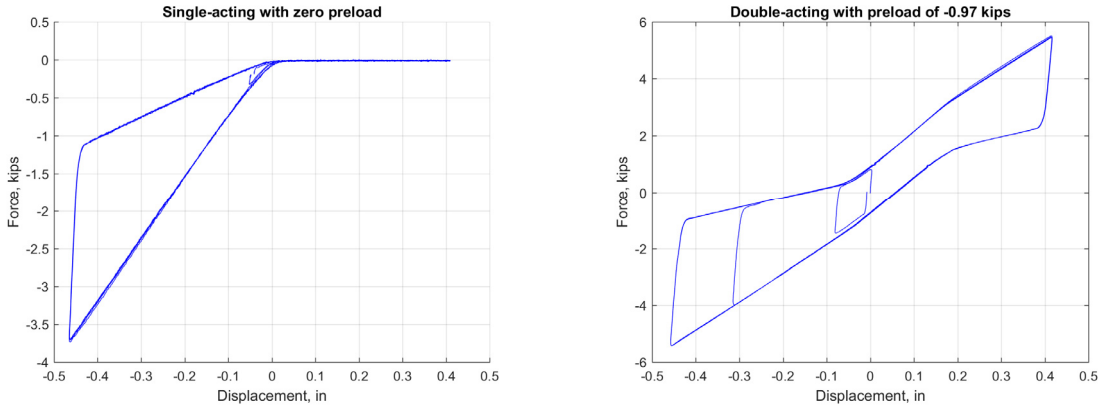

Figure 2: Force vs. displacement from component testing in single-acting with no preload (left) and double-acting with preload (right) configurations.

In addition to that, one of the dampers can be preloaded in compression, which is very common when the dampers are installed in a vertical configuration and the bottom damper is compressed under the dead weight of the equipment. The case with a preload of -0.97 kips is presented in the right image of Figure 2.

The dampers used in this study were installed in a double-acting configuration, when there is a dumper on each side of the loading point. The latter results in symmetric behavior in tension and compression. A testing protocol followed recommendations of the upcoming version of the IEEE693 document [3], which is presented in Figure 3 on the left. The displacement D_{PL} corresponds to the maximum displacement of the device to be achieved at High Performance Level [4]. A typical result for cyclic tests with increasing amplitude is presented in the right image of Figure 3.

It is worth noting, that for structural applications, the friction dampers are studied in many publications (see [2] as an example).

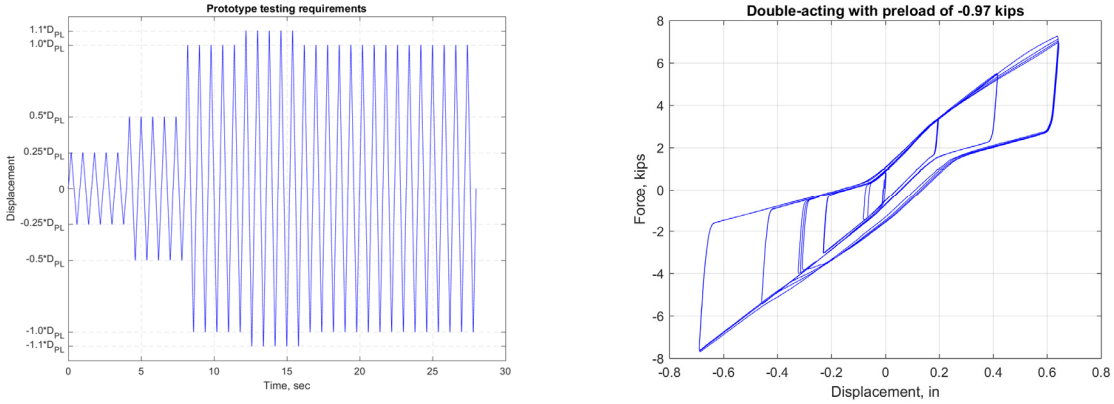

Figure 3: Component testing: protocol (left) and sample test results (right).

As presented in the left image of Figure 4, the equivalent viscous damping of the damper is estimated from a single cycle based on the well-known expression (see, for example, [5] – the graphical representation of which is shown in the right image of Figure 4):

$$\zeta_{eq} = E_D/E_{S0}/(4\pi), \tag{1}$$

where E_D is the energy dissipated over the cycle, E_{S0} is the strain energy, which is calculated from equivalent stiffness, k, and the cycle's amplitude, u_o:

$$E_{S0} = k u_o^2/2. \tag{2}$$

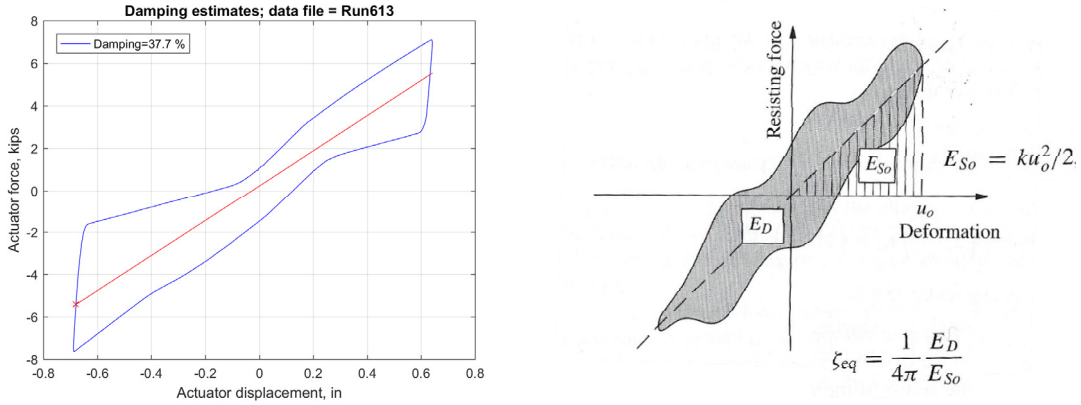

Figure 4: Estimation of equivalent viscous damping (left) based on [5] - right.

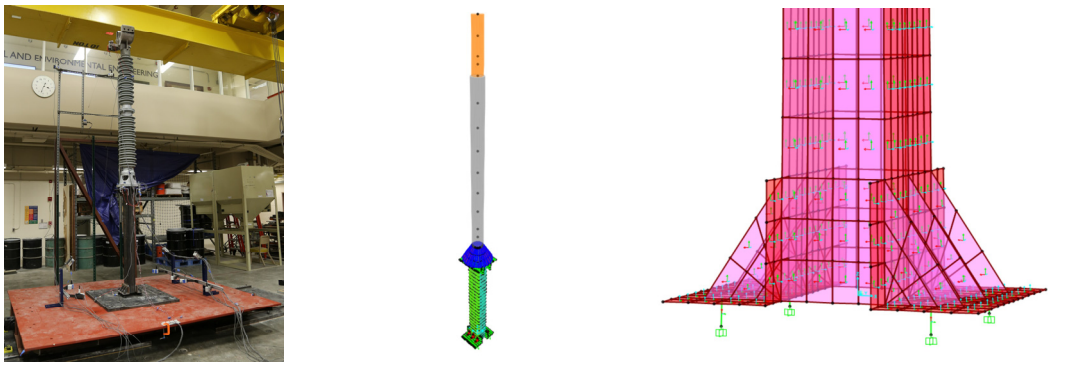
The equivalent viscous damping of the double-acting friction damper with a preload of -0.97-kips was estimated at 37.7% as presented in the left image of Figure 4.

3 HIGH-VOLTAGE EQUIPMENT AND FE MODEL

In this study, a typical model of high voltage equipment consisting of a 230-kV porcelain insulator with a terminal pad assembled on top of a steel support structure was studied. It is presented in Figure 5. A similar model was studied earlier [6] when it was isolated by Wire Ropes. The fixed based configuration was also previously tested on the shaking table [7]. In both cases studied earlier, the support structure was supported by eight anchors. In this study, only four anchors were considered at the bottom of the support structure as shown in Figure 5c. The modelling is conducted in SAP2000 [8]. The results of numerical simulations are reduced in the Matlab environment [9].



a) Fixed base configuration on shaking table

b) FE model

c) Number of anchors is limited to four

Figure 5: High-voltage equipment on a support structure.

Several finite element (FE) models were created. The first model (Model A) was simulating a fixed base configuration. The second model (Model B) was isolated by utilizing a model of the friction damper [8] without a preload. There were several models simulating HV equipment isolated by friction dampers with different values of preload as presented in Table 1. The resonant frequency of the fixed based model was close to that measured by a snap-back test of a real specimen [7] as shown in Table 1. The latter means that the dynamic properties of the equipment's model were closely correlated to that of real equipment.

To ensure that the resonant frequency for each model is captured correctly in nonlinear numerical analysis, all models were subjected to a sine sweep excitation in the X axis. The level of excitation was the same and high enough to cause about the same axial force in the friction damper. In other words, the demand of sine sweep excitation on the models was about the same at the resonant frequency of the system.

The normalized transfer functions of top accelerations from numerical simulations with the sine sweep excitation are presented in Figure 6. The transfer function plot of models with a preload steadily widens while the preload is increasing. It means that the damping of the model is increasing. The damping based on the half-power bandwidth method (see [5], for example) is estimated in the same figure. Since the half-power bandwidth method works for relatively low values of critical damping, only few damping estimations for some models are presented in this plot. Two major conclusions can be made from these results. First, the force versus displacement curve of the friction dampers with a preload is much wider than that

without a preload. Second, the resonant frequency of the isolated equipment steadily increases while the preload increases.

In the next step, all models were subjected to a seismic excitation by using a strong motion time history matched to the IEEE693 spectrum at 5% damping, TestQke4IEEE5-4 [10]. The excitation was only applied in the X direction.

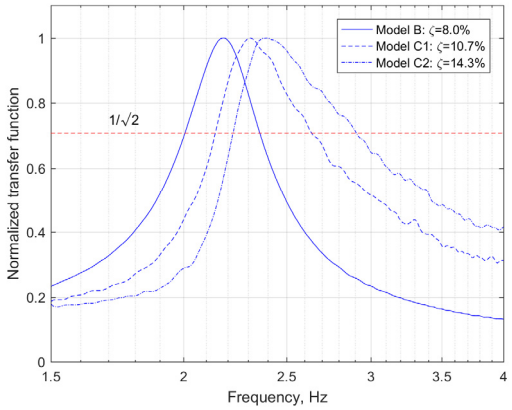


Figure 6: Normalized transfer functions from sine sweep runs were used in the damping estimates based on half-power bandwidth method [5].

Configuration	Resonant frequency (X), Hz	Damping, %	Preload, in
Snap-back test of actual specimen	4.9	NA[!]	NA
Model A: fixed base	5.0	5.0	NA
Model B: friction damper	2.2	8.0	0.0
Model C1: friction damper	2.3	10.7	-0.05
Model C2: friction damper	2.4	14.3	-0.07
Model C3: friction damper	2.9	NA[&]	-0.10
Model C4: friction damper	3.5	NA[&]	-0.15

[!] – damping was not estimated in the test; [&] - damping is too high to be estimated by means of half-power band-width method

Table 1: Resonant frequencies and damping values of actual specimen and FE models.

The friction damper model [8] was based on the stiffnesses of the Ringfeder damper experimentally measured in the component testing. The resultant hysteresis loops of the friction dampers for Model B and Model C4 are presented in Figure 7.

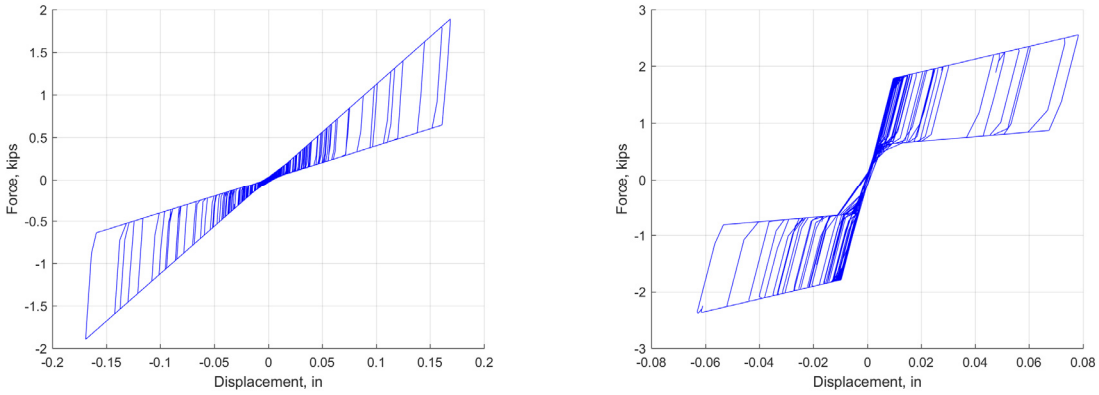

Figure 7: Force vs. displacement without (left) and with (right) preload: Model B vs. Model C4.

For all models, the peak maximum acceleration and displacement on top and moment at the bottom of the insulator is investigated. All these results are normalized to corresponding peak values for Model A. The normalized values are summarized in Table 2.

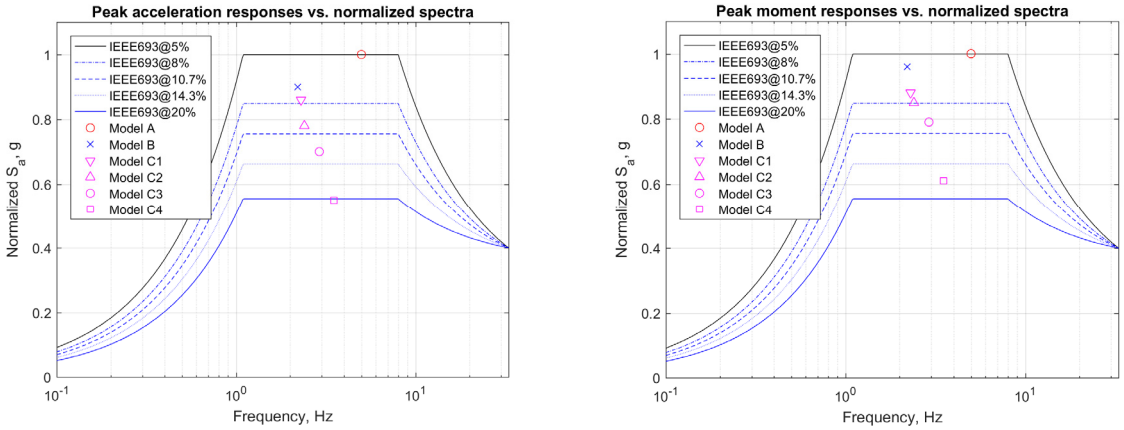
Normalized peak value	Model A	Model B	Model C1	Model C2	Model C3	Model C4
Acceleration on top	100%	90%	86%	78%	70%	55%
Moment at bottom of insulator	100%	96%	88%	85%	79%	61%
Displacement on top	100%	448%	381%	352%	302%	186%

Table 2: Normalized peak values of seismic performance.

As shown in Table 2, the peak acceleration on top and moment at the bottom of the insulator is less than that of the non-isolated model (Model A). Preloading improves the performance of the isolated equipment and the highest reduction of peak acceleration and moment resulted in Model C4. In the case of the latter model, the peak acceleration was reduced by about 45% and the moment at the bottom by about 39%. Since excessive moments can lead to failure of the porcelain insulators, this parameter is very important for acceptable seismic performance of the HV equipment.

This reduction of moments is closely correlated to the reduction in peak accelerations as presented in Figure 8. This serves as evidence that the first mode vibrations are dominating and that they control the seismic performance of the HV equipment.

The IEEE693 spectrum decreases when the damping is increasing as presented in Figure 8. The latter figure presents all other spectral plots normalized to the plateau of the IEEE693 spectrum with damping of 5%. As it can be seen from Figure 8, the reduction factors are somewhat consistent with the reduction estimated by the IEEE693 spectral plots [4]. In the figure, all lines correspond to the IEEE693 spectra for different damping values, the points correspond to the normalized peak values at the system frequency.



a) Peak acceleration responses b) Peak moment responses

Figure 8: Normalized peak responses vs. normalized spectra.

The peak relative displacement on top of the isolated equipment with no preload (Model B) increased about 4.5 times in respect to the fixed base model (Model A) as presented in Table 2. This increase is expected due to increased flexibility of the base support dampers. Preloading increases the effective damping of the system and as such the peak displacement decreases and for Model C4 is it just 1.86 time greater than the fixed based model. The relative

displacements at the insulator's terminal location are very important for estimating the cable length when the HV equipment is connected to other substation equipment by flexible bus power cables.

The results of this study demonstrate that even simple models of the friction damper shows its efficiency. In the next phase of the study, the friction dampers will be installed at the bottom of the HV equipment and the system will be tested on a long stroke 1D shaking table and 6D shaking table. A more accurate model of the friction damper will be utilized and a nonlinear time history will be conducted on a FE model isolated by friction dampers. The results of the shaking table tests will be compared to the numerical predictions of this simplified model and to that with more sophisticated model of friction damper. This phase of the project is ongoing.

4 CONCLUSIONS

- This paper highlights results of component tests conducted on friction dampers. The test results show that the effective viscous damping of the friction dampers can be as high as 37.7%.
- Based on a simplified model of the friction damper [8], the efficiency of the seismic isolation is demonstrated. It was shown that the peak moments and accelerations can be reduced by about 39% and 45%, respectively. The peak displacements on top of the equipment will increase in respect to the fixed base model, that can be reduced by increasing preload.
- There is a need for a study with a more sophisticated model of friction dampers to be investigated in a nonlinear time history numerical simulation. The sophisticated model of the HV equipment needs to be calibrated based on the system level tests on a shaking table. A study on these issues is ongoing.

ACKNOWLEDGEMENTS

The project is sponsored by the Electric Power Research Institute (EPRI) whose support is greatly appreciated. The research team thanks Mr. Robert Cochran of Seattle City Light for donating Ringfeder friction dampers. Special thanks are due to the staff of the Structure Laboratory at the University of California, Berkeley. Special thanks are due to Mr. Llyr Griffith, Mr. Phillip Wong, and Mr. Matthew Cataleta. The successful completion of the testing phase of the project would not be possible without their technical support. Technical help by Ms. Sage Shamsai (CEE, UC Berkeley) on preparing 3D drawings and testing is greatly appreciated.

Keywords: Sliding Bearing, Hysteretic Behavior, Phenomenological Model.

Abstract. *This paper presents a uniaxial phenomenological model for the simulation of the hysteretic behavior typically exhibited by sliding bearings deforming along one of their transverse directions under the effect of an axial compressive load. The proposed hysteretic model is able to take into account the dependency of the device restoring force on the velocity of sliding, on the bearing pressure, and on the condition of the sliding interface. Furthermore, it allows for a considerable reduction of the computational effort of nonlinear dynamic analyses since the model hysteretic variable is evaluated by solving an algebraic equation. The numerical accuracy and computational efficiency of the proposed model are assessed by means of numerical simulations.*

1 INTRODUCTION

Base isolation represents one of the most effective techniques for the seismic protection of buildings and bridges [1, 2, 3]. Such a technique requires the use of special devices, called seismic isolation bearings, having flexibility and energy dissipation capacity along their transverse directions and a large axial stiffness [4, 5].

Seismic isolation bearings can be divided into two main categories, that is, elastomeric and sliding bearings. The latter, of particular interest in this work, are devices made up of rigid plates that can slide with respect to each other. Looking at the type of sliding surface, it is possible to distinguish between flat surface sliding bearings and curved surface sliding bearings [6].

Sliding bearings deforming along one of their transverse directions under the effect of an axial compressive load display a hysteretic behavior due to the friction occurring at the sliding interface. Experimental tests results available in the literature show that the device restoring force depends not only on the device transverse displacement but also on the device transverse velocity. In particular, the dependency of the device restoring force on the velocity of sliding is due to the variation of the kinetic friction coefficient with the sliding velocity [7, 8].

Several hysteretic models have been proposed in the literature for simulating the complex behavior occurring in sliding bearings [9]. Among existing models, the one proposed by Mokha et al. [10] seems to be the most suitable one since it allows for an accurate prediction of the hysteretic response of both flat and curved surface sliding bearings by using a relatively small number of parameters. In particular, such a model is able to take into account the dependency of the restoring force on the velocity of sliding, on the bearing pressure, and on the condition of the sliding interface. Unfortunately, this model is not computationally efficient since it requires the numerical solution of a first-order nonlinear ordinary differential equation for the evaluation of the hysteretic variable at each time step of a nonlinear dynamic analysis.

This paper presents a uniaxial phenomenological model able to predict the hysteretic behavior generally displayed by sliding bearings. Compared to the model formulated by Mokha et al. [10], the proposed one not only offers the important advantage of accurately simulating the response of such devices, but it also allows for a considerable reduction of the computational effort required by nonlinear dynamic analyses since the model hysteretic variable is evaluated by solving an algebraic equation. Furthermore, it is based on a smaller set of parameters and can be easily implemented in a computer program.

2 SLIDING BEARINGS

Sliding bearings are seismic isolation devices consisting of a slider that moves on a sliding surface. Such devices, having an axial stiffness that is very much greater than the transverse one, display an energy dissipation capacity due to the friction damping occurring at the sliding interface [4].

According to the type of sliding surface, sliding bearings can be classified into two main categories, namely, Flat Surface Sliding Bearings (FSSBs) and Curved Surface Sliding Bearings (CSSBs) [6].

In this section, the main characteristics of the two above-mentioned types of sliding bearings are illustrated with particular emphasis on the brief description of the hysteretic behavior displayed along their transverse directions under the effect of an axial compressive load.

2.1 Flat Surface Sliding Bearings

Figure 1a shows the sectional view of a typical FSSB in deformed configuration. Such a device has a slider generally made up of an upper sliding plate and a lower polished stainless steel plate. The flat sliding surface is typically overlain by unfilled or filled Polytetrafluoroethylene, referred to as PTFE or Teflon.

FSSBs deforming along one of their transverse directions under the effect an axial compressive load display both rate-dependent and rate-independent hysteretic behaviors. Indeed, experimental test results available in the literature [7, 8] show that the device restoring force f depends not only on the device transverse displacement u but also on the device transverse velocity $\dot{u}$. Figure 1b shows the typical hysteresis loop shape displayed by FSSBs.

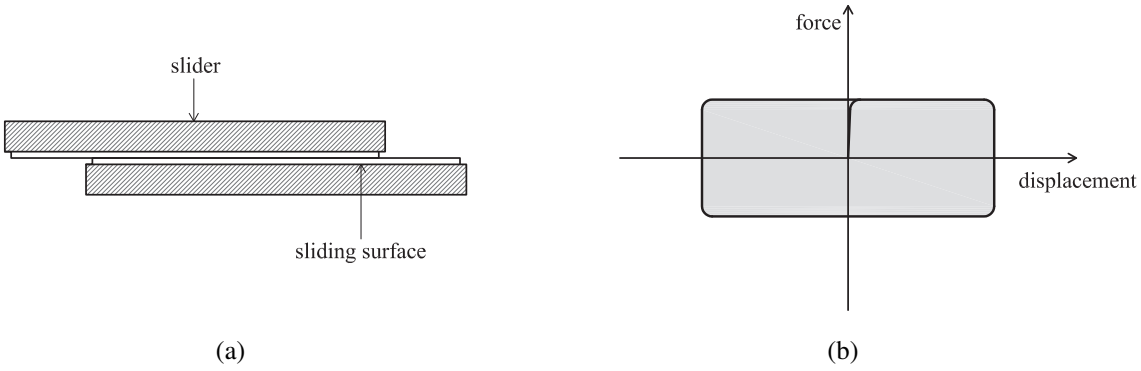

Figure 1: Typical FSSB: sectional view in deformed configuration (a) and hysteresis loop shape (b).

2.2 Curved Surface Sliding Bearings

Figure 2a shows the sectional view of a typical CSSB in deformed configuration. Such a device, denominated Friction Pendulum Bearing (FPB), has an articulated slider generally coated with a low-friction and high-pressure capacity composite material, typically PTFE. The curved sliding surface, having radius of curvature R, is generally overlain by polished stainless steel.

FPBs deforming along one of their transverse directions under the effect an axial compressive load display both rate-dependent and rate-independent hysteretic behaviors. Figure 2b shows the typical hysteresis loop shape displayed by FPBs.

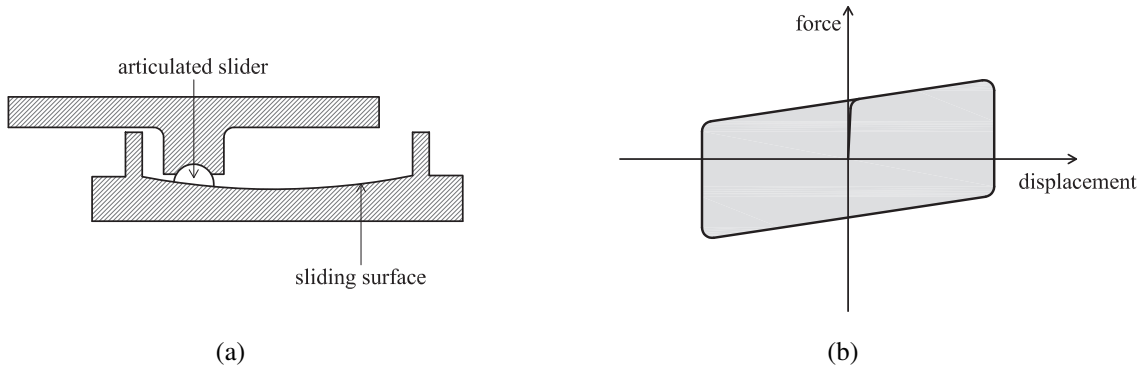

Figure 2: Typical FPB: sectional view in deformed configuration (a) and hysteresis loop shape (b).

3 PROPOSED HYSTERETIC MODEL

In this section, we first present the proposed hysteretic model formulation; subsequently, we illustrate a schematic flowchart of the model to allow for an easy computer implementation.

3.1 Model Formulation

The restoring force of a sliding bearing may be evaluated as [10]:

$$f\left(u,\dot{u}\right)=\frac{N}{R}u+\mu\left(\dot{u}\right)Nz\left(u\right), \tag{1}$$

where N is the axial compressive force acting on the bearing, R is the radius of curvature of the sliding surface, $\mu\left(\dot{u}\right)$ is the kinetic coefficient of friction, $z(u)$ is a dimensionless hysteretic variable, whereas u and $\dot{u}$ are the bearing transverse displacement and velocity, respectively.

The kinetic friction coefficient $\mu\left(\dot{u}\right)$ may be computed as [8]:

$$\mu\left(\dot{u}\right)=\mu_{max}-\left(\mu_{max}-\mu_{min}\right)e^{-a|\dot{u}|}, \tag{2}$$

where μ_{max} (μ_{min}) is the value of the kinetic friction coefficient at large (low) bearing transverse velocity, and a is a parameter, having units of time per unit length, that rules the velocity of transition of $\mu\left(\dot{u}\right)$ from μ_{min} to μ_{max}. Note that the values of μ_{max}, μ_{min}, and a depend on the bearing pressure, temperature, as well as condition of the sliding surface.

The dimensionless hysteretic variable $z(u)$ is a function of u and has a unit maximum absolute value, that is, $max\left\{|z(u)|\right\}=1$; in particular, if u cycles between two values, $z(u)$ traces a hysteresis loop bounded by two parallel horizontal straight lines.

In the model proposed by Mokha et al. [10], such a variable is evaluated by solving the following differential equation, typical of the celebrated Bouc-Wen model [11, 12]:

$$Y\dot{z}+\gamma\left|\dot{u}\right|z\left|z\right|^{n-1}+\beta\dot{u}\left|z\right|^{n}-A\dot{u}=0, \tag{3}$$

where $Y>0$ is a parameter having dimension of displacement, whereas A, β, γ, and n are dimensionless parameters. Unfortunately, the numerical solution of Equation (3) for each time step of a nonlinear dynamic analysis may significantly increase the overall computational effort.

To decrease the computational burden of the analyses without decreasing the accuracy of the numerical results, we propose to evaluate $z(u)$ by employing a specific instance of the general class of uniaxial phenomenological models formulated by Vaiana et al. [13, 14].

According to such a general formulation, a generic hysteresis loop, in the z-u plane, can be described by means of four types of curves, that is, the upper c_u and the lower c_l limiting curves and the generic loading c^+ and unloading c^- curves.

As shown in Figure 3, the upper (lower) limiting curve c_u (c_l) intercepts the vertical axis at $z=\bar{f}$ ($z=-\bar{f}$). Furthermore, the generic loading (unloading) curve has a starting point, lying on the lower (upper) limiting curve, having abscissa u_i^+ (u_i^-) and an ending point, lying on the upper (lower) limiting curve, having abscissa u_j^+ (u_j^-), with $u_i^+=u_j^+-2u_0$ ($u_i^-=u_j^-+2u_0$).

In the generic loading case, $z=c^+$ when $u_i^+\leq u<u_j^+$, and $z=c_u$ when $u>u_j^+$, whereas, in the generic unloading case, $z=c^-$ when $u_j^-<u\leq u_i^-$, and $z=c_l$ when $u<u_j^-$.

Specifically, in this work, the expressions of the upper c_u and lower c_l limiting curves are:

$$c_u=\bar{f}, \tag{4}$$

$$c_l=-\bar{f}, \tag{5}$$

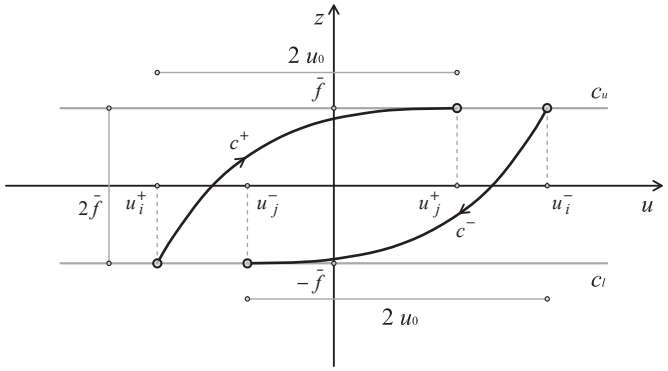

Figure 3: Curves c_u, c_l, c^+, and c^- defining the dimensionless hysteretic variable $z(u)$.

whereas, the ones of the generic loading c^+ and unloading c^- curves are:

$$c^+\left(u, u_j^+\right) = k_a \left[\frac{\left(1 + u - u_j^+ + 2u_0\right)^{(1-\alpha)}}{1-\alpha} - \frac{(1+2u_0)^{(1-\alpha)}}{1-\alpha} \right] + \bar{f}, \tag{6}$$

$$c^-\left(u, u_j^-\right) = k_a \left[\frac{\left(1 - u + u_j^- + 2u_0\right)^{(1-\alpha)}}{\alpha-1} - \frac{(1+2u_0)^{(1-\alpha)}}{\alpha-1} \right] - \bar{f}, \tag{7}$$

where k_a and α are model parameters to be calibrated from experimental tests, whereas u_0 and $\bar{f}$ are two internal model parameters that can be expressed as a function of k_a and α. In particular, $k_a > 0$, $\alpha > 0$, $\alpha \neq 1$, $u_0 > 0$, and $\bar{f} > 0$.

The internal model parameters u_0 and $\bar{f}$ can be evaluated as follows:

$$u_0 = \frac{1}{2}\left[\left(\frac{k_a}{\delta_k} \right)^{\frac{1}{\alpha}} - 1 \right], \tag{8}$$

$$\bar{f} = \frac{k_a}{2}\left[\frac{(1+2u_0)^{(1-\alpha)} - 1}{1-\alpha} \right], \tag{9}$$

where δ_k may be set equal to 10^{-20}, as explained in [13, 14].

Finally, for the generic loading case, the expression of the history variable is:

$$u_j^+ = 1 + u_P + 2u_0 - \left\{ \frac{1-\alpha}{k_a} \left[f_P - \bar{f} + k_a \frac{(1+2u_0)^{(1-\alpha)}}{1-\alpha} \right] \right\}^{\left(\frac{1}{1-\alpha}\right)}, \tag{10}$$

whereas, for the generic unloading case, it becomes:

$$u_j^- = -1 + u_P - 2u_0 + \left\{ \frac{\alpha-1}{k_a} \left[f_P + \bar{f} + k_a \frac{(1+2u_0)^{(1-\alpha)}}{\alpha-1} \right] \right\}^{\left(\frac{1}{1-\alpha}\right)}, \tag{11}$$

where (u_P,f_P) are the coordinates of the initial point P of the generic loading or unloading curve.

Note that, in order to have $max\left\{|z(u)|\right\} = 1$, the parameters k_a and α need to be selected so that Equation (9) gives a unit value of $\bar{f}$.

1. Initial settings.
1.1 Set the model parameters: N, R, μ_{max}, μ_{min}, a, k_a, and α.
1.2 Compute the internal model parameters: $u_0 = \frac{1}{2}\left[\left(\frac{k_a}{\delta_k}\right)^{\frac{1}{\alpha}} - 1\right]$ and $\bar{f} = \frac{k_a}{2}\left[\frac{(1+2u_0)^{(1-\alpha)}-1}{1-\alpha}\right]$, with $\delta_k = 10^{-20}$.
2. Calculations at each time step.
2.1 If $s_t s_{t-\Delta t} < 0$, update the history variable: $u_j = u_{t-\Delta t} + s_t\,(1+2u_0) - s_t\left\{\frac{s_t(1-\alpha)}{k_a}\left[z_{t-\Delta t} - s_t\bar{f} + k_a\frac{(1+2u_0)^{(1-\alpha)}}{s_t(1-\alpha)}\right]\right\}^{\left(\frac{1}{1-\alpha}\right)}$.
2.2 Evaluate the dimensionless hysteretic variable at time t: if $u_j s_t - 2u_0 \leq u_t s_t < u_j s_t$: $z_t = k_a\left[\frac{(1+s_t u_t - s_t u_j + 2u_0)^{(1-\alpha)}}{s_t(1-\alpha)} - \frac{(1+2u_0)^{(1-\alpha)}}{s_t(1-\alpha)}\right] + s_t\bar{f}$, otherwise: $z_t = s_t\bar{f}$.
2.3 Compute the kinetic friction coefficient at time t: $\mu_t = \mu_{max} - (\mu_{max} - \mu_{min})\,e^{-a\lvert\dot{u}_t\rvert}$.
2.4 Evaluate the restoring force of the sliding bearing at time t: $f_t = \frac{N}{R}u_t + \mu_t N z_t$.

Table 1: Proposed hysteretic model algorithm.

3.2 Computer Implementation

To allow for an easy computer implementation, Table 1 presents a schematic flowchart of the proposed hysteretic model. To this end, we suppose that a sliding bearing is subjected to a given transverse displacement history and that a displacement-driven solution scheme has been adopted. Because of these assumptions, the displacements $u_{t-\Delta t}$ and u_t, the velocities $\dot{u}_{t-\Delta t}$ and $\dot{u}_t$, as well as the restoring force $f_{t-\Delta t}$ are known over a time step Δt, and the restoring force f_t has to be evaluated.

The implementation scheme of the proposed hysteretic model, summarized in Table 1, is composed of two parts. In the first one, called *Initial settings*, the model parameters, that is, N, R, μ_{max}, μ_{min}, a, k_a, and α are assigned and the internal ones, namely, u_0 and $\bar{f}$, are evaluated. In the second one, called *Calculations at each time step*, the history variable u_j is updated if the sign of the transverse velocity at time t, that is, $s_t = sgn(\dot{u}_t)$, changes with respect to the one at time $t - \Delta t$, that is, $s_{t-\Delta t} = sgn(\dot{u}_{t-\Delta t})$; then, the dimensionless hysteretic variable z_t is computed by using the expression of the generic loading/unloading curve if $u_j s_t - 2u_0 \leq u_t s_t < u_j s_t$; otherwise, it is computed by adopting the expression of the upper/lower limiting curve. Finally, after updating the value of the kinetic friction coefficient μ_t, the restoring force of the sliding bearing f_t is evaluated.

4 VERIFICATION OF THE PROPOSED MODEL

This section presents the validation of the Proposed Hysteretic Model (PHM), described in Section 3. Specifically, numerical accuracy and computational efficiency of the proposed model are assessed by performing Nonlinear Time History Analyses (NLTHAs) on a base-isolated rigid block and comparing the results obtained by modeling the restoring force of each sliding bearing on the basis of the PHM with those obtained by using the model developed by Mokha et al. [10], given by Equations (1)-(3) and referred to as the Mokha Hysteretic Model (MHM) for simplicity.

4.1 Analyzed Mechanical System

Figure 4 illustrates the analyzed mechanical system that consists of a rigid block isolated by two FPBs placed between a shaking table and the rigid block.

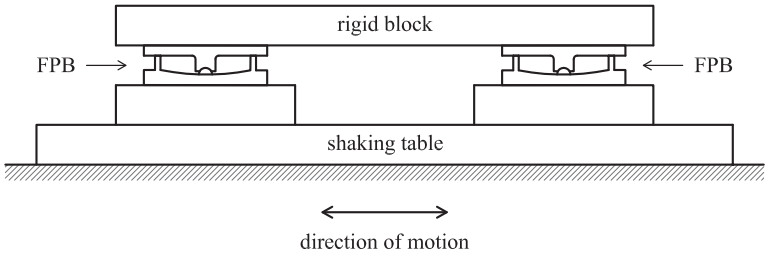

Figure 4: Mechanical system adopted for the numerical verification.

The motion of such a system is described by the following equation:

$$m\ddot{u} + 2c\dot{u} + 2f(u, \dot{u}) = p(t), \tag{12}$$

where m denotes the rigid block mass, c the viscous damping coefficient of each bearing, u, $\dot{u}$, and $\ddot{u}$ the mechanical system displacement, velocity, and acceleration relative to the ground, respectively, f the restoring force of each FPB, and p the external force depending upon time t.

If the mechanical system is subjected to an earthquake excitation, p represents the effective earthquake force, that is, a force acting opposite to the acceleration and equal to mass m times the ground acceleration $\ddot{u}_g$. Thus, Equation (12) is replaced by:

$$m\ddot{u} + 2c\dot{u} + 2f(u, \dot{u}) = -m\ddot{u}_g(t). \tag{13}$$

The rigid block has a mass of 11685.94 $\mathrm{Ns^2m^{-1}}$, whereas the two FPBs, characterized by negligible mass and viscous damping coefficient, have the same properties as the one tested by Mokha et al. [10]. Their nonlinear behavior is simulated by using the hysteretic models parameters listed in Table 2.

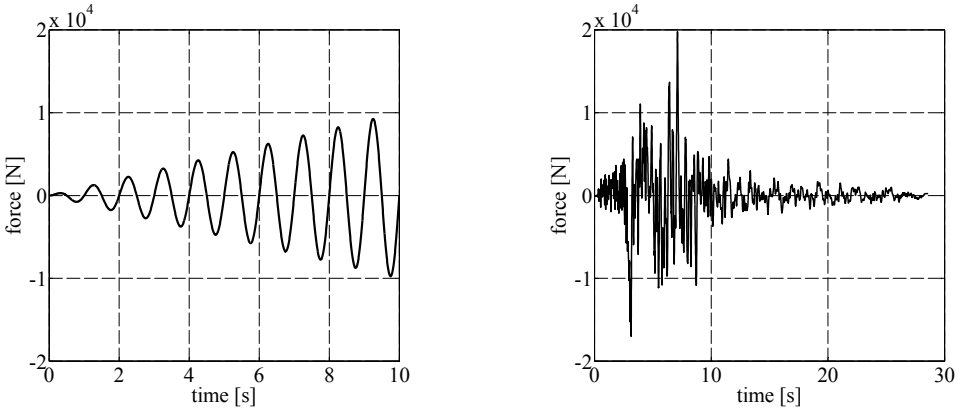
4.2 Applied External Forces

The nonlinear dynamic response of the mechanical system is evaluated for two different external forces, namely, a harmonic force and an earthquake force.

The harmonic force, shown in Figure 5a, is a sinusoidal force characterized by an amplitude p_0 that increases linearly with time from 0 to 10^4 N, a forcing frequency $\omega_p = 2\pi$ rad/s, and a time duration $t_d = 10$ s.

MHM	N [N]	R [m]	μ_{max}	μ_{min}	a [s/m]	Y [m]	A	β	γ	n
	57300	0.247	0.075	0.040	43.30	0.0001	1	0.1	0.9	1.1
PHM	N [N]	R [m]	μ_{max}	μ_{min}	a [s/m]	k_a [m^{-1}]	α			
	57300	0.247	0.075	0.040	43.30	15500	7750			

Table 2: Hysteretic models parameters.



(a) (b)

Figure 5: Applied external forces: harmonic (a) and earthquake force (b).

The earthquake force, shown in Figure 5b, is evaluated by adopting the SN component of horizontal ground acceleration recorded at the Jensen Filter Plant station during the Northridge earthquake of January 17, 1994. The original ground acceleration record, having time step equal to 0.005 s, has been scaled by a factor of 1/3 in order to reach a peak mechanical system displacement, relative to the ground, that is close to the maximum displacement attained by the FPB during the experimental tests conducted by Mokha et al. [10].

4.3 Results of the Nonlinear Time History Analyses

In this subsection, the results of some numerical simulations are presented to assess the numerical accuracy and the computational efficiency of the PHM.

The equation of motion, given by Equation (12) or (13), according to the type of applied external force, has been numerically solved by employing a widely used explicit time integration method, that is, the central difference method [15, 16], and adopting a time step of 0.005 s. In addition, the first-order nonlinear ordinary differential equation characterizing the MHM has been numerically solved by adopting the unconditionally stable semi-implicit Runge-Kutta method [17] and using 50 steps. The numerical time integration algorithm as well as the hysteretic models have been implemented in MATLAB and run on a computer having an Intel®Core™i7-4700MQ processor and a CPU at 2.40 GHz with 16 GB of RAM.

Tables 3 and 4 present the NLTHAs results obtained for the harmonic and earthquake forces, respectively.

The numerical results confirm the accuracy of the PHM since the maximum and minimum

			$u\,[\mathrm{m}]$		$\dot{u}\,[\mathrm{ms}^{-1}]$		$\ddot{u}\,[\mathrm{ms}^{-2}]$	
	$tct\,[\mathrm{s}]$	$tctp$	max	min	max	min	max	min
MHM	9.55	-	0.0350	-0.0321	0.2078	-0.2255	1.4296	-1.5581
PHM	0.07	0.73%	0.0350	-0.0320	0.2077	-0.2253	1.4286	-1.5573

Table 3: NLTHAs results obtained by applying the harmonic force.

			$u\,[\mathrm{m}]$		$\dot{u}\,[\mathrm{ms}^{-1}]$		$\ddot{u}\,[\mathrm{ms}^{-2}]$	
	$tct\,[\mathrm{s}]$	$tctp$	max	min	max	min	max	min
MHM	27.00	-	0.0218	-0.0345	0.1392	-0.1406	1.6221	-1.1974
PHM	0.22	0.81%	0.0218	-0.0346	0.1391	-0.1408	1.6227	-1.1896

Table 4: NLTHAs results obtained by applying the earthquake force.

values of the relative displacement, velocity, and acceleration of the mechanical system, evaluated by employing the proposed model, are quite close to those predicted by the MHM.

Furthermore, the numerical results also show that the computational burden of the PHM, expressed by the total computational time tct, is significantly smaller than the one characterizing the MHM. Since the parameter tct depends upon the amount of the back-ground process running on the computer, the relevant memory, as well as the CPU speed, a fully objective measure of the computational benefits, associated with the use of the PHM with respect to the MHM, is obtained by normalizing such a parameter as follows:

$$\mathrm{PHM}\ tctp\ [\%] = \frac{\mathrm{PHM}\ tct}{\mathrm{MHM}\ tct} \cdot 100\ . \tag{14}$$

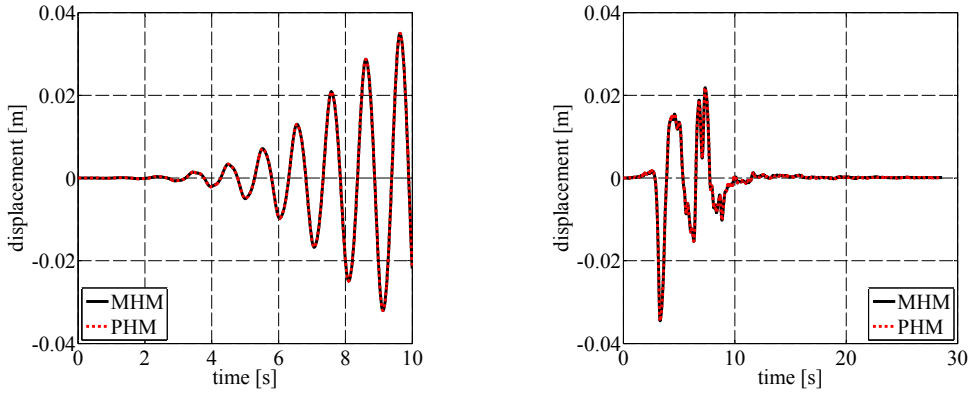
Figures 6, 7, and 8 illustrate, respectively, the time histories of the relative displacement, velocity, and acceleration of the mechanical system, whereas Figure 9 shows the restoring force-displacement hysteresis loops displayed by each FPB. Generally speaking, the comparison between the responses simulated with the PHM and the MHM shows a very good agreement.

5 CONCLUSIONS

We have presented a uniaxial phenomenological model able to simulate the complex hysteretic behavior typically displayed by sliding bearings deforming along one of their transverse directions under the effect of an axial compressive load.

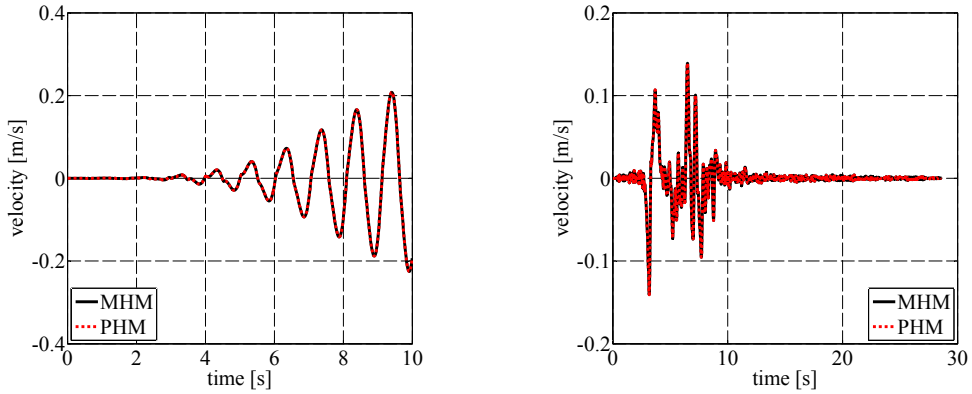
The proposed model allows for the evaluation of the device restoring force taking into account its dependency on the sliding velocity, bearing pressure, and sliding surface conditions. Furthermore, such a model requires the solution of an algebraic equation for the evaluation of the hysteretic variable and can be easily implemented in a computer program.

The numerical accuracy and the computational efficiency of the proposed model have been assessed by performing nonlinear time history analyses on a single degree of freedom mechanical system, for two different external forces, that is, a harmonic force and an earthquake force, and comparing the results of the PHM with those associated with the MHM. Specifically, the following conclusions can be drawn:



(a) (b)

Figure 6: Relative displacement time history obtained by applying the harmonic (a) and the earthquake force (b).



(a) (b)

Figure 7: Relative velocity time history obtained by applying the harmonic (a) and the earthquake force (b).

- the numerical results of the PHM closely match those predicted by the MHM, for both types of external force;
- the total computational time required by the PHM is equal to 0.73% (0.81%), for the harmonic (earthquake) force case, of the one associated with the MHM.

Current research is focusing on the extension of the proposed model to the two-dimensional case through the definition of an interaction domain involving restoring forces. Furthermore, in forthcoming papers, the presented model will be combined with recent strategies to address the nonlinear behavior of framed [18] or shear wall structures [19] in order to analyze base-isolated buildings by exploiting the concept of seismic response envelopes [20].

Abstract

This paper presents the results of a numerical and experimental study aiming to define the vertical and horizontal stiffness of Fiber-Reinforced Elastomeric Isolators (FREIs). In FREIs, the conventional steel shims of laminated rubber bearings are replaced by flexible fiber reinforcements. The axial and lateral response of these bearings is influenced by the flexibility of these layers. This study describes results of an analytical model capable of providing an accurate estimation of the vertical and horizontal stiffness of the bearings under static and dynamic loads. Results of this analytical model are compared to output of finite element analysis (FEM) available in literature. The influence of the geometry of the isolator (i.e., strip and circular shape), its shape factor and type of reinforcement on the vertical and horizontal stiffness are discussed. Considerations are also given on the effects of the compressibility of the rubber on the axial and lateral response of the devices.

Keywords: FREI, Unbounded Isolators, Analytical Modeling, FEM modeling, Low cost Isolators.

1 INTRODUCTION

The fiber-reinforced elastomeric isolators (FREIs) have been developed in the last years as alternative to the conventional steel reinforced elastomeric isolators (SREIs) [1] in the attempt of reducing the weight, manufacturing time and cost of rubber based devices [2]–[4], and with this to permit their application to all type of structures, including low-cost residential buildings.The main characteristics of the FREIs are: traditional steel plates are replaced with fabric reinforcement layers of different kind [5]–[9]; and the bearings are not bonded to the structure. This latter feature together with the lack of flexural rigidity of the fiber-reinforcements allow the bearings to roll-of the supports when deformed in shear, eliminating the high tensile stresses developed in a bonded isolator when it is displaced horizontally [10], [11].
Studies have been conducted to determine the vertical and horizontal behaviour, under cyclic and monotonic loads, of FREIs based on the behaviour of the SREIs, leading to a better understanding of their performance. These investigations have considered the influence of the variation of the reinforcement and matrix materials as well as the influence of the vertical pressure by comparing experimental investigations and finite element analyses [6], [12]–[17]. However, the lack of a complete analytical solution that combines the lateral and vertical response of FREIs has limited the possibility ofpredicting their response under large levels of deformation (i.e., strain up to 100%) [16].
The aim of this paper is to compare the vertical and horizontal behavior of FREIs with different reinforcement, shape and geometry under cyclic and monotonic loads. This comparison will be based on the results of analytical model proposed by the authors in a previous investigation [18] and results of finite element analysis (FEM) available in literature [15].

2 ANALYTICAL MODEL

Based on experimental outcomes, the authors confirmed that the vertical stiffness obtained by Eq. 1 proposed by Konstantinidis and Kelly [19] can satisfactorily estimate the vertical stiffness, K_{Vd}, of FREIs :

$$K_{Vd} = \frac{E_c^f A}{H_r} \tag{1}$$

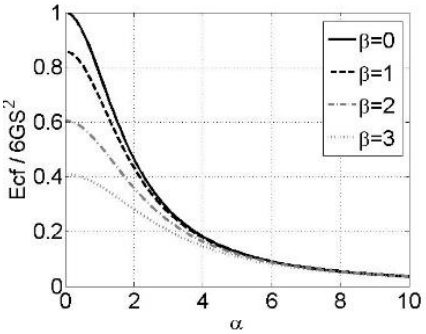

Figure 1: Dimensionless ratio of fiber-reinforced and steel-reinforced compression moduli as a function of parameter α [20].

where E_c^f is the compression modulus of the confined elastomeric compound, when fiber reinforcements are used [20]. For circular bearings, this equivalent compression modulus can be determined from Figure 1, where $\alpha^2 = 12(1-\upsilon^2)G_{20}R^2/(E_f t_f\ t_r)$ and $\beta^2 = 12G_{20}R^2/Kt_r^2$, with υ as the Poisson's ratio of the fiber, G_{20} is the shear modulus at a strain level of

20%, R is the radius of the isolator, E_f is elastic modulus of the fiber, t_f is the thickness of the fiber reinforcement and K is the bulk modulus of the rubber [18]. E_c^s is the compression modulus for steel reinforced isolators defined as $E_c^S = 6G_{20}S^2$, where the shape factor is $S = D/(4t_r)$, with D as the diameter of the device and t_r the thickness of each rubber layer.
In a previous work [18], the authors developed an accurate analytical model capable of predicting both the horizontal and the vertical stiffness of U-FREIs. The main steps required to estimate the horizontal stiffness of FRBs are summarized below. The method adopts an formulation in which the horizontal stiffness $K_H = G_{eff}\, A_{eff}/t_r$ is function of both the effective shear modulus of the rubber and the contact area of the bearings. This procedure also takes into account the axial load on the bearings. The method can be divided into four steps:

Step 1: In the first step, the effective shear modulus (G_{eff}) is obtained from the rubber characterization curve for the expected deformation levels. This curve is usually supplied by the rubber manufacturer.

Step 2: In the second step, the height of the compressed isolator (h), defined as $h = H - u_P$, is estimated analytically once a compression test on a prototype isolator has been performed. The authors derived an expression that considers the vertical displacement under the design load (u_P) as the summation of the displacement of the unconfined (u_r) and confined rubber (u_{rf}) (Eq. 2):

$$u_P = u_r + u_{rf} \tag{2}$$

The first part, u_r, is calculated as the product of the initial height H and the deformation ε at the stiffness change limit point ($u_r = H\varepsilon$). This deformation ε is obtained from the compression test results carried out on the pure rubber once the stiffness change limit point is known from the isolator under study. The second part, u_{rf}, is calculated using the expression $u_{rf} = \Delta P/K_{Vd}$, where ΔP is the maximum applied load (P) minus the load in the stiffness change limit (P_{sc}). The theoretical vertical stiffness K_{Vd} is obtained from Eq. 1. Further investigations will be devoted to studying the stiffness change point depending on the reinforcement type.

Step 3: The effective area is calculated according to the strain level. For this purpose, the Russo et al. [6] method was applied. As a result, the isolator's portion in contact with the support and subjected to pure shear (A_{eff}) will be equal to the total area (A) minus the area of the detached semicircle (A_d) (Figure 2a). In the case of circular isolator, the detached area is calculated as $A_d = R^2/2 * (\theta - sin\theta)$, with $\theta = 2\arcsin(c/2R)$ and the length $c = \sqrt{((R - s/2) * 8s)}$. The detachment point ($d_0$) and the detached portion length (s) are calculated as $d_0 = \sqrt{H^2 - h^2}$ and $s = d - d_0$, respectively. A_{eff} is calculated as in Eq. 3 based on d_0 and the displacement level (d):

$$\begin{cases} A_{eff} = A & for\ d \le d_0, \\ A_{eff} = A - A_d & for\ d > d_0 \end{cases} \tag{3}$$

In the case of rectangular or strip isolator, the effective area is equal to the product of the isolator side length in the direction perpendicular to the applied load, L, and the side length, B, minus the detached portion, s, in the direction parallel to the applied load [6] (Eq. 4, Figure 2b).

$$A_{eff} = L * (B - s) \tag{4}$$

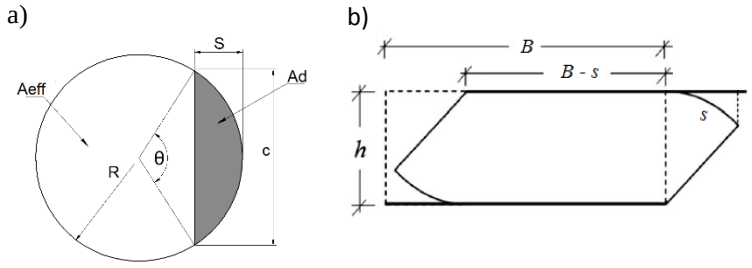

Figure 2. Effective area for isolators (A_{eff}): a) circular [18], and b) strip [12].

Step 4: In the final step, K_H is calculated at different levels with the obtained values of G_{eff} and A_{eff}. Two important aspects of this method should be highlighted. First, it is possible to assume that all the lateral surface will be in contact with the top support when $s = s_{max} = \pi H/2$. This means that the total rollover displacement is $d_{max} = d_o + s_{max}$. The method could be applied until that point with good accuracy, i.e. until the rollover is completed. Based on the proposed equations, it can be stated that isolators experiencing higher vertical displacement under the design load *P* are expected to be stiffer in the horizontal direction, because the detachment process will take longer to start, thus ensuring a full contact area.

The above mentioned formulation has been applied for a comparison to a numerical model available in literature [15].

3 NUMERICAL FINITE ELEMENT ANALYSIS

In a previous study, Kelly and Calabrese [15] studied the mechanics of FREIs comparing linear elastic theory and the outputs of finite element (FEM) analyses. The former had been previously developed by Kelly and Takirov [20] by pressure solution.

The authors of [15] developed an accurate FEM model accounting for rubber incompressibility and flexibility of the fiber layers.

The rubber is modeled by a single Mooney-Rivlin material (i.e., Neo-Hookean) with strain energy function that is the constant shear modulus $G = 0.7MPa$ and a bulk modulus $k = 2000MPa$. The reinforcement is modeled as a rebar element, i.e. a tension element of a linear elastic isotropic material with Young's modulus $E = 14.000\ Pa$ and thickness $t_f = 0{,}07mm$ (SET1) or $t_f = 0{,}25mm$ (SET2).

Two analysis cases are considered in the following for the sake of comparison:

Infinitely long strip isolator under lateral loading: different shape factors are obtained by increasing the values of the base of the device (B=250; 300; 350; 400; 450; 500 mm), to which the following shape factors correspond ($S = B/(2t_r)$; S = 19,6; 23,5; 27,5; 31,4; 35,3; 39,2 for SET1; and S = 20,3; 24,3; 28,4; 32,4; 36,5; 40,5 for SET2 by a $t_r = 6.37mm$ and $t_r = 6.17mm$ for SET1 and SET2, respectively. Each device is made of 29 fiber layers with 28 interleaf rubber sheets (

1. Figure 3). The total height of isolators is 180.4mm for SET1 and 180.0mm for SET2.

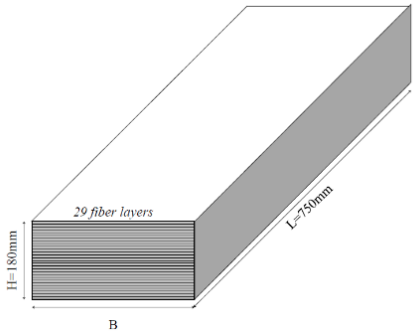

Figure 3: Strip type bearing showing reinforcements and dimensions [15].

2. Circular bearings under vertical loading: different shape factors ($S = \varphi/(4t_r)$; S = 10,1; 12,2; 14,2; 16,2; 18,2; 20,3) are obtained by increasing the values of the diameter of the device (φ =250; 300; 350; 400; 450; 500 mm). Each device is made of 29 fiber layers with 28 interleaf rubber sheets. Each rubber layer is $t_r = 5.75mm$ (Figure 4).

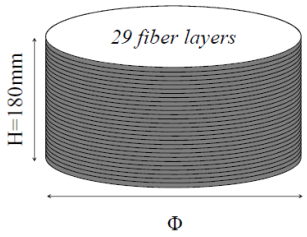

Figure 4: Circular type bearing showing reinforcements and dimensions [15].

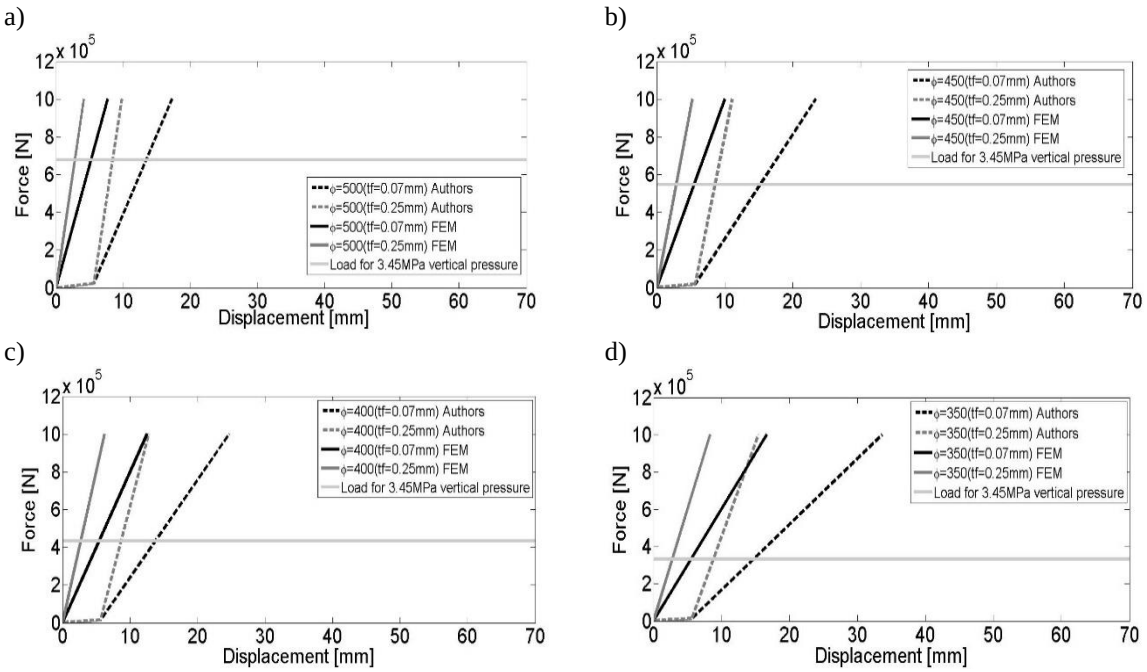
4 COMPARISON BETWEEN MODELS

4.1 Vertical behavior

In Figure 5, the graphic comparison between the different formulations is given:



e) f)

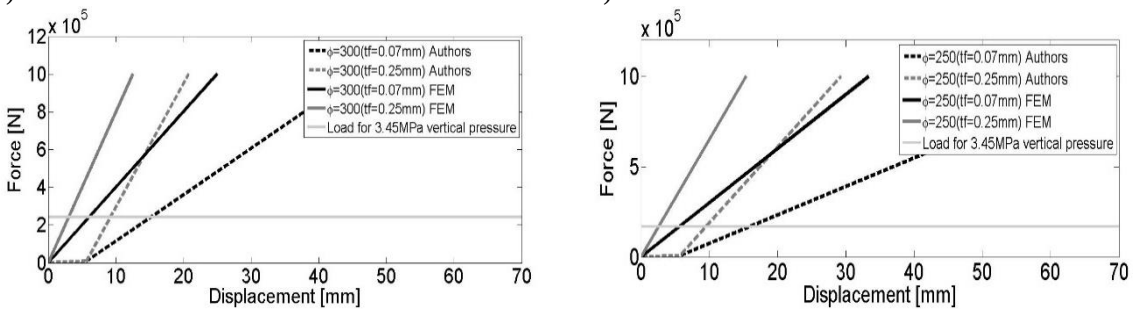


Figure 5: Vertical test results (authors vs. authors solution) for isolator with diameter of: a) 500mm, b) 450mm, c) 400mm, d) 350mm, e) 300mm, and f) 250mm.

The main difference between the models lies in the different assumption at the initial load phase. In particular, the analytical model provided a bilinear behavior in order to take into account the initial unconfined behavior with the pure rubber carrying the load (u_r). This phenomenon has been mentioned for other authors, also [6]. Once the internal fibers have been preloaded, the tangent stiffness is practically the same according to pressure solution and FEM estimate. The stiffness change limit point is calculated assuming a rubber deformation of 3,5 % according to experimental results from a previous investigation [18]. With the bilinear model, the vertical displacement under design load is approximately two times higher than with linear model. This difference also affected the estimation of the horizontal stiffness and as a result the selected design period of the structure [18]. The secant vertical stiffness at the design load of 3,45MPa has been calculated and is plotted in the following Figure 6:

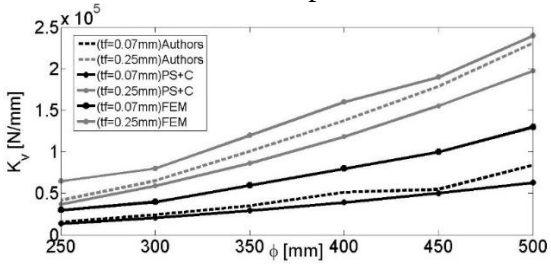

Figure 6: Secant vertical stiffness results

It can be noted that authors' formulation falls between FEM and elastic theory provision, the latter obtained according to the pressure solution also assuming compressibility of rubber (PS+C).

4.2 Horizontal behavior

In Figure 7, the graphic comparison between the authors' and FEM results is given for the strip isolators of

Figure 3:

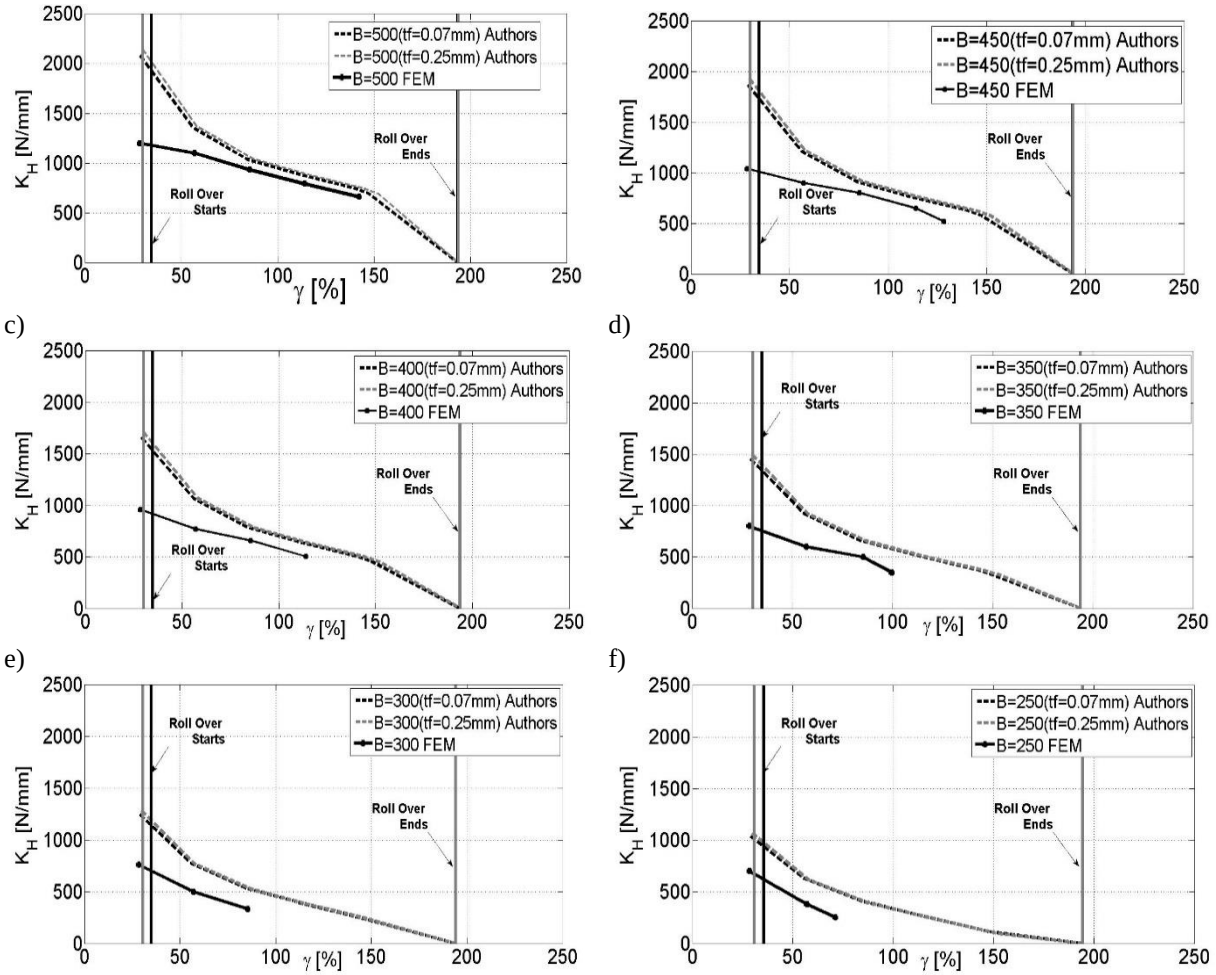

Figure 7: Horizontal stiffness vs deformation (authors vs. authors solution) for isolator with base of: a) 500mm, b) 450mm, c) 400mm, d) 350mm, e) 300mm, and f) 250mm.

It can be noted that analytical formulation provides a higher value of lateral stiffness, due to initial contribution of rubber compressibility to vertical displacement under design load. This was also confirmed by experimental observations [18], [21]. It can be noted that displacements where roll-over begins and is complete change for all geometries. This is due to the following: in order to determine the total vertical displacement (u_P), while u_r remains constant (H_r is almost constant for all prototypes), u_{rf} changes according to the characteristics of the fiber and the geometrical dimensions of the isolator. Numerical provision is only given up to a limited value of the shear strain $\gamma = B/(2H_r)$, according to stability limit found by the authors as corresponding to horizontal tangent stiffness of the force-displacement curve. As far as the influence of the fiber reinforcement is concerned, it can be said that according to analytical model, for a constant value of the total rubber height, SET1 was expected to be stiffer in the horizontal direction due to higher settlement under design load. In reality, SET 1 was lightly more flexible in horizontal direction due to lower total rubber height than SET2 thus determining a lower contribution of u_r. No difference arises in terms of FEM provision.
For the analytical model, a different value of G was assumed for each strain level, according to experimental results from a previous investigation, where a value of 0.6 MPa for large strain levels (up100%) was obtained, which is similar to the value used in the FEM analysis (0.7 MPa) [21].

5 CONCLUSIONS

The paper presented an interesting comparison between analytical formulations and numerical FEM results available from literature. The following conclusions can be drawn:

- The analytical model provided a bilinear constitutive behavior for the vertical stiffness of FREIs, considering a first part where the pure rubber is carrying the load and a second part with the fiber becoming effective in confining the rubber.
- The horizontal stiffness assessment by analytical formulation permits to account for both contact area and modulus reduction whereas FEM analysis are usually stable under particular model assumptions;
- The horizontal behavior can be investigated by analytical formulations even at larger displacements up to a complete rollover of the bearing;
- The analytical model can be applied with excellent accuracy for different geometries (square, strip or circular), materials, and dimensions of the isolators by implementing the suggested formula and steps in a simple spreadsheet.

Abstract

This paper presents the results of an investigation on full-scale innovative low-cost unbounded polyester-fiber reinforced high-damping elastomeric isolators (UPFREIs) to be used for seismic protection of residential buildings in Colombia, South America. In order to characterize the mechanical behavior of the UPFREIs, two full-scale prototypes were manufactured and tested at the Structures Laboratory of the Universidad del Valle. The experimental results were compared with results from the same test performed with two traditional connected steel reinforced isolators (SREIs). Both isolation systems were designed for a residential 5-story building with a target period of 2,5s located in a medium-high seismicity region. A dedicated set-up was designed and built specifically for the experimental tests. Results from shear tests up to 100% shear strain with sustained axial load exhibited very satisfactory behavior of the UPFREIs versus the SREIs with no residual deformation after unloading. An enhanced damping mechanism with damping ratio between 10 and 15 % was provided by the frictional fiber interface. Lower horizontal stiffness of the UPFREIs was obtained at higher deformation levels due to the typical rollover deformation. Despite the higher axial flexibility with respect to SREIs, UPFREIs also provided an adequate vertical to horizontal stiffness ratio. The results show that the developed UPFREIs have great potential to be implemented as a low-cost seismic isolation system of residential buildings.

Keywords: *UPFREIs, SREIs,* High Damping Rubber, Unbounded Isolators, Polyester Fiber Reinforcement, Seismic Isolation.

1 INTRODUCTION

Base isolation is a technique through which the structure is uncoupled from the ground by installing flexible bearings at the foundation's level. This reduces the potentially damaging motion that earthquakes transmit to the structure and decreases the economic and human life losses after the event [1]. The isolation system has been widely studied [2]–[5] and implemented in developed countries with more than 12000 projects [6], and its effectivity has been proved during different seismic events worldwide [7], [8]. An important number of developing countries are considered as high seismic activity regions, with the most devastating earthquake records in the last decades; however, the isolation system is rarely implemented in their infrastructure. Colombia is a distinct example of this, with seismic events like Armenia (January 1992, magnitude 6.6) earthquakes, which caused more than 2500 human losses, 6000 wounded, 43000 houses damaged and 50000 destroyed, in total. However, until 2016, only three buildings were isolated for a special use (education and health). The limited implementation is related to two main aspects. First, the most common type of isolation device is the steel-reinforced multilayer elastomeric isolator (SREI) [9], which is generally large, heavy and expensive due to the highly labor-intensive manufacturing process [10]. Second, the absence of manufacturing companies in Colombia requires the devices be imported which considerably increases the final cost of the isolator. For these reasons, their application has been only justified for large and expensive buildings, and they have not been accepted for typical residential buildings [11]. The production of low-cost seismic isolation systems, using a relatively simple manufacturing process, could encourage the applications of this type of earthquake-resistant strategy to ordinary housing and commercial low-rise buildings (three to five stories), which represent more than 80% of the constructions projects in the urban areas of the country.

Reducing an isolators' cost and weight can be achieved by replacing the traditional steel plates with fabric reinforcement [12]. This type of device is known as fiber-reinforced elastomeric isolator (FREI), which can be manufactured using conventional fiber, such as carbon (bi-directional or quadri-directional fabrics), glass or nylon [13]–[17]; and non-conventional fibers, such as carbon-fiber-reinforced plastic meshes, polyamide and engineering plastic sheets [18]–[21]. The type of connection used between the FREIs and the structure is another aspect that can be modified [22] by selecting between fully anchored (bonded condition) or unanchored (unbonded condition). In the first case, the isolator is bonded to two steel end plates that are mechanically fastened to the supports; in the second case, these plates are eliminated and the isolator is placed between the upper and lower supports with no mechanical restraints [23]. This option results in less weight, lower cost and easier installation of the isolator. Regarding the behavior, during horizontal displacements the corners of unbonded FREIs roll off the supports due to the unbonded condition and the lack of flexural rigidity of the fiber reinforcement. This eliminates the high tensile stress regions developed in a bonded isolator when it is displaced horizontally [24], [25].

The aim of this paper is to evaluate a novel unbounded polyester-fiber reinforced high-damping elastomeric isolators UP-FREIs, proposed for low-rise residential buildings, which are the most common type of projects in the principal cities of Colombia. The full-scale devices were manufactured with materials and technology commercially available in Colombia, in an unbonded condition, without lead core and with a high damping rubber (HDR) matrix. As a reinforcement material, a polyester fiber mesh was proposed and compared with the tra-

ditional SREIs. The specimens were tested under shear and compression loads applied simultaneously, to determine mechanical properties, such as stiffness and damping.

2 DESIGN AND MANUFACTURING OF THE PROTOTYPES

The prototypes were designed for a five-story structure whose dimensions are shown in Fig. *1*, and represents a typical building in the city of Santiago de Cali, Colombia. The structure has a total self-weigh of 21310kN with a natural period of 0.5s in the fixed base configuration and 2.5s in the base isolated one. The assumed location of the structure was the seismic Zone 2 of the city, which has a design acceleration of SM1=0.50g corresponding to a 950-year return period event. The prototypes were design according to FEMA450 requirements [26], adopting the formulations developed by Naeim and Kelly [27], the characteristics of the ground motion at the site and the properties of the materials used for manufacturing. The maximum design displacement (D_M = 320mm) was calculated according to the maximum acceleration at the site, assuming an equivalent damping ratio of 6%. The building is considered to be supported by 20 isolators, each one designed for an ultimate vertical load of 2000kN and a target stiffness of 681N/mm. Assuming a design shear strain of 114% and a vertical pressure of 6.8 MPa, an isolator with 277.4 mm total rubber height and 620 mm diameter is defined. According to these characteristics, the building was modelled in SAP2000 for an assessment of the expected behavior. In particular, the maximum base shear, story drift and accelerations reduce by 60 to 70% in the isolated configuration with respect to the fixed base one, thus confirming the capacity of the isolation system to reduce most relevant response parameters.

With the aim of selecting an efficient reinforcement and connection system for the isolators, from both economical and functional point of view, a different configuration was investigated using a high damping rubber compound developed by the authors [22]. Instead of the classical steel reinforcement, polyester fibers were considered. SREIs were only tested in bolted configuration in order to define a benchmark for FREIs. SREIs were not considered in unbolted configuration since this alternative is not deemed satisfactory in terms of both mechanical behaviour, due to flexural rigidity of internal steel shims, and higher cost and weight with respect to FREIs. Konstantinidis and Kelly [23] demonstrated that the usual thick and inflexible steel plates can be replaced by thin and flexible reinforcements to produce low-cost rubber isolators one order of magnitude cheaper. Considering the influence of the internal reinforcement cost (fiber layers versus steel plates) and different manufacturing process, the cost of UP-FREIs is estimated in the order of 30% less than the SREIs. Additionally, UP-FREIs have lower weight and provide additional benefits in terms of handling and installation process.

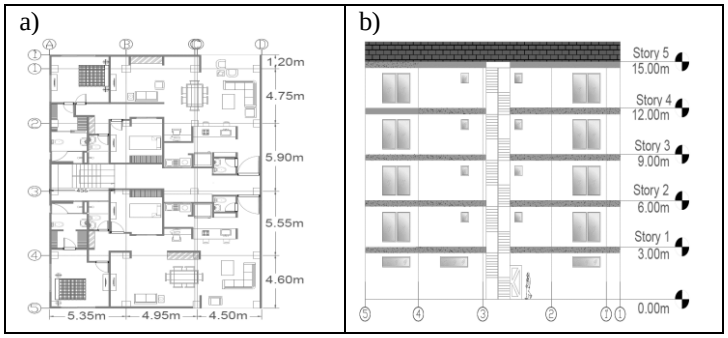

Fig. 1. Dimensions of the design structure a) plan view and b) front view.

Two different sets of isolators were manufactured with a different reinforcement and the same number of layers ($n_f = 37$): i) (SREI) type 1 (T1), 1.9mm A-36 steel plates with yield stress of 254MPa and ultimate stress of 408MPa (*Fig. 2*a); and ii) (UP-FREI) type 2 (T2), 1.1mm bidirectional polyester fiber fabric with an elastic modulus of 1.176MPa (*Fig. 2*b). For all prototypes, the same diameter (exterior $\phi_e = 620$mm and interior $\phi_i = 610$mm), rubber thickness ($t_r = 7.3$mm) and number of layers ($n_r = 38$) were assumed, with a secondary shape factor (external diameter/total rubber height) of 2.2. Steel top and bottom plates ($t_{T,B} = 25$mm) with six fixed bolts of 22mm diameter were provided for the connection system of the SREIs. In total, four specimens were tested, two for each type (Table 1).

Type	Sample	Reinforcement	Connection
1	a b	Steel plates	Bolted
2	a b	Polyester fiber	Unbolted

Table 1. Types of isolators for experimental campaign.

3 SHEAR TEST SETUP AND PROTOCOL

The prototypes were tested under simultaneous shear and compression loads. In the vertical direction, a 2000kN load was used and the corresponding vertical displacement was measured. A displacement protocol, considering the testing program in FEMA450 [26], was applied horizontally, which should be carried out on the isolators prior to installation by using the design displacement as the maximum deformation (114%). The protocol was composed by three parts: part 1, consisted of three fully reversed cycles of loading at each increment of displacement ($0.25D_M$, $0.50D_M$, $0.67D_M$, $1.00D_M$); in part 2 three fully reversed cycles of loading at the maximum displacement ($1.00D_M$) were applied; in part 3 ten continuous fully reversed cycles of loading at 0.75 times the total maximum displacement ($0.75D_M$) were used (*Fig. 3*a) [26]. Due to the characteristics of the setup and the rollover process of the T2 prototypes, the third part of the protocol was applied up to $0.90D_M$ (102% strain) (*Fig. 3*b); and for both cases, according to the control system of the setup a period of $T = 100s$ was possible used. The correspondence between the percentage of D_M and γ_s is presented in Table 2.

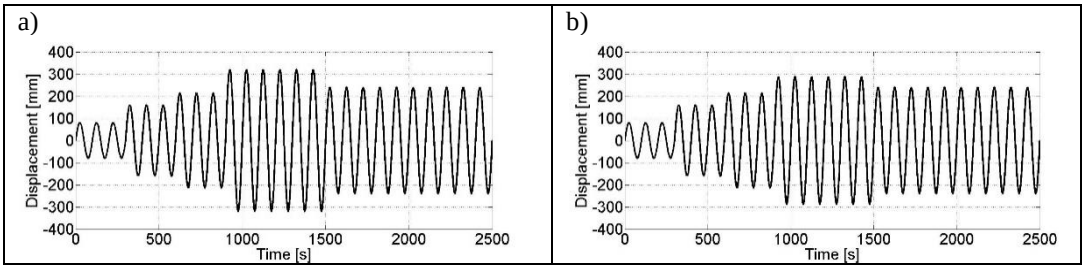

Fig. 3. Displacement protocols for the shear tests for: a) T1, and b) T2.

$\%D_M$	γ_s [%]	Displacement [mm]
0.25	29	80
0.50	57	160
0.67	77	214
0.75	86	240
0.90	105	290
1.00	114	320

Table 2. Equivalence between percentage of D_M and γ_s.

For the shear test program an experimental platform was designed and built at the Laboratorio de Pruebas para Homologaciones (MaP-H) of the Universidad del Valle. The setup was made by steel frames with a dedicated reaction framework. The setup allows to apply a total cyclic horizontal load up to 1000kN to two isolators in double shear configuration under a constant vertical load of 2000kN. The vertical load was applied through two hydraulic actuators with a capacity of 1000kN each and 100 mm stroke. For the horizontal load a hydraulic actuator with a stroke of ±500mm and a force capacity of 1000kN was used. Finally, instruments to measure the sliding guides position, the vertical load and the lateral load time-histories were employed (*Fig. 4*).

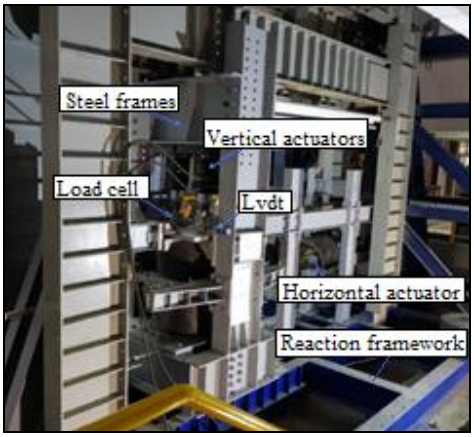

Fig. 4. Shear test setup.

4 SHEAR TESTS RESULTS

Through the shear tests, the hysteresis loops shown in *Fig. 5* were obtained. In all cases, a stiffness reduction with respect to the first cycles was observed for each deformation levels, due to the rupture of the bonds among the polymer chains and the reinforcement particles (Mullins effect) [28]. Secant stiffness and equivalent damping ratios parameters [29] were calculated for each step of the applied protocol (*Fig. 6* and *Fig. 7*). The T2 prototypes showed lower stiffness than T1 (50% less for the design level) due to the reduction of the contact area, when top and bottom faces roll off the contact supports, as a result of their unbonded conditions (rollover deformation) [14]. However, these prototypes showed a stable rollover and returned to their initial position after each test without residual deformation. Regarding the target horizontal stiffness (680N/mm), with T1 a lower period in the building will be obtained (2.3s); however, due to the minimum difference (8%), an acceptable behavior in the isolated building could be expected. Meanwhile, with T2 a period higher than the design one will be achieved (3.2s) because, for compari-

son purpose, the same dimensions of T1 was used without taking account the detachment of the area during the roll over process.

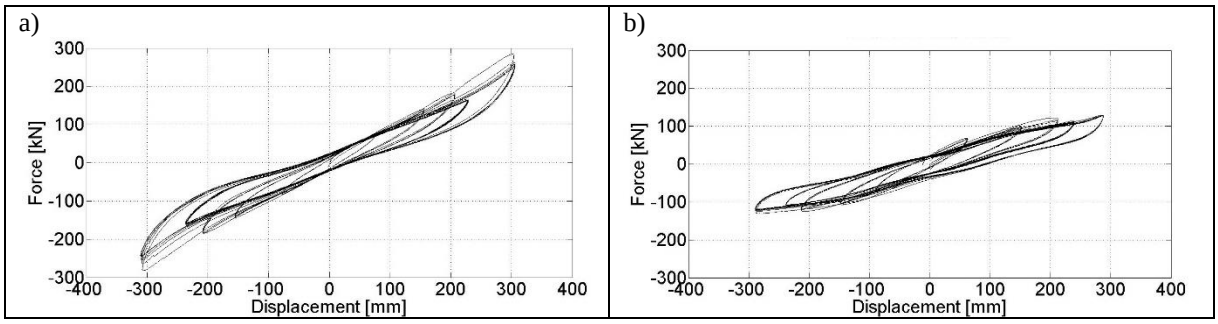

Fig. 5. Hysteresis loops isolators: a) T1, and b) T2.

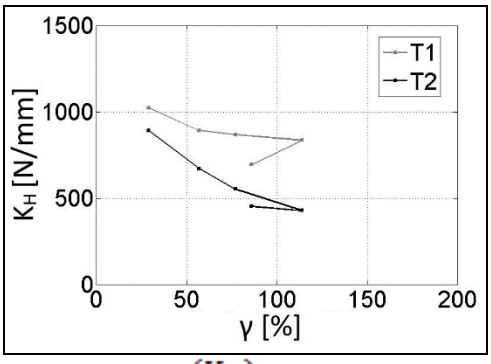

Fig. 6. Horizontal stiffness (K_H) versus shear deformation (γ_s).

As expected, in all cases the damping ratio was higher than the one obtained for the pure rubber (*Fig. 7*) [15], due to interaction with the reinforcement, being this effect more significant in prototypes T2. However, for both cases the damping ratio was higher than the required value for the design process (6%). It can be noticed that, for all deformation levels, the damping ratios of the unbonded isolators tends to be larger than those of the corresponding bolted one. Specifically, for T2 damping ratios higher than 10% were always attained, which are expected values for FREIs with high damping rubber [14]–[16], [30], [31]. Even though the secant stiffness of UP-FREIs was lower than steel reinforced one (T1) (*Fig. 6*), higher values of damping ratios can ensure a superior hysterical behavior of UP-FREIs with respect to SREIs (*Fig. 7*). With respect to the design target stiffness, UP-FREIs exhibited a 37% lower value despite to SREIs having 22% higher stiffness.

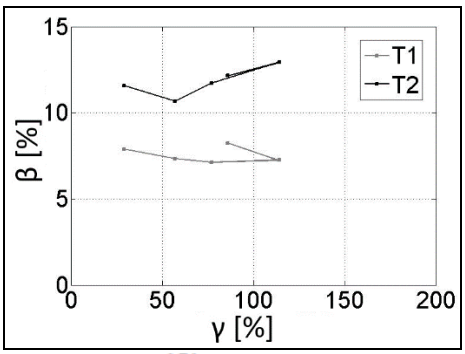

Fig. 7. Damping ratio (β) versus shear deformation (γ_s).

In T2, the flexibility of the reinforcement allowed the unbonded surfaces to roll off the loading surfaces and relieving the tensile stresses [12], achieving the design deformation without damage (*Fig. 8*b). In one of prototypes T1, the failure occurred due to the delamination of some layers. This detachment may be produced by a deficient impregnation process when the adherence material was applied to the steel plates and by the high tensile stress regions developed in this bonded device (*Fig. 8*a). In Table 3, the results for the tested deformation levels are summarized.

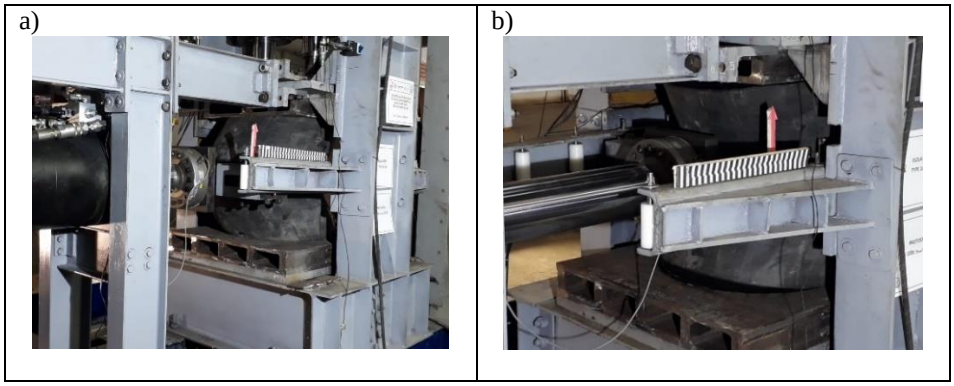

Fig. 8. Deformation of the isolators during the shear test: a) T1, and b) T2.

Table 3. Isolator's properties for $\gamma_s = 29\%, 57\%, 77\%, 105\%$ and 114%.

Regarding the vertical behavior, displacements during initial axial loading were measured in order to estimate a secant vertical stiffness (K_{Vs}) of the devices (Table 4) to be compared with the horizontal one at the design displacement level. The lower vertical stiffness of FREIs compared with classical SREIs has been commonly acknowledged [23]. This aspect can be seen in Table 4, where, as expected, UP-FREIs are more flexible than SREIs in the vertical direction due to lower stiffness of fiber layers [13]. Since the horizontal to vertical stiffness ratio is one order of magnitude lower in the case of UP-FREIs, at the current state of development these isolators could be mainly devoted to low rise buildings that would produce lower settlements under self-weight. (Table 4). Results on UP-FREIs confirmed that analytical models for stiffness evaluation have to take into account both contact area and shear modulus reduction [32]. A deeper investigation is ongoing on stability issues and vertical stiffness of FREIs, as well as different fiber reinforcing layers.

Type	K_{vs} [kN/mm]	K_H [kN/mm]	K_{vs}/K_H
T1	2500	0.84	2976
T2	100	0.43	233

Table 4. Isolator's vertical stiffness and vertical and horizontal stiffness ratio.

5 CONCLUSIONS

- This paper presents a preliminary investigation of novel FREIs reinforced with polyester fiber, whose mechanical properties were obtained through a full-scale experimental program, according to the requirements of FEMA450.

- Compared to SREIs, the UP-FREIs showed a satisfactory behavior with a lower horizontal stiffness due to the rollover deformation and higher damping ratio. In order to obtain a target horizontal stiffness in unbounded applications, the variation of the contact area and the shear modulus should be considered simultaneously.

- A satisfactory behavior of UP-FREIs was obtained in the horizontal direction, thanks to lower stress at the interface between different layers, achieving the design strain without failure. They showed a positive tangent stiffness and stable roll over. Also, the UP-FREIs provided an adequate vertical to horizontal stiffness ratio, which could ensure a stable behavior of the isolators under vertical and horizontal loads.

- The results highlight an interesting comparison between UP-FREIs and SFREIs, with both satisfying required design values. Nevertheless, taking into account the fact that the price of polyester fiber is less than steel plates and that manufacturing process of the UP-FREIs is cheaper, this seems to be a very promising option, with greater potential to be implemented as a lighter and lower-cost seismic isolation system for developing countries.

Keywords: Seismic isolation, Metamaterials, Periodic structures, local resonant foundation

Abstract. *This paper presents an attempt to evaluate the feasibility and the effectiveness of an innovative foundation, which relies on the concept of local resonance, from a practical point of view. The proposed composite foundation integrates the well-established isolation system of lead rubber bearings in a layered structure form with reinforced concrete slabs, in order to tackle the inherent drawbacks of the bearing isolation. The novel foundation concept is implemented in a realistic structural geometry, designed according to the current standards, and the seismic performance is evaluated and compared against the corresponding typical base isolated and conventional stiff designed buildings. The results show that the proposed foundation concept achieves superior seismic performance in comparison to standard base isolation, providing an applicable and cost efficient solution in the framework of metafoundations.*

1 Introduction

The often catastrophic consequences of earthquakes have stimulated research in the field of seismic isolation (SI) since more than 100 years. Many works summarize the state of the art in SI ([1], [2]). As stated by [1] "achieving the level of performance provided by seismic isolation is virtually impossible through conventional construction". From the designer's point of view, SI systems are displacement- rather than force-sensitive and better comply to displacement-based design methods as these are more physically consistent [3]. Furthermore, the nonlinear response of SI systems is concentrated in the isolator and damping devices with known force-displacement relations, thereby facilitating the realistic modelling of the behavior of the system in the nonlinear range. The idea to decouple the structure from the ground motion, though conceptually simple, fails to prevail conventional fixed-based designs in the majority of the implementations. The failure of SI to establish itself as a broadly applicable design solution stems from the inherent weaknesses of the existing seismic isolation solutions, namely the large deformations at the isolation level during ground motions and the resulting displacements. These problems are usually tackled with additional costly damping devices that, however, rarely reach an equivalent global viscous damping above 20%, setting questions on the efficiency of the displacement reduction through energy dissipation [3], [4]. Therefore, it becomes essential to further optimize the base isolation concepts, in order to extend their applicability to conventional structures.

The aforementioned limitations of typical base isolation systems led numerous researchers to the possibility of employing new anisotropic materials to develop innovative earthquake protection systems. Several studies present applications of such materials on foundations, introducing the term periodic foundations or metafoundations [5, 6]. The potential advantage of metafoundations against conventional base isolation is in reducing the large displacement demand by reflecting the incoming energy on the interfaces and/or by dissipating energy through local resonance. Since the pioneering works on phononic crystals and metamaterials [7, 8, 9], a lot of recent interesting studies in the framework of metafoundations have been published [5, 6, 10, 11, 12, 13, 14, 15, 16]. The crucial challenge is the realisation of a sufficient band gap, targeting the main frequency content of the earthquake excitation and the characteristic frequencies of the isolated structure (normally between 0.5-10 Hz), while maintaining the dimensions of the foundation in a realistic range. Dertimanis et al. [17], [18] analytically investigated the feasibility of reaching a frequency band gap focusing in the range of [0.5, 5] Hz by implementing locally resonant structures. Recently, Casablanca et al. [19] designed a composite foundation comprising four reinforced concrete slabs, each vertically disconnected from the others through a combination of steel and Teflon layers. The foundation was tested experimentally under harmonic excitation, without considering the coupling between foundation and superstructure, the effect of realistic vertical loads and the lateral stiffness against minor horizontal loads. Although recent works provide optimistic results, the proposed concepts are far from applicable to engineering practice. The disproportional large dimensions of the proposed unit cells cannot be justified even for special structures, while there are still plenty of unresolved issues, for instance the reach of an effective band gap, the transmission of the vertical loads to the ground and the reach of sufficient lateral stiffness against minor horizontal loads. To this end, a novel local resonant foundation, tailored to an example realistic structure, is designed to fulfil the codal requirements and its performance is numerically tested and compared against the current state of the art.

Figure 1: Overview of the foundation concepts

2 Conceptual design of the novel foundation

In this study, we present an innovative foundation concept, namely local resonant foundation (LR), based on the combination of alternating lead rubber bearings (LRB) and reinforced concrete slabs (Figure 1c). The substantial vertical stiffness and bearing capacity pertaining to the LRBs guarantee the safe transfer of the vertical loads to the ground, while the lead core and the high damping coefficient provide increased initial stiffness and suppress the oscillations due to wind and ambient excitations. The concrete slabs provide masses that introduce additional degrees of freedom to the system in the horizontal direction. The additional modes act as a filter on the induced seismic motion through local resonance of the concrete slabs. With proper tuning, the filter range can target the frequency of the oscillating superstructure and essentially reduce the induced seismic response. In order to further optimize the foundation geometry, the metafoundation blocks are placed directly below the stiffening elements of the structure. The novel foundation concept is implemented in a realistic structural geometry and the seismic performance is evaluated and compared with the corresponding typical base isolated and conventional stiff-designed buildings (Figure 1). The performance of a proper designed local resonant foundation, tailored to the specific structure, proves to be remarkably superior and more robust in comparison to the equivalent base isolated structure, while keeping the costs in approximately the same range.

3 Application on the seismic design of a conventional building

In order to evaluate the performance of the novel foundation in a realistic framework, a simplified, though realistic, structural geometry was selected. A six-storey, shear wall building was designed according to the current standards for three different foundation cases: conventional fixed base structure (FX), base isolated structure (BI) and local resonant isolated structure (LR). An overview of the building geometry and the different foundation concepts is given in Figure 1. In order to focus on the effect of the foundation, the structural geometry is selected to be symmetric and to conform with the simplicity criteria prescribed in Eurocode 8 (EC8). The seismic design was conducted according to EC8 for a region of high seismicity (PGA = $0.36g$). The target spectrum, illustrated in Figure 2, corresponds to soil conditions C and equivalent

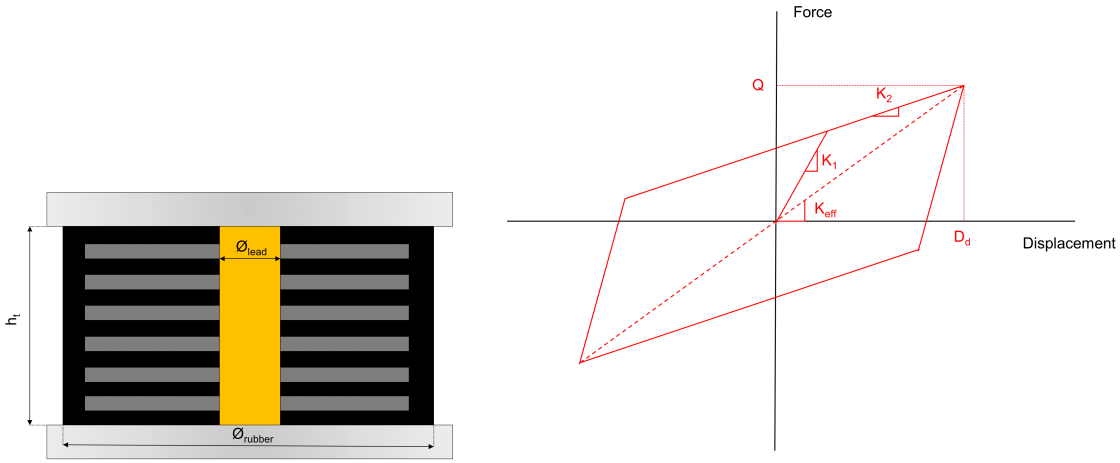
1230	ST576	Izmit	1999	4.52/3.21

Table 2: Selected ground motions

For the comparison of the different foundation configurations nonlinear time-history analyses were conducted. A group of seven ground motion records, combatable with preliminary criteria summarized in Table 1, was selected from the European Strong-motion Database (ESD). Both horizontal components of each record were simultaneously applied on the 3D numerical models, according to EC8. The selected ground motions were properly scaled to match the target spectrum. The selection and scaling of the ground motions was conducted with the software packet REXEL [21]. Information regarding the selected ground motions are summarized in Table 2, while the corresponding frequency spectra are depicted in Figure 2.

The conventional fixed-base design yields tension forces on the foundation level due to the high bending moment. A pile foundation is designed in order to transfer these forces to the ground. It is well understood that in order to eliminate or reduce the tension forces, it could be possible to optimize the dimensions of the shear walls. For comparison reasons, however,



(a) schematic cross-section (b) bilinear modelling of LRBs

Figure 3: Lead rubber bearings

the structural system is considered identical for all different foundation cases. The BI case was designed based on the current standards. The nonlinear modelling of the isolators is based on the bilinear approximation, as suggested by [20] (Figure 3). The properties of the isolators are summarized in the Tables 3 and 4. A total of 28 isolators was implemented for the design of the base isolated building (Figure 1b).

Table 4: Material and structural properties of the lead rubber bearings

The LR foundation is designed to support the vertical loads according to the current standards. The performance against horizontal excitation is studied through nonlinear time-history analysis. To further optimize the material and the geometry, the novel foundation is designed for placement directly beneath the stiff elements of the structure. In the present case, the shear walls form the horizontal resisting system that transfers the seismic energy to the upper floors. The columns are supported directly to the ground with pinned joints, in order to allow for minor displacements and rotations due to horizontal loads. For a direct comparison, the same isolator configurations, as for the BI case, were used for the design of the LR foundation. For the proposed configuration a total amount of 48 isolators was implemented. The novel foundation concept is presented in Figure 1c.

4 RESULTS

4.1 Modal characteristics

This section overviews the dominant modal shapes that primarily contribute to the response of each system. The fundamental period of the fixed-base structure (FX) is 0.88 sec and corresponds to the bending mode of the building. The BI structure initially responds as a rigid body, with a fundamental period of 2.67 sec. The second characteristic period is equal to 0.56 sec and refers to the bending mode of the building. The LR foundation system also mainly responds as a rigid body with a period of 5.65 sec. The second modal shape describes the rotation around the central vertical axis of the building (1.18 sec). In the third mode (0.53 sec) the bending response of the building is activated. Finally, the fourth mode describes the local resonance of the foundation layers (0.4 sec). It is important to mention that the local-resonance mode is tuned to result close to the characteristic mode that expresses the bending response of the building. As a result, the seismic energy in this frequency range is significantly dissipated already at the level of the foundation, before reaching the structure, leading to a remarkable reduction of the internal demand (Figure 4).

4.2 Displacement response

This section discusses the response of the systems, in terms of displacements. For reasons of clarity, only the results of two representative time history analyses are examined. The Waveform 0333 is requires the lowest scale factor to match the target spectrum, providing more realistic results, while the Waveform 1230 comprises a broad frequency content in the vicinity of the

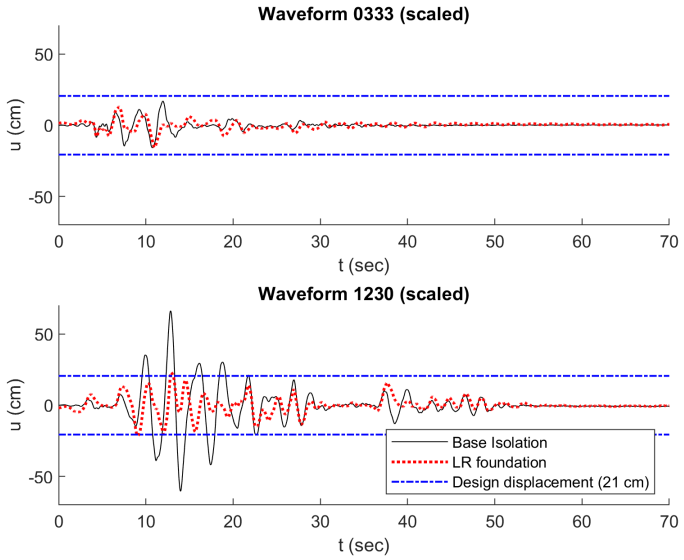

Figure 5: Bottom displacements

Waveform ID	BI	LR
0333	17	16.6
1230	66.2	24.2

Table 6: Maximum bottom displacements [cm]

structural bending mode (Figure 2b). Considering that the structural stiffness is uniformly distributed both in plane and in height, the top-bottom drift comprises a reliable indicator of the structural demand. Figure 4 contrasts the top-bottom drift response of the three different systems. The absolute maximum drift-displacements are summarized in Table 5. As it would be expected, the BI structure yields $50-65\%$ reduced drift-displacements in comparison to the fixed-base structure. The LR foundation provides a further reduction of 74% in comparison to the drift of the BI structure. In other words, the LR foundation reduces the elastic structural demand up to 85% compared to the FX structure.

In order to obtain an overview of the global response of the novel foundation, it is of interest to examine the base displacements of the two isolated systems. Figure 5 illustrates the base displacements due to the examined ground motions. The absolute maximum base displacements are summarized in Table 6. For the waveform 0333 both systems yield displacements of approximately similar amplitude, lower than the design displacement of the LRBs (20.6 cm). For Waveform 1230, however, the BI structure yields displacements up to 66 cm corresponding to more than three times the design displacement of the isolators. For a regular BI design this would require the application of external dampers to the system, in order to reduce the displacements to the acceptable range. For the same excitation, the LR foundation experiences displacements in the range of the design displacement, 63% lower than the BI system. Overall, the performance of the LR foundation proves to be superior to the performance of regular base isolation. By filtering out the frequency content in the vicinity of the structural bending mode, the LR foundation manages to reduce the structural demand without compromising the stability of the structure.

4.3 Cost considerations

Taking into account the applicability and the cost efficiency of an engineering solution is crucial even at the very beginning of the conceptual design. For this reason, the proposed novel foundation concept is designed according to the current standards, while the structural details are formed as simple as possible. Since the LR foundation is actually a composite structure, consisting of precast concrete slabs and LRBs, the application should not remarkably affect the overall costs. Considering that the LR foundations are placed locally beneath the structural walls, the extent of the application is limited, compared to base isolation, which extends to the whole ground floor area. According to the actual market prices, the designed isolators would cost ca. $5'000$ Euro/piece. The BI was designed with a total amount of 28 LRBs, while for the LR foundation the amount of the isolators increases to 48. This translates to an additional investment of approximate $100'000$ Euro for this specific example. According to the analyses, the BI system requires additional damping units to provide acceptable performance, the application and the material costs of which are expected to exceed this amount. Finally, regarding the FX structure, the installation and application costs for a pile foundation is certainly the most expensive solution. One should also consider the additional time for the necessary installations and the execution of the pile driving. Once again it is mentioned that in such a case it would be more reasonable to adjust the structural system in order to reduce or even eliminate the need for a pile foundation. For comparison reasons, however, the structural system is here considered the same for all foundation concepts.

5 CONCLUSIONS

The application of metamaterials for the development of a new generation of seismic isolation is currently a very attractive field for interdisciplinary research. Scientists combine knowledge from different domains in order to build a new line of defence against the destructive force of earthquakes. So far, however, no practical configurations, of reasonable dimensions, that could provide desirable performance against vertical and horizontal loads exist. In the present study, a novel foundation concept, consisting of LRBs and precast concrete slabs is designed to fulfill the normative requirements for the support of vertical and minor horizontal loads. The seismic performance proves to be remarkably superior to the equivalent base-isolated and fixed-base structures, for an example realistic geometry of a conventional building. The promising results of this preliminary study set the basis for the further investigation on the use of composite local resonant foundations to filter out the seismic energy content in the frequencies of interest.

Abstract

High-voltage equipment representing a tall and slender system is quite common. Capacitor racks and valve towers are common examples of such equipment. A representative example of such equipment is analyzed in this paper. Due to electrical isolation purposes, this type of equipment is usually comprised of brittle porcelain insulators or polymer insulators with low damping. The insulators are used as columns, main load carrying elements. The system is relatively tall and slender. Because of the large masses installed at various elevations of the system and the narrow footprint in one of the horizontal directions, the system has a relatively low resonant frequency. Seismic protection of such systems with a potentially large overturning moment and low resonant frequency is quite challenging. For example, a regular seismic isolation has limited use. To improve the seismic performance of the system, friction dampers are introduced into the system. The friction dampers are studied extensively in full-scale component tests, as it is required by the current draft of the IEEE693 document. The results of component tests are used in the development of a numerical finite element model, which is subjected to an IEEE693-spectrum compatible strong motion to evaluate the seismic performance of the seismically protected system.

1 INTRODUCTION

High-voltage equipment representing a tall and slender system is quite common. Capacitor racks and valve towers are common examples of such equipment. A representative example of such equipment is analyzed in this paper. Due to electrical isolation purposes, this type of equipment is usually comprised of brittle porcelain insulators or polymer insulators with low damping. The insulators are used as columns, main load carrying elements. The fully assembled system is relatively tall and slender. Because of the large masses installed at various elevations of the system and the narrow footprint in one of the horizontal directions, the system has a relatively low resonant frequency. Seismic protection of such systems with a potentially large overturning moment and low resonant frequency is quite challenging. For example, a regular seismic isolation has limited use. To improve the seismic performance of the system, friction dampers are introduced into the system at its base. Performances of fixed base and isolated base equipment are discussed in this paper.

2 ELASTIC FINITE ELEMENT MODEL OF UNPROTECTED EQUIPMENT

A detailed finite element model of the equipment was generated in Nastran [1] as presented in the left image of Figure 1. It represented a five-story structure without any bracing system. The footprint of the system is very narrow in the Y direction of the global coordinate system. The shelving system is loaded with concentrated masses as presented in the left image of Figure 1. To increase the capacity in the Y direction, five insulators are installed in each row along the Y direction at the first two levels.

The first mode of vibration is presented in the right image of Figure 1. The second and the third modes of vibration are presented in Figure 2.

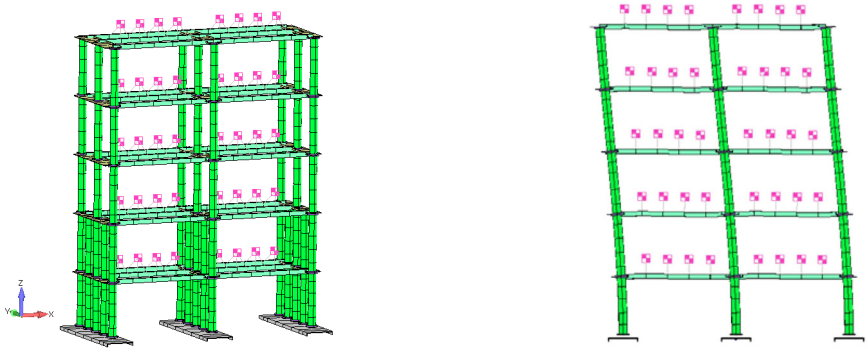

Figure 1: FE model (left) and first mode of vibration (right).

Figure 2: Second (left) and third (right) modes of vibration.

The first mode is a bending vibration mode in the X direction, the second mode is a bending vibration mode in the Y direction, and the third mode is related to the torsional vibrations of the model.

The Nastran model was used to perform an elastic spectral analysis. The IEEE693 spectra at 3% damping anchored at 0.5g was used in this analysis [2], which is presented in Figure 3. As required by the IEEE693 document [2], the same scaling factor of unity was used for spectral demands in the X and Y axes, whereas the spectral demand in the Z direction was at 80% of the one presented in Figure 3.

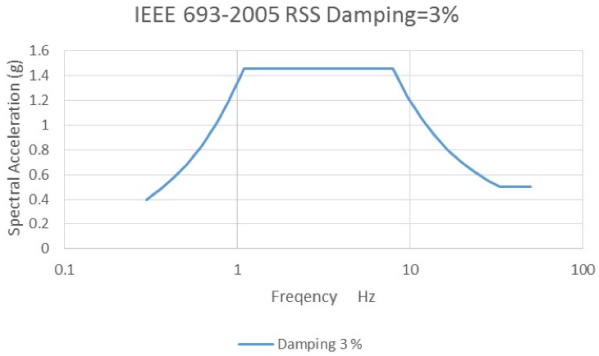

Figure 3: IEEE693 high required response spectrum (RRS) at 3% damping [2].

The spectral analysis revealed that the peak displacement on the top of the shelving system is 315.8 mm. Due to clearance issues, it is anticipated that the peak displacement on the top of the shelving system will remain under 200 mm. More importantly, the stresses in the insulator's polymer tubing were exceeding allowable stresses. The allowable stresses were estimated for a polymer tubing with cantilever load on the top at the half of Specified Mechanical Load (SML) value [2]. The capacity of polymer insulator controls acceptancy of the system's seismic performance, whereas the clearance limitations can be addressed by creating more separation from the neighboring equipment. A summary of the spectral analysis results is presented in Table 1.

Peak value	Results of spectral analysis	Clearance requirements or capacity	Demand to capacity ratio
Displacement at the top	315.8 mm	200 mm	158%[&]
Stress at the bottom of polymer tubing	147 MPa	95 MPa[§]	155%

Note: [§]-corresponds to 50% of SML stress in cantilever loading; [&]-not critical and can be addressed by increasing clearance

Table 1: Results of spectral analysis compared to clearance requirements or capacity.

Since the equipment could not meet both the clearance requirements and the tensile stress capacity of the polymer insulator, there was a need to use a protection device to improve its seismic performance. Based on previous successful applications (see [3], as an example), it was decided to introduce friction dampers [4] at the bottom of the shelving system and study the feasibility of using friction dampers in improving seismic performance of the system.

To follow the requirements of the upcoming version of the IEEE693 document [5], the friction dampers were tested in a component test setup to quantify their properties and performance.

3 COMPONENT TESTING OF FRICTION DAMPERS

The friction dampers were tested in a special test setup that was created for component testing of the dampers. As presented in Figure 4, the test setup simulates loading of the friction damper in a typical installation when the damper is installed as a stiffness and damping component of the anchoring system. Since the friction dampers work in compression only, there are several ways of using friction dampers as seismic protection devices. For example, if only one friction damper is used in the so-called single-acting configuration, the force will be developed in compression only as presented in the left side image of Figure 5. In this case, another spring or friction damper needs to be used on the tension side that corresponds to positive force and displacement to resist tension forces. When there is a damper on each side of the loading point, they create the so-called double-acting configuration. The force versus displacement curve is more symmetric in this case as presented in the right image of Figure 5.

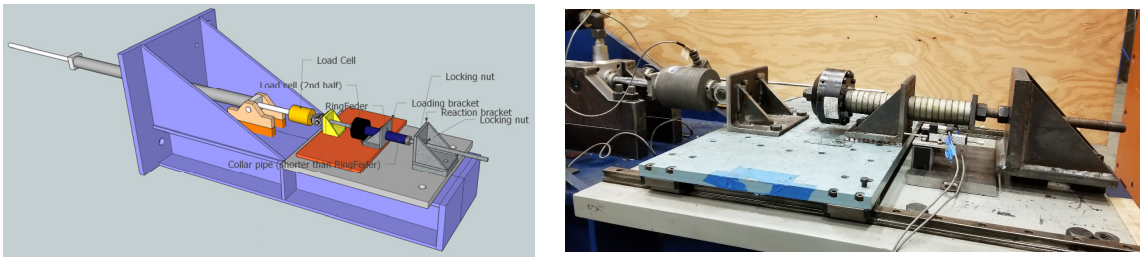

Figure 4: Component testing setup for Ringfeder friction dampers: sketch (left) and photo (right).

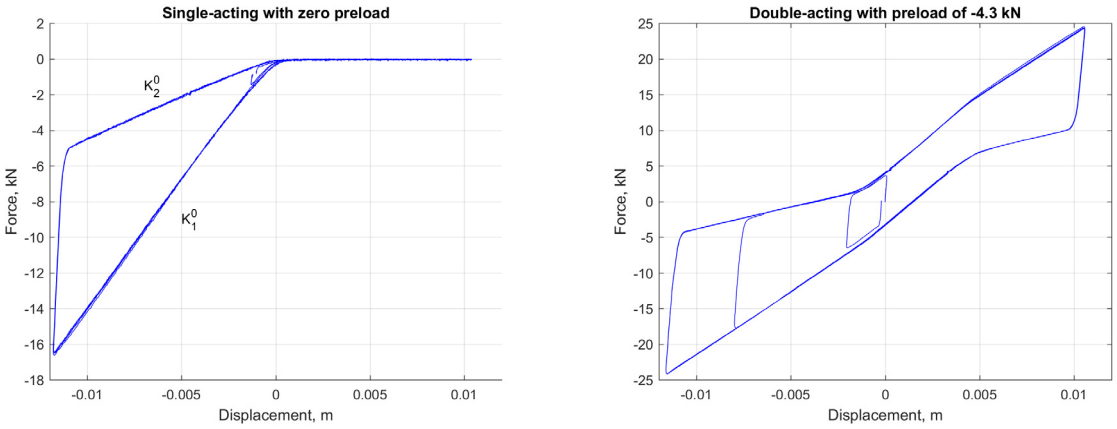

Figure 5: Force vs. displacement from component testing in single-acting with no preload (left) and double-acting with preload (right) configurations.

In addition to that, one of the dampers can be preloaded in compression, which is very common when the dampers are installed in a vertical configuration and the bottom damper is compressed under the dead weight of the equipment. The case with a preload of -4.3 kN is presented in the right image of Figure 5.

The dampers used in this study were installed in a double-acting configuration, where there is a damper on each side of the loading point. The latter results in symmetric behavior in tension and compression. A testing protocol followed recommendations of the upcoming version of the IEEE693 document [5], which is presented in Figure 6 on the left. The displacement D_{PL} corresponds to the maximum displacement of the device to be achieved at High Perfor-

mance Level [2]. A typical result for cyclic tests with increasing amplitude is presented in the right image of Figure 6.

More details on the numerical analysis of a high-voltage system with a double-acting friction damper can be found in [6].

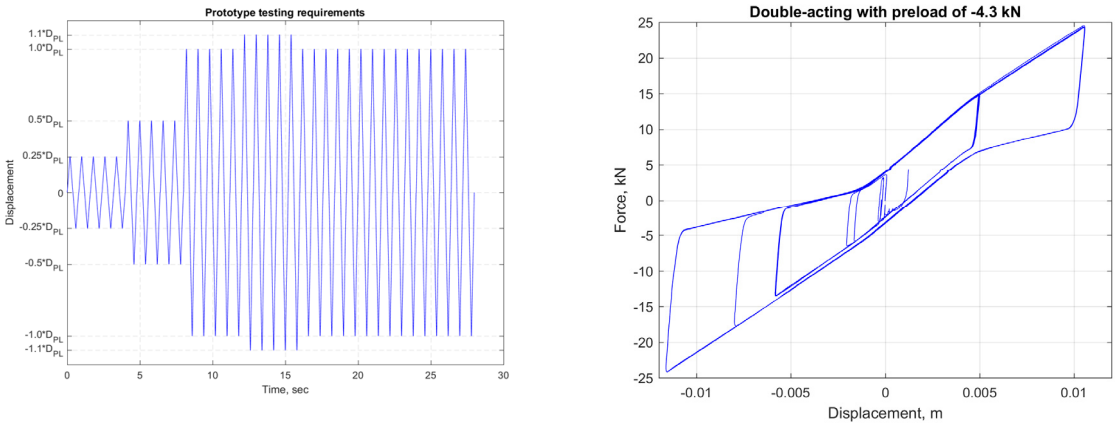

Figure 6: Component testing: protocol (left) and sample test results (right).

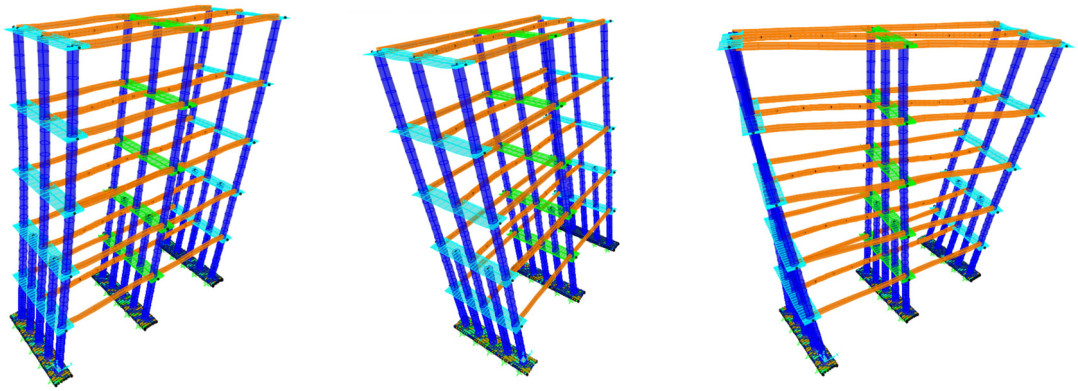
4 NONLINEAR FINITE ELEMENT MODEL OF PROTECTED EQUIPMENT

Another model of the equipment was generated in SAP2000 to utilize the friction damper model of this finite element software package [7].

The resonant frequencies are summarized in Table 2. The first three modes of vibration are the same as for the Nastran model as shown in Figure 7. The frequencies of the model generated in SAP2000 are slightly lower than that of the Nastran model as presented in Table 2, which is considered acceptable.



a) First mode b) Second mode c) Third mode

Figure 7: Elastic modes of SAP2000 model.

Model	Frequency of mode 1, Hz	Frequency of mode 2, Hz	Frequency of mode 3, Hz
Nastran	1.35	1.88	2.46
SAP2000	1.28	1.87	2.41

Table 2: Resonant frequencies of two elastic models.

In the next step of the study, the model generated in SAP2000 was subjected to tri-axial seismic excitation by utilizing TestQke4IEEE2, the IEEE693-spectrum compatible time histo-

ry [8]. This three-component time history was matched in a time domain to the IEEE693 spectra at 2% damping. Since the latter damping was closer to the critical damping of 3% estimated for this equipment shelving system, the newly generated IEEE693-spectrum compatible time histories matched to 5% spectra were not used [9]. The response spectra of each component of the input time history are presented in Figure 8. All results of experiments and numerical simulations presented herein are reduced in the Matlab environment [10].

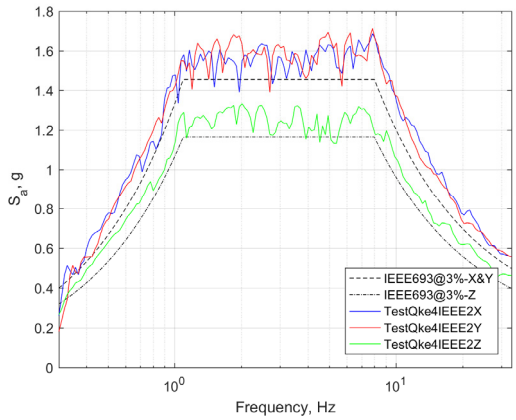


Figure 8: Response spectra of TestQke4IEEE2 [8] versus IEEE693 spectra.

Several finite element (FE) models were created. The first model, Case A, was simulating a fixed base configuration. All other FE models were generated by introducing friction dampers at the anchor locations attaching the bottom channels to the foundation as presented in Figure 9.

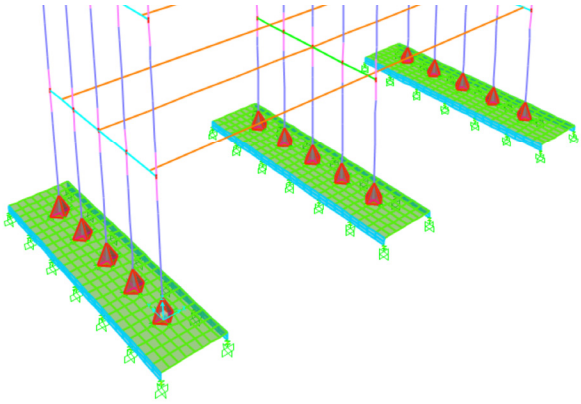

Figure 9: Friction dampers were introduced at anchor locations attaching bottom channels to foundation.

Depending on the presence of a preload, a finite element model of the friction damper [7] yields two typical force versus displacement diagrams as presented in Figure 10. It is worth noting that a simplified model of a friction damper [8] was utilized in this study. It was considered acceptable to investigate the feasibility of the system's performance improvement, if any.

The next model, Case B, was isolated by utilizing a model of the friction damper without a preload. There were several models simulating HV equipment isolated by friction dampers with different stiffness variations while keeping the preload the same as presented in Table 2.

All other models (Cases C1 through C4) were utilizing a model of a friction damper with the same preload. The stiffnesses K_1 and K_2 (shown in Figure 10a) varied from model to model as presented in Table 3. The stiffnesses were scaled up from the corresponding values measured in the test, which are shown in the left image of Figure 5.

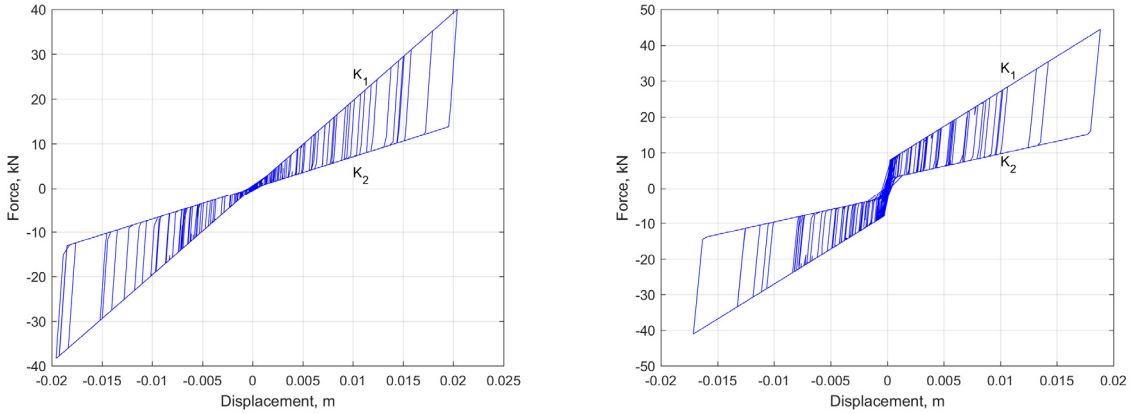

Figure 10: Typical force vs. displacement for double-acting configurations without (left) and with (right) preload: Case B vs. Case C1.

FE model	K_1/K_1^0	K_2/K_2^0	Preload, mm	1st frequency, Hz
Case A: fixed base	1.0	1.0	NA	1.28
Case B: friction damper	1.0	1.0	0.0	0.90
Case C1: friction damper	1.0	1.0	-3.81	0.90
Case C2: friction damper	2.0	2.0	-3.81	0.95
Case C3: friction damper	5.0	5.0	-3.81	1.01
Case C4: friction damper	10.0	10.0	-3.81	1.04

Table 3: SAP2000 FE models studied.

As it shown in Table 3, the low stiffness of the friction damper results in low frequency of the system, which is expected. The system with the lowest resonant frequency corresponds to the friction dampers tested in the component testing with no preload (Case B). The bending stress in the insulator is the smallest in this case as presented in Figure 11. However, the maximum displacement on the top of the system is very large (0.480 m in X direction and 0.243 m in Y direction). This is related to the fact that this system is much more flexible than the original system with a fixed base. The situation can be improved by pre-loading the friction dampers. In this case (Case C1), the maximum bending stress is still much lower than that of the fixed base system and peak displacements are reduced to 0.468 m. The bending stress is a little better for Case C1, but the system is still too flexible. Further optimization of the system performance leads to the Case C2 system, where maximum bending stress of which is slightly lower than the capacity of the polymer insulator. The maximum displacements go down to 0.424 m, which still requires a relatively large clearance around the system. All other FE models resulted in the bending stress that does not provide enough reduction in respect to the original system with a fixed base. A summary of the results is presented in Table 3. It worth noting that all systems with friction dampers have resonant frequencies below 1.1 Hz which is a corner frequency of the IEEE693 spectral plateau [2]. In other words, the demand on the systems is also reduced because the frequencies are located on the descending side of the

spectrum. Hence, the reduction of bending stress can be explained by both reduction of spectral demand and increase in overall damping of the system.

The following conclusion was made from the analysis of numerical models. The most optimal seismic performance is achieved for the Case C2 model. The results of nonlinear time history numerical simulations of the latter model show that the bending stress is right under the capacity of the polymer insulator. The peak displacement is still relatively high at 0.424 m, which is difficult to avoid due to increased flexibility of the system. The stiffnesses of the corresponding friction damper model are two times greater than those of the friction dampers tested in the component testing. The damper is used in the double-acting configuration with a preload.

More numerical simulations are planned for the future. A more sophisticated model closely replicating the actual performance of the friction damper depicted in the right image of Figure 5 will be utilized in the future study. Based on the results of this and future studies, the manufacturer of the friction damper will be approached with a request to provide this type of friction damper.

	Case A	Case B	Case C1	Case C2	Case C3	Case C4
Bending stress at bottom of polymer insulator to capacity, %	155.0%	77.2%	82.9%	99.8%	124.7%	133.7%
Displacement in X direction, mm	334	480	468	424	427	457
Displacement in Y direction, mm	154	243	233	217	194	169

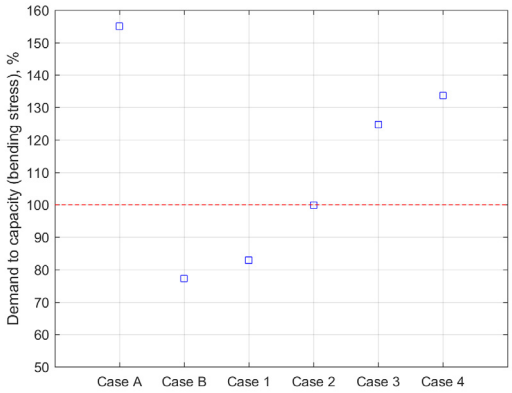

Figure 11: Variation of bending stress of the polymer insulator in respect to its capacity

5 CONCLUSIONS

- Based on a simplified model of the friction damper [7], the efficiency of the seismic isolation is demonstrated. It was shown that the peak moments can be reduced to remain under or meet the capacity. The peak displacements on top of the equipment will increase in respect to the fixed base mode. The peak displacement can be reduced by increasing the preload, but this reduction is limited.
- The most optimal seismic performance is achieved for the Case C2 model. The results of nonlinear numerical simulations show that the bending moment is right under the capaci-

ty of the polymer insulator. The stiffnesses of the corresponding friction damper model are two times greater than those of the friction dampers tested in the component testing.

- There is a need for a study with a more sophisticated model of friction dampers to be investigated in a nonlinear time history numerical simulation. A study on these issues is ongoing.

ACKNOWLEDGEMENTS

The project is sponsored by the Mitsubishi Electric Corporation whose support is greatly appreciated. The research team thanks Mr. Robert Cochran of Seattle City Light for donating Ringfeder friction dampers. Special thanks are due to the staff of the Structure Laboratory at the University of California, Berkeley. Special thanks are due to Mr. Llyr Griffith, Mr. Phillip Wong, and Mr. Matthew Cataleta. The successful completion of the testing phase of the project would not be possible without their technical support. Technical help by Ms. Sage Shamsai (CEE, UC Berkeley) on preparing 3D drawings and testing is greatly appreciated.

Abstract

Over the past decades the shift towards performance-based design and assessment of structures has led to the consideration of additional measures of structural performance other than just the structural response. Among these measures of performance, the expected economic losses after an earthquake event have attracted the attention of the research community because of their direct link with seismic risk and utility for post-earthquake emergency planning. The main objective of this study is to assess the accuracy and suitability of Nonlinear Static Procedures (NSP) for the computation of seismic fragility curves, which are then employed in the quantification of seismic risk, through annual rates of collapse exceedance and expected annual losses (EAL), for reinforced concrete (RC) bridges. The relative accuracy of different NSPs, when applied to a bridge population, is compared with estimations obtained implementing Nonlinear Time History Analysis (NTHA), considered as the benchmark prediction. Seven NSP approaches, from single-mode conventional pushover-based methods to multi-mode conventional or adaptive pushover-based procedures are implemented. Results indicate that when bridges can be classified as higher-mode sensitive, the performance of multi-mode procedures is marginally superior, whereas for first mode dominated bridges, although the latter still present advantages, the relative performance of single-mode procedures justifies its implementation.

Keywords: Bridges, multi-mode pushover, non-classical first mode, fragility assessment, loss assessment.

1 INTRODUCTION

Over the past decades, bridges have been identified as one of the most seismically vulnerable components within transportation networks [1, 2]**.** It is therefore necessary, for proper risk assessment and development of earthquake loss models in a certain region of interest, to reliably characterise of the seismic response of such structures. Several steps are key for the development of earthquake loss models at the regional (or individual) level and, in general, they encompass: the characterization of the seismic hazard, the assessment of the structural response and the development of measures of seismic vulnerability, and the implementation of tools for the calculation of economic losses (direct and indirect) based on the assessed seismic hazard and seismic vulnerability. Such framework has been implemented in the past in tools such as HAZUS [3, 4]. HAZUS manages the vulnerability assessment of a bridge stock with the use of fragility curves, which relate the expected intensity level of an earthquake event with the expected level of damage in the structure(s). Furthermore, HAZUS proposes fragility curves for typical bridge configurations, although it is allowed (and expected) that the user will input case-specific fragility curves for any type of configuration [4].

Seismic vulnerability assessment methods have been extensively studied during past decades [5, 6], from these, analytical fragility curves emerge a suitable and reliable tool to this end. Analytical fragility curves are constructed from results of structural analysis, which can be implemented with Linear Elastic, Nonlinear Static, or Nonlinear Dynamic approaches. Analytical fragility curves are often preferred over other approaches because they overcome the perceived subjectivity and/or scarce post-earthquake damage information that other methodologies require. Regarding RC bridges specifically, past studies have implemented analytical fragility curves for the seismic vulnerability assessment of individual bridges, bridge classes and bridge populations, Linear Elastic (e.g. [7]), Nonlinear Static (e.g. [8-10]) and Nonlinear Dynamic (e.g. [12-14]) analyses have been implemented for the structural response estimation.

Studies that have implemented Nonlinear Dynamic analyses for the estimation of the structural response have the advantage of working with "exact" predictions for the construction of fragility curves; however, when developing them for large portfolios of structures, this analysis approach becomes seldom practical, in terms of computational effort and time demand. Furthermore, past research for the development of fragility curves using alternative structural analysis procedures (i.e. Linear Elastic and Nonlinear Static analyses) have been limited in a number of ways, e.g., considering a unique or few similar structural configurations, evaluating the performance of a single or few Nonlinear Static Procedures (NSP), or comparing the response in terms of engineering demand parameters only, without extending it to the computation of expected economic losses. It is thus clear that additional research for identifying a more efficient, yet accurate alternative, for the computation of seismic risk in bridge populations is necessary.

The main goal of this study, in view of the above discussion, is to assess the suitability of NSPs for the computation of seismic risk of multi-span reinforced concrete (RC) bridges. For this purpose, a portfolio of 50 bridges is constructed using data from existing bridges. Structural response estimations are computed and fragility curves are developed using results from Nonlinear Time History Analysis (NTHA), was well as seven NSPs, namely, the N2 Method (N2), Capacity Spectrum Method (CSM), Extended N2 Method (Ext-N2), Modal Pushover Analysis (MPA), Generalized Pushover Analysis (GPA), Improved Modal Pushover Analysis (IMPA), and Adaptive Capacity Spectrum Method (ACSM). These fragility curves are then used to develop loss curves and then perform the computation of Expected Annual Losses (EAL) implementing the HAZUS approach, considering only direct losses due to physical damage, which serves as a measure of seismic risk. The assessment of the accuracy of the different NSPs is made by direct comparison of EAL results with those coming from NTHA.

2 CASE-STUDY PORTFOLIO

The case-study portfolio is composed of 50 RC bridges taken from a previous study [1]. These bridges are part of the Italian bridge stock, all belonging to the same typology, namely, multi-span with continuous, non-monotonically connected deck with circular section piers. The case-study portfolio features bridges with the number of spans ranging from 3 to 56 and with total length from approximately 95m to 2000m. The span length is rather uniform within the portfolio with a mean value of approximately 31m. The piers cross section diameter varies from 1m to 4.8m. With respect to piers reinforcement layouts and materials, the longitudinal reinforcement ratio varies from 0.5% to 1% with mean yield strength of 440MPa. Furthermore, the cover concrete compressive strength accumulates around 40 MPa, whereas the core concrete compressive strength varies between 42MPa and 52MPa. Pier heights are highly variable among bridges and sometimes within the same bridge, which indicates that the case-study portfolio contains both regular and irregular layouts.

2.1 Preliminary classification

For the expedite assessment of irregular behaviour in bridges, previous research has proposed several indexes that relate the stiffness of the structure and/or its geometrical configuration. Among these, the Relative Stiffness Index [15] and the Irregularity Index [16] were implemented in this study. However, no clear trends could be identified in using these indexes, particularly because the bridge configurations used in this study seem to be outside the scope for which they were originally tested. Since this study makes use of NSPs, single-mode and multi-mode based, it is rather significant to determine the sensitivity to higher modes in the bridges of the case-study portfolio. Such preliminary classification allows for the division of the case-study based on the expected behaviour, i.e., first-mode dominated or higher mode sensitive, and also defines the expectations for the performance of NSP approaches, i.e., single-mode based procedures are expected to perform similarly to multi-mode based approaches in first dominated bridges, whereas the use of multi-mode based procedures should be encouraging in higher-mode sensitive structures.

A critical evaluation of modal analysis results allows for identification of bridges where a classical dominant first mode (defined as the fundamental mode where all piers displace in the same direction) develops and bridges where a classical first mode does not develop or does not strictly exists. A sample of these results is shown in Figure 1. Building on these observations, respectively, 23 bridges were classified as “Classical” whereas 27 bridges were classified as “Non-Classical”. Generally, “Classical” type bridges have a number of spans less than or equal to six and modal mass participating the first mode of no less than 65%, pointing out that this type of bridge can be seen as first mode dominated. “Non-Classical” type bridges are always higher mode sensitive with a modal mass participating in the first mode less than 70%. Observations of this nature seem to indicate that inspection of modal shapes is more efficient than previously proposed indexes for identifying sensitivity to higher modes in bridge structures.

2.2 Structural Modelling Approach

All the bridges were modelled considering the following general characteristics: the deck was modelled as a linear elastic element, the piers were modelled with force-based fibre elements, the Kent-Park model was implemented for concrete whereas a bilinear hysteresis with a post-yield hardening ratio of 0.002 was employed for the reinforcement fibres. The mechanical behaviour of the abutments was considered via a simplified bilinear model, with an initial stiffness of 1400kN/mm, yield force of 4800kN and post-yield hardening ratio of 0.005. Shear keys were employed in the deck-to-pier connection to transfer horizontal forces but not moments.

With this modelling strategy, support devices were not modelled and shear keys are considered (implicitly) with a shear strength always larger than de shear developed in the piers. The foundation was considered as fully fixed, as has been suggested by other studies for bridges belonging to the Italian stock [14]. The structural mass is computed as that contributing from the deck and 1/3 of the piers [17]. Nonlinear geometry was considered via incorporation of P-Delta effects. All structural models were developed in the software OpenSees [18], which allows for the integration of the structural analysis results (either static or dynamic) with the construction of fragility curves and the assessment of economic losses. Furthermore, since not all sources of energy dissipation were considered in the modelling, an inherent tangent stiffness proportional viscous damping ratio [19] of 2% at the predominant period was adopted for NTHA.

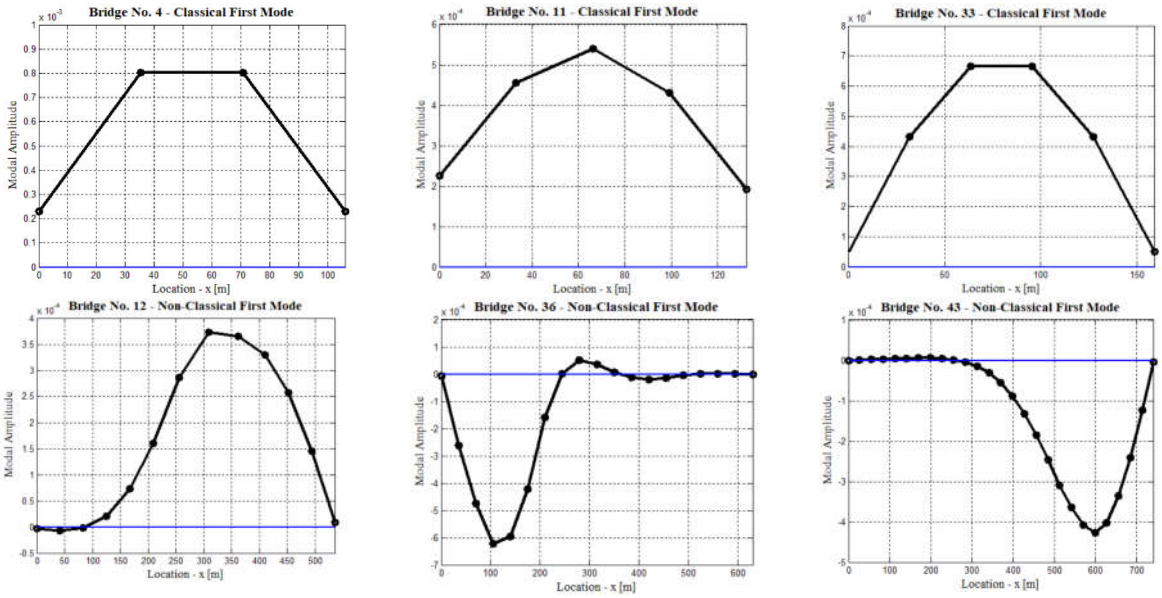

Figure 1: First Mode Shapes, 'Classical' and 'Non-Classical'.

2.3 Nonlinear Static Procedures

Seven NSPs were implemented to assess their capability of computation of EAL in the case-study portfolio. While the reader is referred to specific literature for a complete presentation of the methods, a brief description of their main features as implemented in this study is presented.

- **N2 Method (N2) [20]:** Capacity curves are constructed with a first-mode proportional lateral load vector; performance points are computed using an inelastic spectrum formulation. If the modal mass participating in the first mode is less than 55% of the total seismic mass, a mass proportional lateral load vector is implemented.
- **Capacity Spectrum Method (CSM) [21]:** It is implemented in the same fashion as the N2, however, performance points are computed implemented an overdamped spectrum formulation as presented in FEMA-440 [20].
- **Extended N2 Method (Ext-N2) [22]:** Results from a first mode proportional N2 assessment are updated via correction factors computed using Response Spectrum Analysis (RSA).
- **Modal Pushover Analysis (MPA) [23]:** Capacity curves are computed for each i^{th} mode proportional lateral load vector and corresponding performance points are computed via NTHA on the i^{th} equivalent Single-Degree-of-Freedom-System (SDOF). 'Modal' responses are combined using the Squared-Root-of-the-Sum-of-the-Squares (SRSS) rule.

- **Generalized Pushover Analysis (GPA) [24]:** Generalized Force Vectors and target displacement demand are computed according to Perdomo et al. [25]. The envelope of the response for each Generalized Force Vector is taken as the total seismic demand.
- **Improved Modal Pushover Analysis (IMPA) [26]:** A GPA analysis is first carried out to determine updated 'modal shapes', these updated 'modal shapes' are used to determine the updated displaced state of the structure per each mode. 'Updated modal' responses are combined using the SRSS rule.
- **Adaptive Capacity Spectrum Method (ACSM) [27]:** An adaptive equivalent SDOF is constructed with results from a Force-Based Adaptive Pushover Analysis (FAP) and the tools from Direct Displacement-Based Assessment (DBA). Performance points are computed using an overdamped spectrum formulation following the recommendation from Casarotti et al. [28].

3 GROUND MOTION SELECTION AND SCENARIO EARTHQUAKES

The ground motion record selection method implemented in study is the Conditional Spectrum (CS) Method [29]. For its implementation the method requires input from Probabilistic Seismic Hazard Analysis (PSHA), disaggregation of the PSHA and Ground Motion Models (GMM) information. At each bridge location, the PSHA and its disaggregation was carried out with the software OpenQuake [30] along with a simplified version of the 2013 Harmonized European Seismic Hazard Model (SHARE) [31], for which only the GMM from Akkar and Bommer [32] is required. The Intensity Measure (*IM*) chosen to characterize the expected ground motion input at the site was the spectral acceleration at the first mode period ($S_a(T_1)$), according the results of a recent study [33] that shows that, despite not being always optimal (in terms of efficiency and sufficiency) in general it presents better performance that the commonly used Peak Ground Acceleration (PGA). The first mode period (T_1) was estimated for each bridge through a bilinear fitting to a first-mode proportional capacity curve. Twelve return periods were considered for the characterization of the structural response, construction of loss curves and computation of EAL: 19975, 9975, 4975, 975, 475, 225, 141, 98, 73, 55, 32 and 22 years (probabilities of exceedance of 0.0025, 0.005, 0.01, 0.05, 0.1, 0.2, 0.3, 0.4, 0.5, 0.6, 0.8 and 0.9 in 50 years, respectively).

Once the PSHA and its disaggregation were carried out, the CS was computed for each determined *IM* level at each particular site and 25 records were selected per *IM* level in order to match the CS mean and variance. Real earthquake records were scaled and selected from a databank of approximately 11500 waveforms (one direction) obtained from the European Strong Motion Database, K-Net Japanese database and the PEER NGA West2 database. Sample results for two bridges, three *IM* levels each, are presented in Figure 2, which includes the CS (target mean and standard deviation), the selected records spectra with their corresponding mean and standard deviation and the conditioning period and the limits for matching (from $0.2T_1$ to $2.5T_1$ in all cases), shown with vertical lines. It can be seen in Figure 2 that within the limits for matching the agreement between the target mean and standard deviation and the records' mean and standard deviation is very good, this observation can be extended to all target CS computed and records selected.

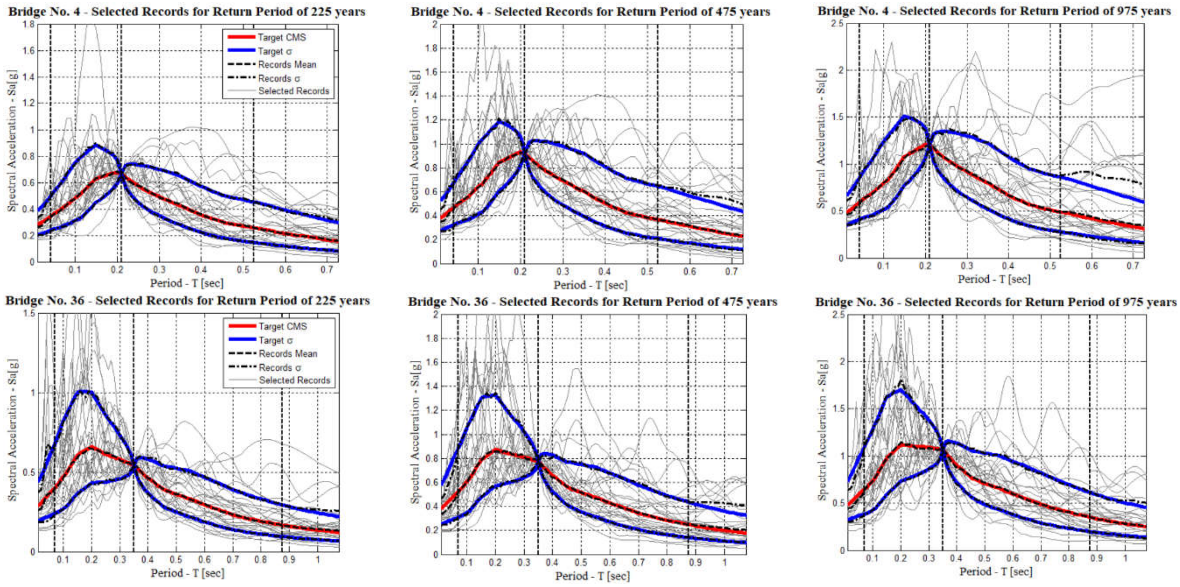

Figure 2: Sample results for CS and selected records.

4 DAMAGE LIMIT STATES AND FRAGILITY CURVES

A structure level criterion, in which an element damage evaluation serves for the quantification of the damage state for the whole structure, was adopted in this study. Keeping in mind the characteristics of the case-study portfolio and based on the work presented on HAZUS [3] and Nielson [34], further developed in Monteiro et al. [35], pier displacement ductility (μ_Δ) was adopted as Engineering Demand Parameter (EDP) and the maximum ductility among the different piers was used for the characterization of the damage state of the entire bridge. Accordingly, four discrete Damage Limit States (DLS) were identified: Slight, Moderate, Extensive and Collapse. The thresholds for the identification of the damage state of any particular pier in terms of displacement ductility are presented in Table 1. The EDP associated with the DLS requires the computation of the piers' top displacement and their yield displacement; the former was obtained directly from the structural analysis results.

DLS	μ_Δ
Slight	1.00
Moderate	1.20
Extensive	1.76
Collapse	3.00

Table 1: DLS in terms of displacement ductility.

Extensive experimental and analytical evidence, summarized in Priestley et al. [36], indicates that the yield displacement of columns is essentially independent from the amount of longitudinal reinforcement, transverse reinforcement and external axial load. Following their recommendations, the yield displacement of a cantilever column (behaviour presented in all piers of the case-study portfolio) can be computed adequately using Equation 1, wherein Δ_y is the yield displacement, H_p is the pier height, ϕ_y is the yield curvature, given in Equation 2, and L_{sp} is the strain penetration length, given in Equation 3.

$$\Delta_y = \phi_y \left(H_p + L_{sp}\right)^2 / 3 \tag{1}$$

In Equation 2, ε_y is the longitudinal reinforcement yield strain whilst D is the pier diameter. Additionally, in Equation 3, f_y is the longitudinal reinforcement yield strength and d_{bl} is the longitudinal reinforcement bar diameter.

$$\phi_y = 2.25\varepsilon_y/D \tag{2}$$

$$L_{sp} = 0.022 f_y d_{bl} \tag{3}$$

Consequently, the displacement ductility at any given pier can be computed according to Equation 4, in which $\Delta_{analysis}$ is the maximum displacement in absolute value found in the structural analysis and μ_Δ is the corresponding displacement ductility.

$$\mu_\Delta = \Delta_{analysis}/\Delta_y \tag{4}$$

The largest value of μ_Δ among the different piers of the bridge was taken as representative of the system and used for the evaluation of the exceedance of the predefined DLS.

Demand estimations from NTHA and all the tested NSP, *IM* levels, and bridges within the case-study portfolio were then obtained and fragility curves for each individual bridge and structural analysis approach were generated. Multiple Stripes Analysis (MSA) [37] was selected for the development of the fragility curves for two reasons: it allows the use of different records in different *IM* levels, and it is not necessary for all records to reach the *IM* level that leads to reaching the DLS under consideration, which is its main advantage. With respect to the fitting, Maximum Likelihood Method (MLE) was preferred for their computation, as it has proven successful in previous research [37]. Moreover, following current practice, a log-normal Cumulative Distribution Function (CDF) was chosen for the description of vulnerability for each structural analysis approach, DLS and individual bridge within the case-study portfolio.

5 EXPECTED ANNUAL LOSSES COMPUTATION

In this study, the simplified HAZUS [3] approach was used for the computation of scenario earthquake losses, loss curves, and finally, Expected Annual Losses (EAL), considering only direct losses due to physical damage. Several past studies [38-41] have used the same approach for the computation of direct losses for bridges at the regional level. Scenario losses were computed based on the compound damage ratio (μ_D), as shown in Equation 5, where DR_j is the damage ratio for DLS j and $P[DLS_j]$ is the probability of being in DLS j.

$$\mu_D = \sum_{j=1}^{4} DR_j P\left[DLS_j\right] \tag{5}$$

Damage ratios, DR_j, for each DLS were taken the same as in previous studies [40, 41], which match the recommendations contained in HAZUS [3], as shown in Table 2. Furthermore, for a scenario earthquake with a given *IM* level, the probabilities of being at each DLS are given by Equation 6.

$$\begin{gathered} P\left[DLS_j\right] = P\left(DLS_j \middle| IM = Sa(T_1)\right) - P\left(DLS_{j+1} \middle| IM = Sa(T_1)\right) \; for \; j = 1, 2, 3 \\ P\left[DLS_j\right] = P\left(DLS_j \middle| IM = Sa(T_1)\right) for \; j = 4 \end{gathered} \tag{6}$$

In Equation 6, $P\left(DLS_j \middle| IM = Sa(T_1)\right)$ is the probability of exceedance for DLS j read from the fragility function for a scenario with $IM = Sa(T_1)$ as determined in the PSHA. Direct mean economic losses for the scenario earthquake were computed according to Equation 7, where C_{REP} is the bridge's replacement cost, computed with Equation 8. In Equation 8, the unit re-

placement cost (UC_{REP}) was taken constant with a value of 2306 €/m^2 according to the recommendations of Dong & Frangopol [38]. The deck width (W) was also taken constant with a value of 10m whereas the length (L) was retrieved for each bridge.

DLS	j	DR_j
Slight	1	0.03
Moderate	2	0.08
Extensive	3	0.25

Table 2: Damage ratios per DLS.

$$\mu_L = C_{REP}\,\mu_D \;\leq\; C_{REP} \tag{7}$$

$$C_{REP} = UC_{REP}\,W\,L \tag{8}$$

Mean direct losses were computed for each of the twelve earthquake scenarios determined in the PSHA, using fragility curves corresponding to each individual bridge developed with NTHA and each tested NSP. Loss curves were produced by plotting together the mean rate of exceedance of each earthquake scenario (as indicated in Section 3) with their corresponding mean direct losses, therefore, for each individual bridge and structural analysis approach. Finally, the area under each generated loss curve was assessed and EAL (as percentage of the replacement cost) were computed with results from NTHA and each tested NSP.

6 EXPECTED ANNUAL LOSS RESULTS

Fragility curves, loss curves and ELA were computed using structural response estimations from NTHA and each of the NSP presented in Section 2, for the scenario earthquakes and selected records presented in Section 3, following the guidelines presented in Sections 4 to 6. Sample results for a "Classical" type configuration and a "Non-Classical" type configuration are presented in Figures 3 and 4, respectively.

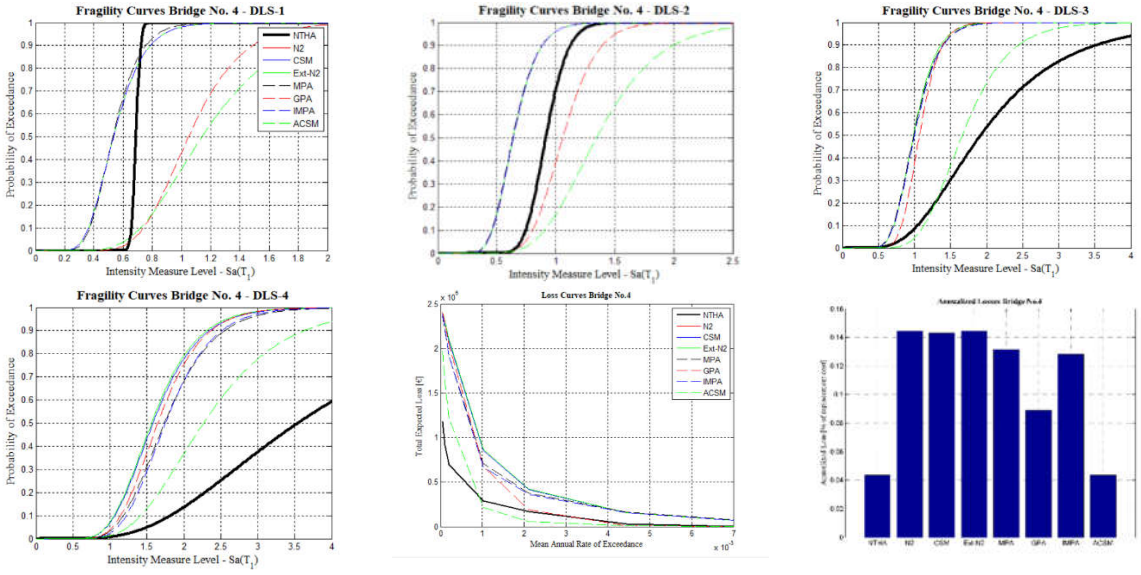

Figure 3: Sample results for fragility curves, loss curves and MLA. "Classical" type configuration.

Figure 3 shows that for this specific "Classical" Type configuration fragility curves computed with NSPs do not present a good agreement with NTHA estimations, except for ACSM

in DLS-3 and DLS-4 where it is the closest. It is also seen that in this case most NSPs yielded similar results in terms of fragility for DLS-3 and DLS-4. This observation clearly translates to the computed loss curves where all NSP tend to cluster in the same shape, except for GPA, that gets closer to NTHA for higher probability of exceedance events, and ACSM which is the closest across all evaluated scenarios. EAL results follow quite clearly this behaviour with N2, CSM, Ext-N2, MPA, and IMPA presenting a similar performance in prediction and ACSM being the closest to NTHA followed only by GPA.

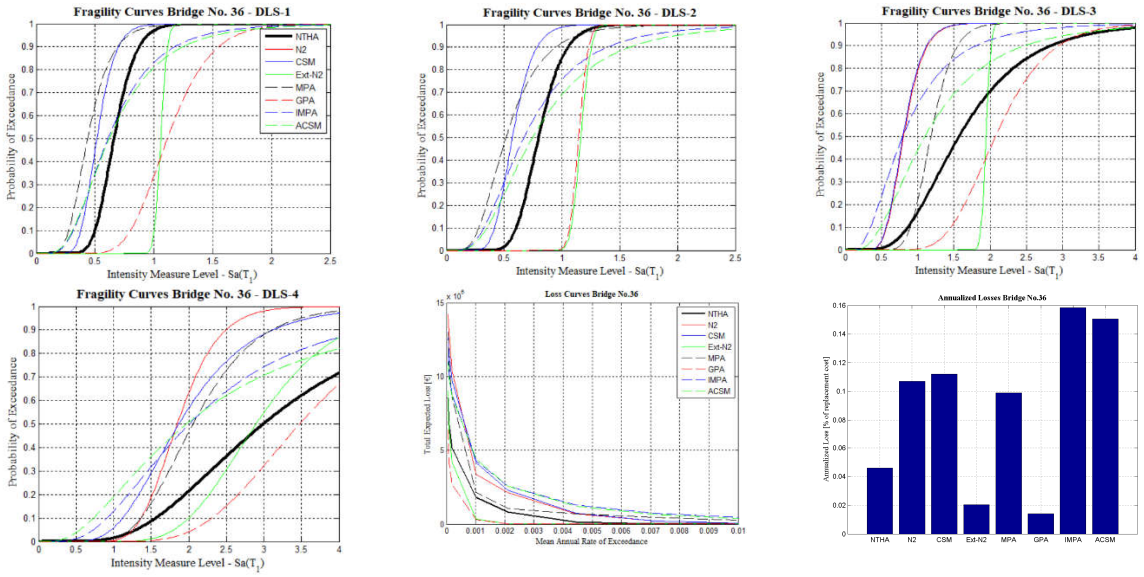

Figure 4: Sample results for fragility curves, loss curves and MLA. “Non-Classical” type configuration.

Figure 4, in turn, shows that for the specific “Non-Classical” type configuration the fragility curves computed with NSPs diverge greatly among them, for all considered DLSs, with different levels of agreement with NTHA. Remarkably, in this case, Ext-N2 and GPA computed slightly less vulnerable behaviour for all DLSs whereas the rest of NSP present opposite results, predicting a more vulnerable system with respect to NTHA. These observations are again clearly sustained by the loss curves and EAL values, where Ext-N2 and GPA curves are below the NTHA curve for low probability of exceedance events, the MPA curve is close to NTHA for some of the low probability of exceedance events, but it is always higher for more frequent events. It is also seen that despite computing different fragility functions, loss curves for other NSPs tend to cluster with a similar shape, higher than NTHA results. EAL values, again, capture this behaviour perfectly, with N2, CSM, MPA, IMPA and ACSM leading to higher losses and Ext-N2 and GPA to lower losses with respect to NTHA. Comparatively, the latter two present the best match to the benchmark results, although their predictions would be non-conservative.

The results presented in Figures 3 and 4 are not fully representative of the behaviour of the case-study portfolio hence the results for EAL values are further scrutinized and analysed statistically. In order to compare NSP results with respect to NTHA predictions, the error in the EAL estimation is computed for each bridge according to Equation 9. In Equation 9, EAL_{NTHA} is the EAL estimated with NTHA, EAL_{NSP} is the EAL estimated with a given NSP (e.g. N2) and EAL_{ε} is the associated error in the prediction.

$$EAL_{\varepsilon} = (EAL_{NSP} - EAL_{NTHA})/EAL_{NTHA} \tag{9}$$

Moreover, EAL_ε values are grouped according to the behaviour typology (i.e., "Classical" and "Non-Classical") and their results are treated separately. EAL_ε results are presented in boxplots in Figure 5. These boxplots present the 25th and 75th percentiles enclosed by the blue box whereas the horizontal red line marks the median of the results and two horizontal green lines are also presented in the plots which mark 30% difference with respect to NTHA predictions.

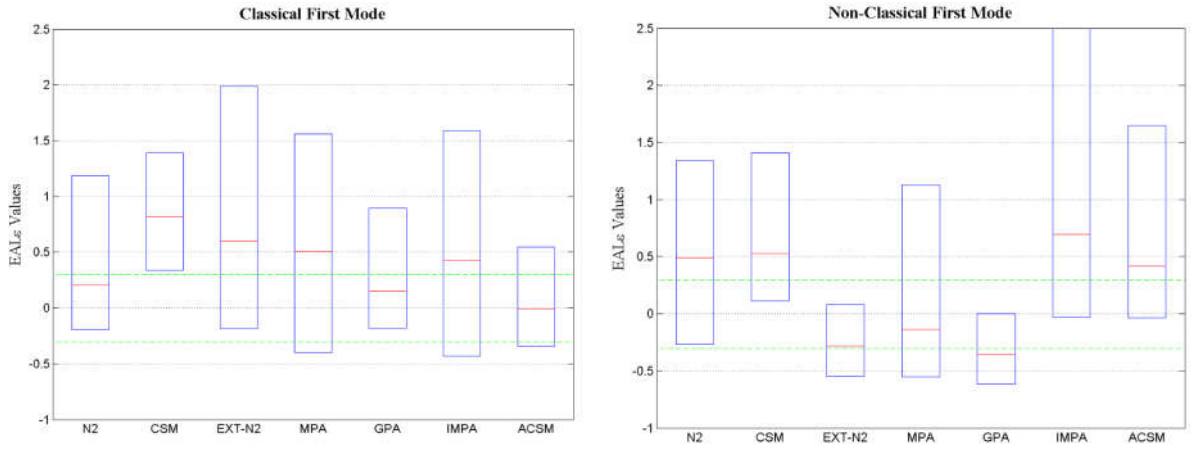

Figure 5: MALε values. "Classical" and "Non-Classical" type configuration.

Figure 5 shows, in terms of median EAL_ε values for "Classical" type configurations, that CSM performs the worst among the tested NSP alternatives, whereas N2 performs better, being within the 30% accuracy with respect to NTHA. Ext-N2, MPA and IMPA perform similarly, however their median EAL_ε values are slightly less accurate than that obtained with the N2. GPA presents itself as the second best alternative with a median EAL_ε value slightly more accurate than N2, whilst ACSM is the best performing method, with a median EAL_ε value essentially matching NTHA predictions. When the dispersion in EAL_ε values is taken into account, ACSM and GPA are still the first and second best performing methods, Ext-N2, MPA and IMPA present similar values of dispersion, larger than other approaches. N2 presents a larger dispersion than CSM nevertheless it is overall more accurate than the latter. In view of the simplicity in implementation of the N2 method, it is seen a viable alternative for the assessment of "Classical" type configurations within the case-study population.

For what concerns the "Non-Classical" type configurations, the median EAL_ε values for N2 and CSM are similar and both outside the 30% accuracy threshold, with respect to NTHA, overpredicting EAL and generally losing accuracy with respect to the "Classical" configurations, especially N2. IMPA and ACSM also lose performance with respect to the "Classical" configurations, with the ACSM median EAL_ε value being just slightly more accurate than N2. Ext-N2 ad GPA have very similar median EAL_ε values, being just on the boundary with the 30% accuracy with respect to NTHA. MPA presents the closest match with respect to NTHA in terms of median EAL_ε value. When considering the dispersion, MPA loses performance with respect to GPA and Ext-N2, with the former having a dispersion quite larger than the latter two, which have similar levels. ACSM would present almost identical performance to N2 and CSM, however it seems just slightly superior. IMPA presented the largest level of dispersion on EAL_ε values among the tested NSP for "Non-Classical" configurations. It is seen that for "Non-Classical" type configurations the use of multi-mode based NSP is encouraging in terms of improved accuracy. Results for the tested case-study portfolio tend to favour Ext-N2 and GPA, with the downside of underpredicting median ELAs. MPA and ACSM present overall a marginally better performance than N2 and CSM.

7 SUMMARY AND CONCLUSIONS

This work studied the accuracy of Nonlinear Static Procedures (NSP) in the prediction of seismic risk levels of reinforced concrete (RC) bridges, using Expected Annual Losses (EAL) as metric. For this purpose, a case-study portfolio of 50 multi-span bridges with continuous but non-monotonically connected deck has been selected from the Italian bridge stock. The bridges were divided in two typologies, "Classical", where a classical first mode shape develops, and "Non-Classical" where a classical first mode shape does not develop or does not exist. Twelve earthquake scenarios have been defined using Probabilistic Seismic Hazard Analysis (PSHA) for chosen mean return periods. The measure of earthquake intensity for each scenario was characterized via the spectral acceleration at the first mode period, allowing for the computation and selection of records using the Conditional Spectrum (CS) method. Furthermore, for the characterization of the structural response at each intensity measure level, 25 real earthquake recordings were scaled and matched in order to fit the CS mean and variance. Structural response estimations were obtained for each record and intensity measure level using Nonlinear Time History Analysis, considered the benchmark results, and seven NSPs, namely, N2 Method (N2), Capacity Spectrum Method (CSM), Extended N2 Method (Ext-N2), Modal Pushover Analysis (MPA), Generalized Pushover Analysis (GPA), Improved Modal Pushover Analysis (IMPA) and Adaptive Capacity Spectrum Method (ACSM). Four discrete damage limit states were defined and fragility curves were developed for each bridge within the case-study portfolio, for each DLS using structural response estimations from NTHA and each of the tested NSPs. The developed fragility curves were then used to compute Expected Annual Losses (EAL) for each of the earthquake scenarios defined previously, implementing the HAZUS approach. The accuracy of each tested NSP for EAL computation was assessed with direct comparison with NTHA predictions using an error measure. For the case-study portfolio investigated in this study, the findings suggest that the following conclusions can be drawn.

When the bridges can be classified as "Classical", the results favour ACSM as the best performing alternative, followed by GPA. At the same time, N2 presents a good performance and in view of its simplicity could be considered as viable alternative for the risk assessment of the "Classical" type configurations of the case-study portfolio. When bridges can be classified as "Non-Classical", results tend to favour multi-mode based NSP, in particular Ext-N2 and GPA, with the downside of yielding slightly non-conservative predictions. MPA and ACSM present only a marginally superior performance than N2 or CSM. Single-mode based NSPs, especially N2, lose performance when compared to the "Classical" type configurations.

Considering the results obtained for the overall portfolio, multi-mode NSPs that consider higher mode effects offer an improvement in the prediction of EAL. With generally similar median prediction estimates and dispersion levels for different types of structures, the choice would likely be made between GPA and ACSM. On the other hand, other aspects, such as computational demand or ease of implementation, should be considered. In such a case, N2 would be confirmed as a viable alternative for what concerns first mode dominated structures or structures where a classical first mode develops.

Overall, these results support the idea that NSPs can be used for large scale seismic assessment of bridge portfolios, while keeping in mind some limitations and improvements for future research. In particular, more research for higher mode sensitive bridges is required to improve the accuracy of alternative structural analysis approaches. It is also emphasized that the simplified approach implemented in this study for the calculation of EAL, i.e. structure level fragility curves along with compounded damage ratios, could conceal further deficiencies (or capabilities) of NSP approaches. As such, studies at the element level, as those currently implemented

for earthquake loss assessment in buildings, are necessary for the loss estimation in bridge structures. Efforts in these directions are expected in the near future.

Abstract

The increasing momentum for Natural Gas exploitation in Europe and worldwide constitutes Liquified Gas terminals indispensable links of energy supply network. Infrastructures of this kind should be resilient against the earthquake hazard and thus designed accounting for as much as possible sources of uncertainty such as modelling issues, analysis methods, seismic input selection, soil effects and others. To date, research efforts have not assessed the response of pipe racks sufficiently, let alone the interaction between the rack and piping system and analysis methods of the past have proved to be neither adequate nor efficient towards evaluating the earthquake hazard potentiality. Further, soil-structure-interaction has not been incorporated into a fragility analysis framework; albeit it is considered as a critical parameter since midstream and downstream facilities are usually rested on alluvial deposits.
In the present work, a supporting RC rack is analysed through a 3D finite element model in the nonlinear regime both as coupled and decoupled vis-à-vis a piping system. The fragility functions are evaluated for structural components and limit states in the global and meso-scale, through the Incremental Dynamic Analysis (IDA) considering far-field conditions. In the end, the SSI is encountered accounting for linear and nonlinear soil, and soil effects are demonstrated by the fragility curves. It is inferred that the fragility of the rack soars considerably by the piping system boundary conditions in the coupled case and the SSI has detrimental impact, and thus should be accounted, particularly, for industrial structures that are located at coastal sites.

Keywords: RC pipe rack, pipelines, dynamic interaction, fragility assessment, far-field, soil-structure-interaction.

1 INTRODUCTION

The strategic role of Liquified Natural Gas (LNG) terminals all over the world and particularly in Europe due to the high energy demands, which have been increasing recently, makes these infrastructures focal points of energy world network. Climate changes due to global warming was, is and will be high on the agenda of societies, and thus the consumption of more environmental friendly fuels e.g. LNG will be prioritized in the future. There are currently 28 LNG terminals (24 ground and 4 floating) along European coastline some of which are planned or being expanded and the number is going to increase considerably in the Mediterranean Sea by the first half of the next decade since the LNG imports are expected to soar by almost 20% by 2040 compared to 2016 levels [1]. Furthermore, ongoing European projects, e.g. EastMed or future exploitation of natural resources in the East Mediterranean regions, will probably support exports to global markets and Europe via LNG or pipelines increasing even more the need for constructing LNG terminals in the region. The terminals play an essential part since their purpose is to store, process and distribute natural gas mainly by freight and pipelines at regional or supra-regional level. There are two types of terminals, namely liquefaction and regasification (or off-loading facility); in the first type, the gas is liquified by compression and cooling to low temperature, whereas in the second case, the LNG is converted to its gaseous form for further distribution to the market (Figure 1a). The natural gas is liquified because it takes up approximately 1/600 less volume compared to gaseous form. In this view, LNG terminals are made of a port, storage tanks and the main process area (Figure 1b) that includes pipe racks, knock-out drum (or vapor-liquid separator) and other process equipment.

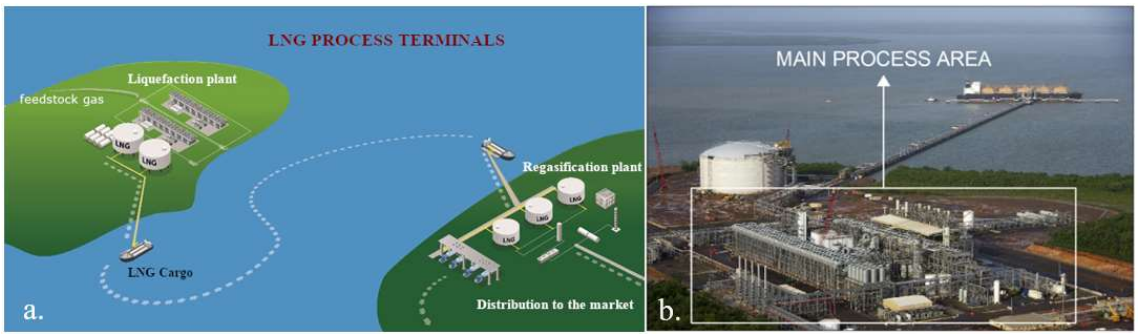

Figure 1: a. LNG process pathway and b. an LNG liquefaction plant ([2])

Many of LNG terminals could impose high risk to human and countries financial state considering that they might be vulnerable against natural hazards such as inundations, fire, earthquake and others. The earthquake hazard potentiality, which the present study intends to examine, is high in Central and East Mediterranean basin in which countries e.g. Italy, Greece and Turkey have experienced severe seismic events during the last decades. The seismic hazard is a key one to be addressed in the analysis of major accident hazards within a well-completed risk assessment of industrial facilities as clearly proved in [3]. A literature review that was conducted at the time showed that 14 seismic events caused damages to 182 equipment items and the 70% of that damage led to Loss of Containment (LOC) events. The number of non-building structures e.g. pipe rack and nonstructural components e.g. pipelines that an LNG or oil refinery encompasses are numerous. To adjudicate what the most vulnerable structures in a process plant are in order to account for their fragility during a quantitative risk assessment process (this kind of risk assessment is out of the scope of the present work), we should examine the seismic behaviour during past seismic events. In particular for oil refinery pipe racks, it has been found that are not the most vulnerable structures themselves against seismic hazard,

however, they could be due to the differential displacement of pipe supports that are not compatible with the pipelines ([4]). Supporting structures or pipe racks carry complex systems of nonbuilding structures and nonstructural components that transfer hazardous substances from one unit to another and thus their seismic integrity is critical.

To-date, the seismic research has focused on the decoupled case by investigating the seismic response of critical components such as elbows, t-joints or bolted flange joints without analyzing the rack and piping system in unison (coupled case) ([5], [6]). This engineering practice of decoupling the response of structural and nonstructural components has been adopted not only for research purposes but also in industrial sector in virtue of simplifying the design process due to the lack of code provisions or due to possible limitation of structural analysis software in the market that causes engineers to overlook important design aspects and overestimate or underestimate the seismic response. These limitations along with the ones that refer to modelling of pipes, the soil deformability or the selection of seismic input increase considerably the number of uncertainties (epistemic and aleatory since they are based both on the lack of knowledge e.g. modelling as well as inherent/unavoidable randomness e.g. soil properties or seismic excitation characteristics) that comes in stark contrast with the magnitude of process plants cruciality. Additionally, the Limit States (LSs) of common building structures are not applicable e.g. for pipe racks considering the exceptional high human, environmental or financial risk that a failure of structural or nonstructural component may induce [7]. That being said, it is essential to assess in a detailed fashion the dynamic interaction of pipe racks vis-à-vis pipelines or other supported components considering also that testing campaigns on this research topic cannot be found in the literature.

Another important aspect that may increase the seismic vulnerability particularly of mid- and down-stream facilities is the soil deformability. The soil beneath LNG terminals and oil refineries that are located at the seaside is rather weak, and thus strengthening measures are undertaken e.g. pile foundation so as to decrease possible settlement by dead loads or enhance the lateral capacity against earthquake loading. As it has been investigated up to a point for common buildings, the soil deformability affects mainly squat and heavy structures by increasing the lateral deformation and lessening the force demand ([8]). Steel and concrete pipe racks come in many sizes and layouts and it is definitely impossible for someone to deduce whether the soil should be considered or not in the final design. This is the reason that seismic code provisions encourage the incorporation of Soil-Structure Interaction (SSI) in the design, however, European ones in particular fail to form a practical way so as the SSI to be considered in the modelling of common buildings let alone for pipe racks that differentiate in many ways e.g. irregularity along the height and in plan. Furthermore, the decision could be even more complex by considering that pipelines are supported flexibly on racks and may be affected by the soil-induced higher displacements. To the best of our knowledge, there is no a probabilistic approach that undertake the seismic vulnerability of mid- or down-stream pipe racks – pipelines systems accounting for SSI, even though the demand for acquiring a better insight of the seismic vulnerability of existing or under design process plants is rather essential.

The present paper is organized as follows: first, the peculiarities of analysis methodologies of nonbuilding structures and nonstructural components as can be found in the current literature and codes of practice are presented in Section 2. Furthermore, it follows a brief review of soil-structure interaction effects and two models for linear and nonlinear soil that are adopted for the case-study (Section 3). In the last section, an LNG RC pipe rack is considered as a representative case study and the vulnerability at global- and meso-scale accounting for the coupled case is evaluated. The objective of the work herein is twofold: i) evaluation of the importance of dynamic interaction between an LNG RC rack and steel pipelines and ii) investigation of soil-deformability effects on structural components by means of Fragility Functions (FFs).

2 ANALYSIS METHODOLOGIES FOR PIPE RACKS

Petrochemical plant pipe racks are usually made by steel to avoid corrosion due to harsh environmental conditions that process plants are exposed to, however, concrete modular frames could be found as more preferable option due to the lower cost of the material, the high uncertainty in the welding process and time constraints relating to the long installation period of steel frames. They are complex systems since numerous nonbuilding structures and nonstructural components are supported on them (Figure 2). The detailed analysis methods of supported components specifically are excluded in this section; however, some references will be made to the point that are related to the connection with the supporting structure.

2.1 Code provisions

The main European (EN) contribution for seismic-resistant design of structures [9] do not make reference to oil refinery pipe racks yet to irregular building structures that, of course, differentiate in many ways e.g. different types of loading due to the supported nonbuilding and nonstructural components or importance class definition compared to nonbuilding structures. Even though EN regulations deal with other type of structures included in process plants such as tanks, silos, towers and pipelines ([10], [11]), the important design aspects of pipe racks along with the pipelines that are outfitted by are not mentioned. On the other hand, the American (AM) code [12] or the petrochemical plant structures guideline [13] encompass a few regulations for the design and analysis of pipe racks. Oil refinery pipe racks are called nonbuilding structures similar to buildings in the codes since they are designed and constructed in a manner similar to buildings, respond to strong ground motion in a fashion similar to buildings and constitute moment, braced or dual systems. Building-like structures share many design parameters and expected behaviour with regard to common building structures but there are also considerable differences.

Figure 2: An oil refinery complex with pipe racks and supported components (source: www.rainbow941.fm)

According to the AM code [12], several parameters should be considered for determining the analysis methodology of nonbuilding structures similar to buildings, viz the vertical and horizontal irregularities, the configuration of nonbuilding structures e.g. heat exchanger or tower vessels mass, the relative rigidity of beams that should not be confused with the rigid or flexible way of supporting e.g. a piping system on a nonbuilding structure, the Seismic Design Category (the SDS in the AM code is defined as a function of importance class, seismicity and site class) and the fundamental period, T. In contrast with the EN codes that are not dealt with

pipe racks, AM ones specify several analysis methodologies and give high latitude to the engineer in selecting the most suitable. Petrochemical pipe racks are usually subjected to vertical irregularities in comparison with horizontal ones (the last are defined in the code based upon the differential drift between perimetrical points when there is diaphragmatic behaviour but pipe racks most commonly have no diaphragms). The vertical irregularity could be due to the inequality of stiffness, strength, geometry and/or weight of adjacent storeys. For instance, it is rather common when a unique floor supports significant mass, whereas other adjacent carry inconsiderable nonstructural components, the equivalent lateral force analysis method may be applied since the response is dominated by the first mode; however, it is also common dissimilarities in stiffnesses and strength to exist due to the distinct vibration of concentrated masses on upper floors as well as geometry e.g. side overhang cantilevers that are necessary to support nonstructural components that run out of the main frame. The fact that pipe racks or other building-like structures present similar skeleton to buildings does not mean necessarily that behave like them. The resulting pendulum modes that come from the support of suspended vessels and other equipment may have strong impact on pipe rack response depending on the clearance and make the use of dynamic analysis inevitable. Another reason that necessitates the use of response spectrum or time history analysis is the higher local modes that come from the weakness of beams compared to columns or braces and may contribute substantially to the total response. This is a common behaviour of nonbuilding structures with absence of floor slab.

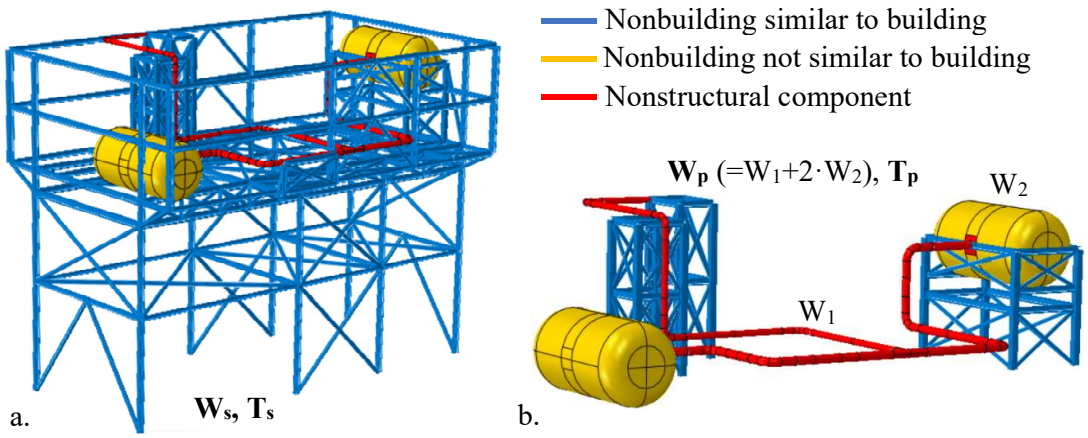

Figure 3: a. A steel nonbuilding structure, b. the piping system considering the towers that is support

To assess further what the AM code proposes regarding the interaction between supported nonbuilding structures and/or nonstructural components and supporting structure, a nonbuilding steel rack is demonstrated in Figure 3a consisting of a unique pipeline that runs across the third floor and connects two horizontal pressure vessels. When the weight of nonbuilding structure similar to building W_s (Figure 3a) and nonbuilding structures not similar to buildings as well as nonstructural components W_p (Figure 3b) is less than the 25% of the W_t (W_s+W_p), the decoupled case (no interaction) between them should be considered according to the code requirements. This is a very rough rule that relies on the low influence the supported components will have on the system response and intents some nonlinearity to be appeared on the nonbuilding structure to avoid resonance response and lessen the interaction. Also, the supporting structure and nonstructural components design parameters e.g. behaviour factor or component amplification factor a_p (this factor multiplies the design force and takes value between 1 and 2.5 for rigid and flexible supported components) are defined separately. Should this not be the

case, the dynamic interactıon is accounted for; however, if nonbuilding structures and/or non-structural components (the AM code states only the nonbuilding structure but implies the non-structural components e.g. pipes) are rigidly attached to the supporting structure (T_p<0.06s, the value is estimated by considering the flexibility of beams that the components is attached to e.g. the towers in Figure 3b), they should be analysed as rigid elements considering only the behaviour factor of the rack, otherwise both the supporting and nonbuilding structure should be modelled together in a combined model (Figure 3a) adopting the lesser behaviour factor between them. Finally, the two predominant dynamic analyses proposed by the code is the response spectrum and dynamic linear analysis probably due to safety reasons since nonlinearity increases the number of uncertainties in modelling and interpretation of results, however, the code implicitly recommends the use of nonlinear time-history to be used with caution.

2.2 Previous studies

According to [14], the most commonly causes of industrial accidents are the human factor (commission or omission errors), the organization/management errors e.g. design deficiencies or lack of maintenance and equipment/mechanical failure e.g. material failure or malfunctioning of equipment. The investigation of 284 case studies that referred solely to chemical process plants accidents by [15] was in unison with the previous statement, but it yielded additionally that the majority of accidents (25%) was related to piping system. That conclusion indicates that the piping network is one of the most prone parts within a process plant and due consideration should be given to technical human errors e.g. defective design by positioning unjustifiably the pipes on the rack or incorrect pipe bents configuration for increasing the flexibility of the system due to thermal pressure.

To-date, it still remains to be examined the dynamic interaction between a supporting structure and a piping system towards highlighting the most critical design challenges and preventing accidents in the future that put human lives and environment at risk. To the best of our knowledge, the research is rather limited on this topic; the majority of research has focused on the analysis of piping system or critical components individually ([5] &[16] among others), whereas the analysis of the combined models (supporting structure and piping) is rather obscure. An interesting research upon the effects of dynamic interaction on pipe-way and piping system response by considering different weight ratio, diameters and end-condition of pipes as well as thickness of U-ring elements (they are used to capture the pipes along the perimeter restraining only the movement in vertical and transverse direction) was conducted in [17]. The governing result of the case-study referred to the significant role the end-conditions and the stiffness of U-bolt rings played in the seismic response; the last two parameters may sensationally affect the whole system more than the weight ratio. The outcomes of the research showed that in case of multi-secondary structures e.g. pipelines that are multiply supported on a supporting structure, the relative stiffness of connection and the end-conditions except for the weight ratio should be examined; however, these parameters are missing from the codes which deal with singe secondary systems that are rigidly or flexibly supported on a nonbuilding structure.

3 SOIL-STRUCTURE INTERACTION

This section is devoted in the review of SSI models and effects on buildings and similar to building structures. More attention will be given to former structural type due to the higher research interest depicted in the literature. The limited research on soil deformability influence on the latter structural type demands a better insight to be acquired that can assist during the design process both of structural and nonstructural components. The fact that oil refineries are

located close to seaside where the soil is rather weak makes the examination of SSI phenomenon a sine qua non for the seismic integrity.

3.1 State-of-the-art

Except for the well-known effects of SSI on system response, namely period elongation and damping increase, the SSI has been found to affect mostly heavy and stiff structures. The longer period as well as the added damping in the system reduce the seismic demand forces (lower response spectrum) and thus SSI could be beneficial from this point of view. On the other hand, the higher displacement demand due to the soil deformation could be strictly necessary within the displacement-based design particularly for pipe racks that are outfitted by sensitive to high-deformation pipelines. According to [8], the ratio of $h/(V_s \cdot T)$ (h is the effective height, V_s is the shear velocity and T is the natural period) could be a reliable indicator of the degree of period elongation and damping increase.

Depending on the structural type under investigation, different parameters are of interest to evaluate the effects of SSI. For instance, foundation settlement or sliding and change in dynamic properties could be of interest for common building structures. However, when it comes to nonbuilding structures such as bridges, pipe racks or nuclear power plant reactors, the seismic demand on piles as well as the peak floor acceleration for checking the response of nonstructural components are of importance. Usually, pile foundations are adopted for pipe racks due to the liquefiable alluvial deposits existing at coastal sites and the high area that oil refineries cover making the replacement of soil practically or financially infeasible.

Except for the identification of changes in the response of structures, which is still a challenging task particularly when soil nonlinearity is accounted for, the researchers have been trying during the last decade to evaluate the effects of SSI in a probabilistic manner by estimating fragility functions that constitute an essential tool for assessing the response of existing or under design structures for further loss estimation and risk management. Even though this attempt has been partially completed for common building structures and bridges ([18]–[20]), the research lacks clearly of a probabilistic methodology that investigates the damage of pipe racks in a probabilistic manner accounting for dynamic and soil-structure interaction. The influence of SSI has been examined mostly for storage tanks and nuclear containment structures ([21], [22]), although process plant pipe racks could be stiff due to the vertical and horizontal bracing that intend to keep low the ductility as well as heavy since other nonbuilding structures and components are usually supported on them [7].

3.2 SSI models

This section is the forerunner for the case-study that follows, thus SSI models will be examined in connection with the ones that have been adopted afterwards. The literature abounds with models that are used to describe the soil-foundation-structure interaction. These models can be categorized into three main categories, namely ‘domain type models’ that refer to local scale since the soil is examined by constitutive laws, macroelements (intermediate-scale) where the soil-foundation-structure interface is described by a link element and finally soil springs which is the simpler type of model that is mostly used by practitioners and is based on impedance functions by considering mostly only for the fundamental frequency of the superstructure (global scale). The last type of model could be computationally efficient accounting for soil nonlinearity response and is suggested by code-of-practice provisions as a practically acceptable method [8]. Having said that, this latter type of model will be described hereafter and used for the fragility analysis in the following case study.

Lumped springs that represent the soil compliance are used mainly for shallow foundations making the assumption that the superstructure is underneath by a homogeneous, elastic and semi-infinite medium [23]. The assumption of linear behaviour in the vicinity of foundation could be an acceptable approximation when the foundation is rigid and the seismic excitation is not enough to develop soil inelasticity. The energy dissipation of soil due to radiation and hysteretic damping is represented by dampers. Although the stiffness and damping of soil is frequency-dependent, usually, they are modelled as frequency independent at the fundamental frequency of the structure since the analysis is conducted in time domain.

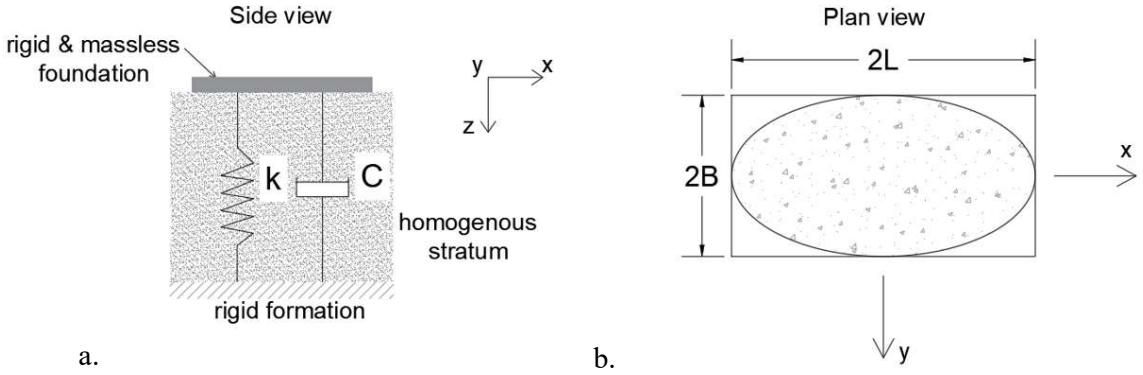

Figure 4: a. Idealisation of soil and foundation as a spring, dashpot and mass system, b. general shaped foundation (L>B) for the calculation of impedance functions

r_x	$\frac{G}{1-\nu} I_t^{0.75}\left(\frac{L}{B}\right)^{0.25}\left(2.4+\frac{0.5B}{L}\right)$	$\rho V_{La} I_{bx} \bar{c}_{rx}$

I & J_t area and polar moment of inertia of the soil-foundation surface around the pertinent axis, $\bar{c}$ a damping factor with $\bar{c}=\bar{c}(L/B, a_o)$, $\chi = A_b/(4L^2)$, G the soil shear modulus, A_b foundation area

Table 1: Static stiffness K and radiation damping coefficient C for arbitrary shaped foundations ([24])

The dynamic impedance function of the system shown in Figure 4a is given by:

$$K(\omega) = \bar{K} + i \cdot \omega \cdot C \tag{1}$$

where both $\bar{K}$ and C are functions of frequency ω. In particular, $\bar{K}$ is called dynamic stiffness and represents the soil stiffness and inertia being frequency independent up to a good approximation for soil properties. The dynamic stiffness is given by:

$$\bar{K} = K_i \cdot k(\omega) \tag{2}$$

The static soil stiffness K_i in the three modes of vibration for a general shaped foundation (Figure 4b) rested on homogenous half-space is given in Table 1. The dynamic stiffness coefficient (k) is a function of L/B, the soil Poisson ratio ν and the dimensionless parameter a_o ($=\omega \cdot B/V_s$, ω is the fundamental angular frequency of the superstructure and V_s is the average soil shear wave velocity commonly estimated at the upper 30 m of a soil deposit). The coefficient k can be found by plots existing in the literature as a function of the aforementioned parameters. Furthermore, the total damping is represented by the product $\omega \cdot C$ where C is the radiation damping (hysteretic damping is zero for linear soil) coefficient that for a general shaper foundation are given also Table 1, where ρ is the soil density, V_{La} is the Lysmer's analog wave velocity ($=3.4V_s/(\pi \cdot (1-\nu))$) and c_i is a factor that is given by plots being a function of the dimensionless ratio α_o and the ratio L/B. The interested reader may find more information about the methodology for the soil springs configuration and the forms of rotational modes of vibration in [24].

The soil behaves in the nonlinear regime under strong-ground motion and in the vicinity of foundation interface (near-field) even at low strain levels. The hysteretic behaviour is described by the inclination (that refers to soil stiffness) and the size of the loop (the larger the loop the higher the energy dissipation, Figure 5a). Usually, the secant stiffness ($G_{sec}=\tau_c/\gamma_c$) is used to describe the average stiffness of soil along an entire loop instead of the tangent G_{tan} and the damping ξ for the dissipation of energy due to the material nonlinearity. The G_{sec} and ξ constitute the equivalent linear soil properties; the increase of shear strain amplitude decreases the secant modulus and increases the energy dissipation due to the hysteresis phenomenon. The change in shear modulus and damping are usually depicted through the G-γ-D curve ([25]) (Figure 5b).

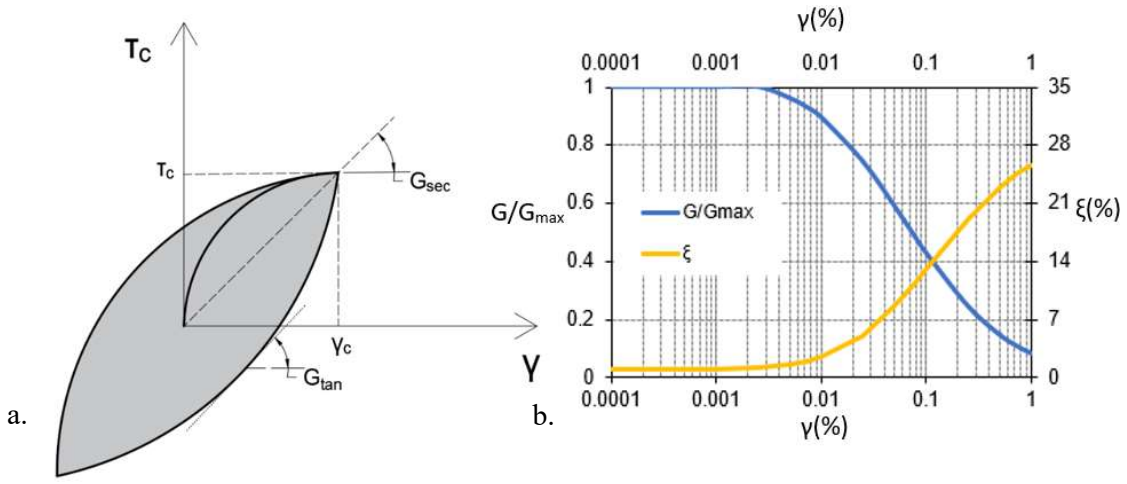

Figure 5: a. hysteresis loop of soil element subjected to symmetric cyclic loafing ([25]), and b. typical G-γ-D curves of a soil deposit

The simplest way to estimate the soil nonlinearity is the equivalent linear method that accounts for the modification of secant and damping during an iterative analysis procedure by considering a percentage (roughly 65%) of the peak strain from the previous step. More information about this method can be found in [26]. The equivalent nonlinear method is a straightforward and simple to be implemented procedure, however, it still remains an approximation of the actual soil behaviour. Thus, plentiful nonlinear constitutive models of different rigorousness and complexity exists in the literature. Soil models with hysteretic behaviour can be rather difficult to be calibrated since they require a lot of parameters. In this regard, a simplified model will be used in the sequel to account for the nonlinear behaviour of soil underneath an LNG RC

rack. That model relies on the Ramberg-Osgood (RO) curve [27], which is described by the following equation:

$$\frac{\gamma}{\gamma_y} = \frac{\tau}{\tau_y}\left(1 + a\left|\frac{\tau}{\tau_y}\right|^{r-1}\right) \tag{3}$$

where γ_y and τ_y are the yield strain and stress ($G_{max}=t_y/\gamma_y$) and the parameters α and r are positive constants ($r\geq1$ and $a\geq0$). When the strain is very small ($\gamma\rightarrow0$ and $\tau\rightarrow0$ given that $r>1$), the eq. 7 can be rewritten according to Masing's rule as follows:

$$\frac{\gamma}{\gamma_y} = \frac{\tau}{G_{max}\cdot\gamma_y}\left(1 + a\cdot\left|\frac{\tau}{G_{max}\cdot\gamma_y}\right|^{r-1}\right) \tag{4}$$

Also, the hysteretic damping according to RO model is defined as:

$$\frac{G}{G_{max}} = 1 - \frac{D\cdot\pi\cdot(r+1)}{2(r-1)} \tag{5}$$

The parameters a, r and γ_y are to be determined by using a code that tries repetitively to estimate the best fit given a soil type with G_{max}. This code has been developed in MATLAB and the results are presented in the following section. Once the parameters are known, D-γ curve can be determined as well.

To represent the soil properties of the following case study by using the G-γ-D curves shown in Figure 5b and calibrate the pertinent curves of RO model, afterwards, the empirical formulae by [28] have used that refer to alluvium deposit of sandy clay to clayey sand with plasticity I_p. The quotation of those formulae is omitted herein for brevity.

4 FRAGILITY ANALYSIS OF A RC PIPE RACK

The seismic fragility of a RC pipe rack is examined herein considering a 3D model in dynamic nonlinear analysis of framed structures software Seismostruct ([27]). Towards achieving robustness in the assessment methodology, a particular number of steps were followed for that purpose: i) material and frame element modelling, ii) modal analysis for identifying the fundamental modes in horizontal and vertical direction, iii) pushover analysis of the rack for determining the weakest direction, iv) selection of 7 spectrum compatible seismic records considering the predefined fundamental period, v) definition of the acceptance criteria for the assessment of structural components and, vi) time-history analyses and results compilation and representation via probabilistic functions. All the following steps are explained in more details in the sequel.

4.1 Model Description

The pipe rack that is examined comes from an existing LNG terminal plant (Figure 6a) and is shown in Figure 6b. Although the LNG terminal is originally placed and designed in a low-seismicity region, the pipe rack is replaced to Priolo Gargalo, a high seismicity area in southeast Sicily, in order to acquire a better insight of the seismic performance. The pipe rack under assessment consists of 2 sub-racks; a 6x9x8.3 m short rack that supports the pipelines that come immediately from the LNG storage tank and a 102x6x7.3 long rack that transfer LNG to nearby units (Figure 6c). All the intermediate spans by the beams are 3 m long. The structural components are made by concrete class C40/50, whereas the 7 pipelines that run along the rack by steel grade ASTM A312/TP304L with yield and ultimate strength 370 MPa and 461 MPa, respectively. More information about the mechanical properties of the rack and pipelines can be

found in [29] and [30]. The concrete material is described by the Mander model, which accounts for transverse reinforcement, and the Menegotto-Pitto one is used for the ribbed reinforcement. The inelasticity of beams and columns is described by force-based frame elements that rely on nonlinear fibre section method [27]. A five-element non-uniform subdivision is adopted for the members.

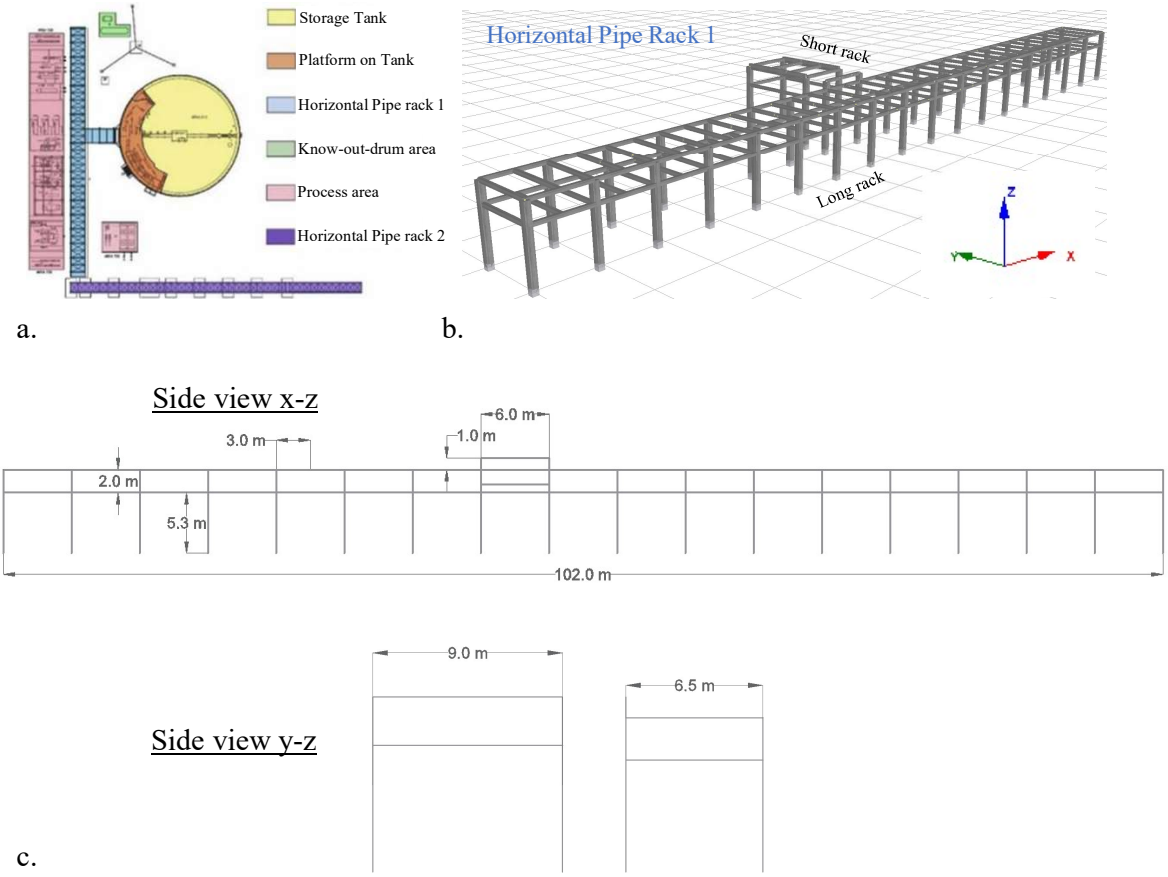

Figure 6: a. LGN terminal layout ([30]), b. RC pipe rack under assessment and c. dimension of the rack

Since the modelling of the entire terminal is not practically feasible due to the excessive computational cost, the assumption of pinned connections at the edges of the pipes that run beyond the pipe rack main frame is made. This decision is an approximation and states on the safe side since pipes that present relative flexibility -mostly bend downwards or upwards after the main frame of the rack- are considered more rigidly restrained. Furthermore, another type of modelling constraint refers to pipe modelling. Although EN and AM codes of pipelines design do not make reference of shell elements yet only to beam ones, the last type of element may be incapable of capturing the exact strain-stress response [7]. In view of the large model under investigation and the availabilities of the analysis software [27] for pipe modelling, stick models both for straight and curved pipe have been used and calibrated according to [32]. It is worth mentioning that the internal operating pipe pressure is low (P_{max}=1.63 MPa) as quoted in [30] and thus neglected in order to remain on the safe side since the pressure increases at low operating levels the bending stiffness of pipe bends ([32]). The pipelines are supported mainly in a flexible way on the rack by keeping free the displacement in the axial direction of the pipe as well as all the degrees of freedom.

Finally, to account for the SSI effects, an elastic footing and strip beams foundation system is designed according to [33] for the new site. A coastal sandy clay to clayey sand soil profile with V_s=210 m/s and G_{max}=105 GPa (STC according to [9]) has been adopted and the linear soil springs for the 6 modes of vibration are estimated according to [24] and placed both under the footings and strip beams as shown in Figure 7.

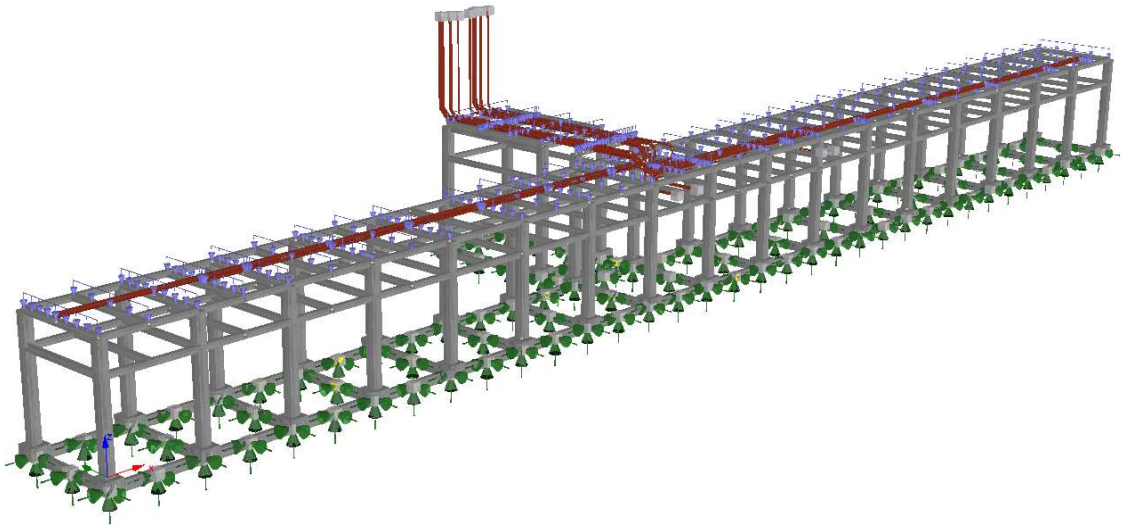

Figure 7: The soil-foundation, pipe rack and pipelines in the same model on Seismostruct ([27])

The original G-γ-D curves of the soil type, which rely on the formulae of [28] are shown in Figure 5. As mentioned in the section 3, the soil nonlinearity is described by calibrating the RO model included in the toolset of [27] for the STC. For that purpose, the unknown parameters of the model are estimated by building up a code in MATLAB ([34]) and the yielded G-γ-D curves are shown in Figure 8a&b for two fitting methods, namely the Root Mean Square Error (RMSE) and the coefficient of determination (R^2). The former was found to calibrate better the G-γ curve and thus the parameters of that fitting are adopted.

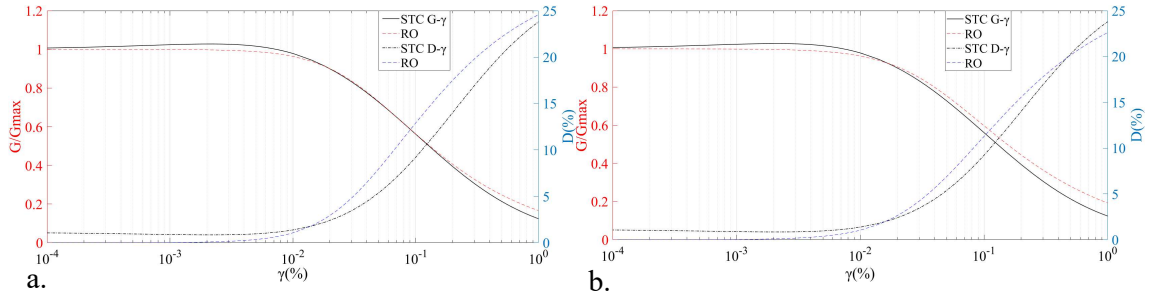

Figure 8: Calibration of RO model for the STC using a. the RMSE and b. R^2 fitting methods

4.2 Seismic assessment

Initially, a modal analysis is conducted for the pipe rack shown in Figure 7 with (W/) and without (W/O) SSI to identify the fundamental modes, which are quoted in Table 2. The maximum increase of the period fluctuated between 17 and 20% for the two modes. To select the seismic records for the fragility assessment of the rack, it is necessary to identify the fundamental period along the weakest direction. This is achieved by means of pushover analysis both for uniform and 1st mode load distribution as well as for the two modes shown in Table 2. The

capacity curves are illustrated in Figure 9 where it is obvious that the principal mode in the Y direction (T_3=0.276 sec) is the weakest one.

	$T_{W/O}$ (sec)	$T_{W/}$ (sec)	ΔT (%)	$M_{W/O}$ (%)	$M_{W/}$ (%)
Mode 3(Y)	0.269	0.315	17	43	34
Mode 5 (X)	0.230	0.276	20	87	55

Table 2: The two fundamental modes of the pipe rack

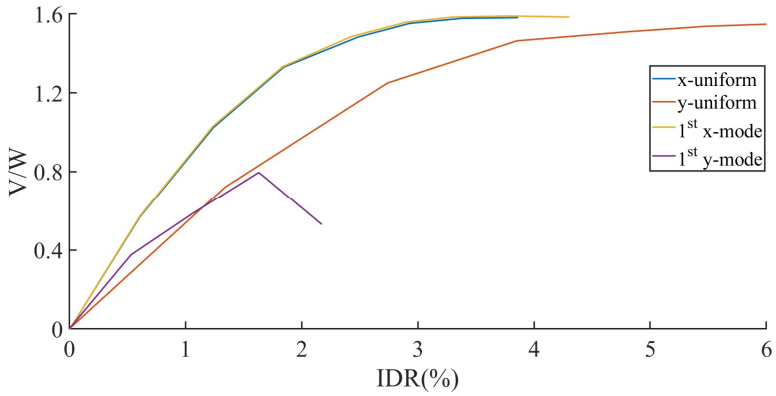

Figure 9: The capacity curves of the first mode and uniform load pattern distribution

Furthermore, 7 compatible records are selected through REXEL software ([35]) in the [0.2 T_3, 2T_3] period range. The spectrum that the compatibility is achieved for refers to SLV limit state, STC and Usage Class III ([36]), although three LSs, namely Serviceability (SLS), Safe Life Limit State (SLLS) and Collapse (CLS) are accounted for the assessment in the following. This topic is under investigation by the Authors since the best option could be records compatibility for each LS. It is also noteworthy that the compatibility of records is difficult to be attained both for the two horizontal and one vertical component, thus, the records shown in Figure 8 have compatibility for the two horizontal ones at least (the vertical component is used in all cases). The epicentral distance of the seismic records is greater than 15 kms (far-field, [37]) and the duration of the records selected for the analysis is bracketed with a_g>0.05 g.

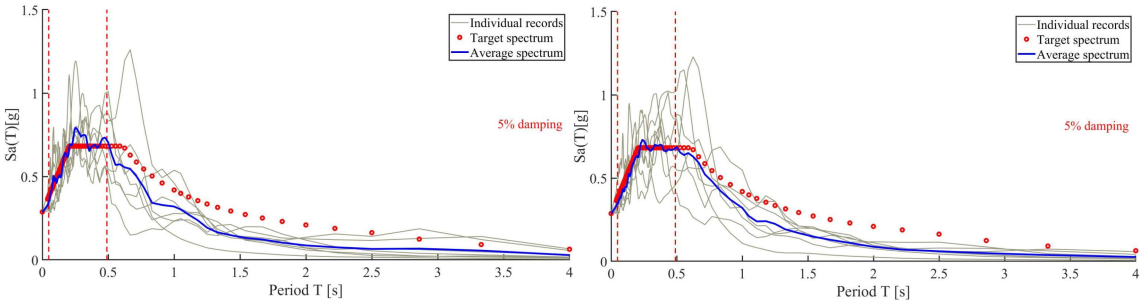

Figure 10: The spectrum-compatible seismic records in far-field conditions for the a. X and b. Y component

4.3 Derivation of fragility functions

Numerous methodologies exist in the literature for the evaluation of fragility functions. A common methodology that proposes the successive scaling of records till structural collapse onset, viz Incremental Dynamic Analysis (IDA, [38]), is adopted in the framework of this study.

The method has the competitive edge against other methodologies such as Multi-Stripes Analysis (MSA) or Cloud Analysis that it can be used even if a limited number of spectrum compatible records can be found for a particular site accounting also for the constraint in the epicentral distance, whereas other methodologies need a considerably greater number ([39]). The constraint of limited number of records is also in connection with the model scale. Before assessing the structural damage, the LSs should be determined. Only the structural members are assessed herein, whereas the nonstructural components will be presented in future publications.

Accounting for the fact that an LNG pipe rack is a critical structure that carries nonstructural components, a multi-scale approach should be considered by discriminating the collapse in local scale e.g. pipelines, meso-scale (structural members) and global scale in order to be utilized in the future within a quantitative risk framework. In particular, the Engineering Demand Parameter (EDP) that is adopted for the meso-scale is the shear force V_E, since it is related to the response of individual macroelement whilst the chord rotation θ_E or IDR can describe the global collapse (joint of more than one element, Table 3). More information about the EDPs of structural components can be found in [40].

Mechanism	Serviceability LS (SLS)	Safe Life LS (SLLS)	Collapse LS (CLS)
Flexure (rad)	$\theta_E \leq \theta_y$	$\theta_E \leq \theta_y$	$\theta_E \leq \theta_{u,\,m\text{-}\sigma}$
Shear (kN)	$V_E \leq V_{Rd.EC2}$	$V_E \leq 0.75 \cdot V_{Rd.EC8}$	$V_E \leq V_{Rd.EC8}$

Table 3: Limit states of concrete members in meso- and global-scale ([40])

The fragility functions of columns and beams are shown in Figures 11&12 only for the meso-scale investigation since the failure under bending was not found to be predominant. The SSI affects detrimentally the response of structural components both in linear and nonlinear case. An interesting result pertains to the dispersion of damage when the two cases are compared. The soil nonlinearity yields much lower dispersion (Table 4) and that might be due to the independence of structural damage vis-à-vis the modelling parameters caused by the energy dissipation of soil. We mention that the probability of exceedance of columns CLS for PGA=0.6g in the decoupled case W/ and W/O SSI soars by 43% and 81% for the linear and nonlinear soil, respectively. The pertinent values for the beams are equal to 55% and 270%.

When it comes to decoupled and coupled case, it is shown that the vulnerability of the pipe rack goes up further, however, the tendency is much higher for the beams since they become considerably fragile. The comparison of beams and columns response W/O SSI deduces that the beams fail earlier for SLS, however, the columns get more fragile for the two consecutive LSs. However, this is not the case for the coupled case for which the beams fail in advance of columns for all LSs. The fragility of beams for the CLS W/O SSI and PGA=0.6g increases by 455% from the decoupled to coupled case. The pertinent raise for the columns is only 40%. This response is justified due to the immediate dynamic interaction of beams with the pipelines. Also, noteworthy is that the pipe rack was initially designed for a low-seismicity area and that make the support of pipes totally inappropriate for the seismicity of the new placement. Also, this proves our statement in the introduction that the type of BCs is considerable in the design of the racks and should be taken into account by the codes in a clear manner considering that only the weight and the rigidity of supported equipment is presently prescribed to be accounted for the analysis.

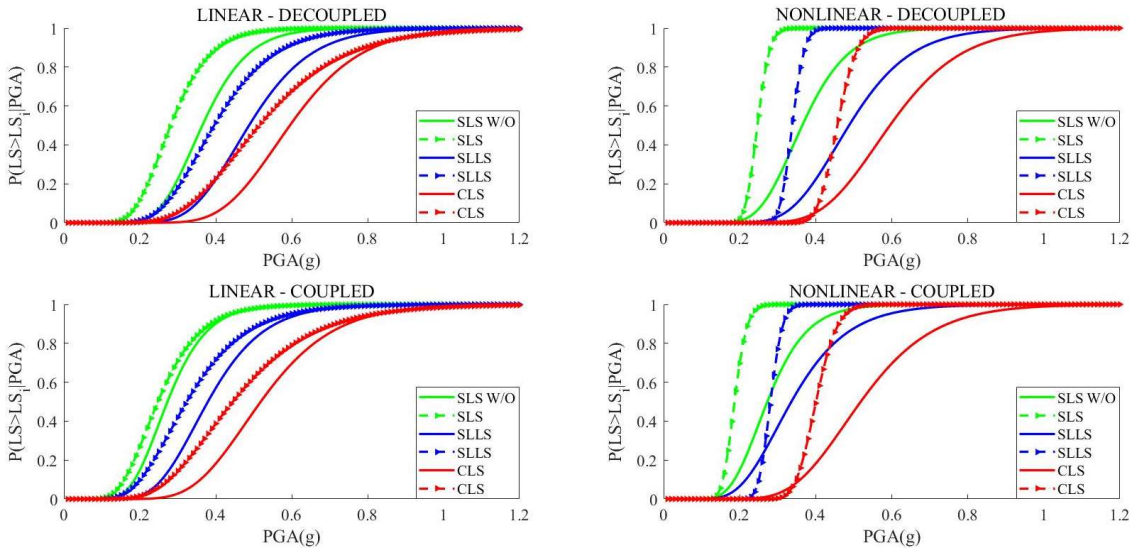

Figure 11: Fragility function for columns

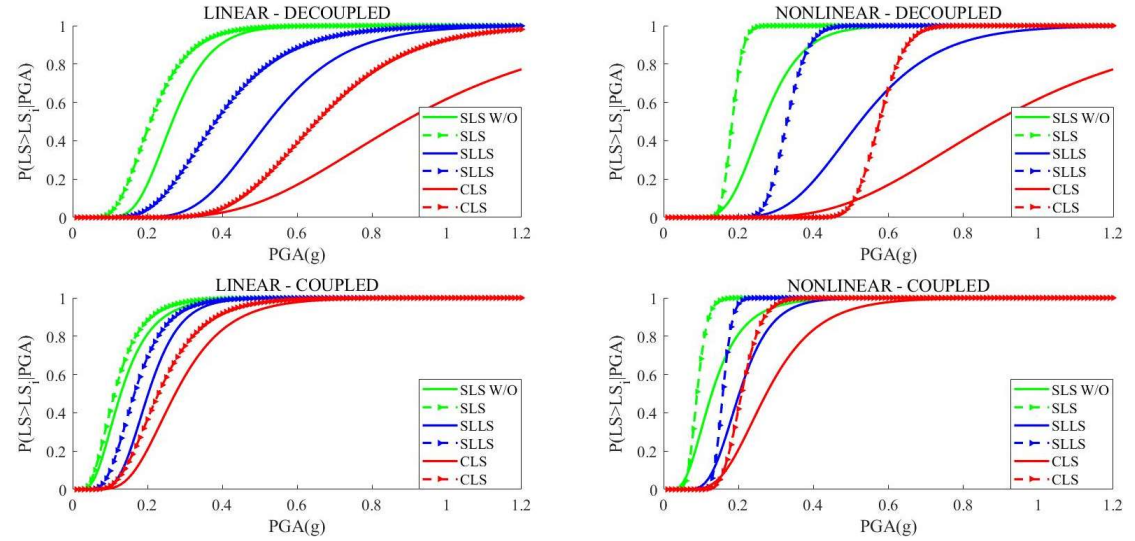

Figure 12: Fragility function for beams

Decoupled	W/O SSI			W/ SSI - Linear			W/ SSI - Nonlinear		
	SLS	SLLS	CLS	SLS	SLLS	CLS	SLS	SLLS	CLS
Columns	0.26	0.26	0.24	0.29	0.30	0.34	0.10	0.07	0.09
Beams	0.31	0.31	0.41	0.37	0.38	0.32	0.12	0.13	0.09

5 CONCLUSIONS

In the present analytical paper, a two-fold purpose was addressed; first the investigation of dynamic interaction between a number of pipelines with the supporting structure, and secondly,

the effects of soil-structure interaction on structural components response. The initial review of codes and technical literature showed that there is a gap of information of code provisions upon the parameters to be considered for the analysis methodology selection. The lack of code prescriptions was confirmed by the case-study, since it was shown by means of fragility curves the tremendous impact the pipeline might have on structural components and beams specifically. The rise on beams fragility was greater than 400% for the ultimate limit state without considering the effects of soil-structure interaction. When the last interaction is considered as well, the fragility of pipe rack increases further over than 50% and 250% for linear and nonlinear soil, respectively. It was also demonstrated that the soil nonlinearity or the higher energy dissipation might constitute the response of the rack independent of modelling and therefore reduce the dispersion of damage. Finally, both beams and columns failure was observed due to shear (meso-scale).

The investigation of pipes fragility and correlation of stress-strain values with LSs of the structural components is considered essential in order to confirm that common LSs cannot apply for nonbuilding structures like the present LNG rack. Also, another important parameter in the design process will be the evaluation of peak floor acceleration that is usually proposed by the codes when nonstructural components exist. Finally, records in near-field conditions as well as compatibility for the vertical component should be considered as well to examine possible variations of the pipe rack-pipes damage. The research on the aforementioned topics is still under investigation by the Authors.

Abstract

Malawi is located within the southern branch of the active East African Rift System, where earthquakes of Mw 7.0 (or greater) can occur along major faults. In Malawi, the majority of dwellings in both formal and informal settlements are non-engineered unreinforced masonry constructions, built by local artisans with little input from engineers. These constructions are highly vulnerable to seismic events due to poor materials and lack of construction detailing. This study develops analytical vulnerability functions that enable the assessment of seismic capacity of typical buildings in Malawi. Since the seismic vulnerability greatly depends on building characteristics, geometrical and structural data are collected by conducting semi-rapid surveys of 300 houses located in urban and rural areas of Central and Southern regions of Malawi. Mechanical properties of the local materials are also obtained from an experimental campaign. In this work, a mechanical method FaMIVE (Failure Mechanism Identification and Vulnerability Evaluation) is adopted and the effects of both in-plane and out-of-plane behaviour of the masonry structures are taken into consideration to derive capacity curves for seismic vulnerability assessment. Special attention is given to 1) the Malawian building typologies as described in the Word Housing Encyclopedia and 2) failure mode classes for the Malawian constructions as calculated by FaMIVE. Hence, the derived vulnerability functions can serve as a benchmark for typical buildings in Malawi. The results and conclusions are also relevant for other East African countries, where similar construction techniques are adopted.

Keywords: non-engineered masonry constructions, mechanical approach, seismic vulnerability, capacity curves, East African Rift System

1. INTRODUCTION

Malawi is located in Sub-Saharan Africa and shares borders with Mozambique, Zambia, and Tanzania. The country is ranked as the third poorest country in the world [1, 2]; where the main economic sector is agriculture, which is often negatively affected by adverse environmental disturbances and hazards (e.g. drought, poor health, heavy rains, windstorms, and floods).

Malawi is also a seismic-prone country within the southern branch of the active East African Rift System, where M_w 7.0 (or greater) earthquakes can occur near major geological faults [3, 4]. In recent years, the most significant earthquake in the country occurred in 1989 with Mw 5.7 in Central Malawi, making 50,000 people homeless [5].

In Malawi, residential buildings are made of unreinforced masonry and are regarded as non-engineered constructions, since they are built by local artisans with little input from qualified engineers. These dwellings are built informally, using poor-quality materials and inadequate structural detailing. Issues related to seismic vulnerability of non-engineered masonry structures need to be investigated through methods for building performance assessment by taking into account geometry and strengths/weakness of local structures. In fact, such an undesirable situation is prevalent across many countries in East Africa and most developing countries around the world.

During the first preliminary investigation carried out in Malawi by the authors to identify the prevalent building features and understand local construction practice, information was gathered from the Malawi Housing and Population Census [6] and World Housing Encyclopedia [7], and the Malawian Safer Housing Construction Guidelines [8]. As discussed in [9], collected data underlined high inconsistencies between datasets, highlighted by different criteria adopted to identify building typologies and distributions and non-compliance with design standards and guidelines.

To overcome discrepancies identified in the available data, in this work on-site investigations on local constructions are carried out with the aim at investigating the real distribution of the local buildings and identify parameters affecting the seismic vulnerability of the selected regions. Based on the collected data, seismic performance of the inspected houses is estimated by using a viable mechanical approach FaMIVE (Failure Mechanism Identification and Vulnerability Evaluation; [10, 11]), which evaluates failure modes and capacity curves by taking into account geometrical/structural features observed on site and mechanical parameters derived experimentally. Results will provide useful data for the development of structural vulnerability evaluation tools for masonry structures in Malawi, and for the implementation of risk assessment frameworks for East African countries [12].

2. METHODOLOGY

In order to enhance the data on building features of the Malawian buildings available from local/global datasets and guidelines [6, 7, 8], on-site structural surveys were carried out on 300 buildings. Data collected during the on-site inspections characterize urban and rural settlements of the Central-Southern Malawi, selected as a representative country in the East African Rift region, where rapid expansion of informal settlements is occurring. Recorded information includes geometry in plan and elevation, structural condition related to connections between walls, roof structures, masonry type and fabric quality, as discussed in Section 3. With reference to the collected data, in Section 4 inspected buildings are classified in building typologies. The adopted classification for the Malawian constructions was proposed by the authors in a World Housing Encyclopedia report [13], where three typologies were identified to classify buildings according to their expected seismic vulnerability.

Seismic performance and actual vulnerability of the three identified building typologies are evaluated in Section 5 using the mechanical approach FaMIVE [10, 11]. The proposed approach was adopted to capture failure modes and derive capacity curves as a function of the geometrical/structural data collected on site. Furthermore, since the major factors influencing the building performance are correlated the strength properties of masonry materials commonly used for housing construction in Malawi, these are also defined following an experimental campaign, carried out on local materials [14]. Results obtained from the laboratory testing and their correlation with different types of materials observed on site are discussed in Section 5.1.

The building performances derived from the urban settlements of Balaka and in the rural settlements in Lifidzi are focused upon. The seismic vulnerability of these buildings is discussed in Section 5.2 where failure mode distributions are illustrated and in Section 5.3, where capacity curves are presented. The results for the two different sites highlight how buildings with the same material types and roof structures, within the same (broad) building class, behave differently and have, consequently, dissimilar vulnerability. This is due to a high variety of construction details (e.g. different fabric quality and connection levels between walls observed for each identified typology) between rural and urban settlements which is extremely dependent on material and resource availability of a specific area.

3. ON-SITE STRUCTURAL SURVEYS

On-site structural surveys were carried out on 300 non-engineered buildings located in formal and informal settlements in the urban areas of Salima and Balaka and in the informal settlements of the rural villages Lifidzi and Golomoti (see Figure 1(a) and 1(b)). For each building, data were collected only for two orthogonal façades, since parallel walls of the inspected buildings had similar opening layouts. Data collection consisted of taking a few geometrical measurements as the ones illustrated in Figure 1 (c) (i.e. plan geometry, building/gable height, and opening dimensions and layout). Information related to structural features, such as masonry and mortar types, roof structure, connection levels between walls, and between walls and roof, were also collected.

Furthermore, since the inspected houses were constructed using locally-sourced materials with poor quality control, and construction materials differ considerably in shape, homogeneity, consistency, density, and brittleness, the fabric quality of the observed construction materials was recorded and defined as:

(1) good fabric quality: bricks have regular shapes and regular mortar layers. The clay has a homogeneous texture. Overlapping of bricks is regular. The bricks might have hairline cracks or cracks are apparently absent.
(2) medium fabric quality: bricks have uneven shapes and partially regular mortar layers. The clay has a medium porosity. Overlapping of bricks is partially regular. The bricks might have light cracks or small holes.
(3) poor fabric quality: bricks have irregular shapes and mortar layers. The clay has high porosity. Overlapping of bricks is irregular. The bricks have deep cracks or are partially lost.

Deficiencies derived from poor structural detailing, presence of damage, material loss and lack of maintenance were also investigated during the structural survey to take into account how existing structural weakness impacts on the performance of the investigated buildings.

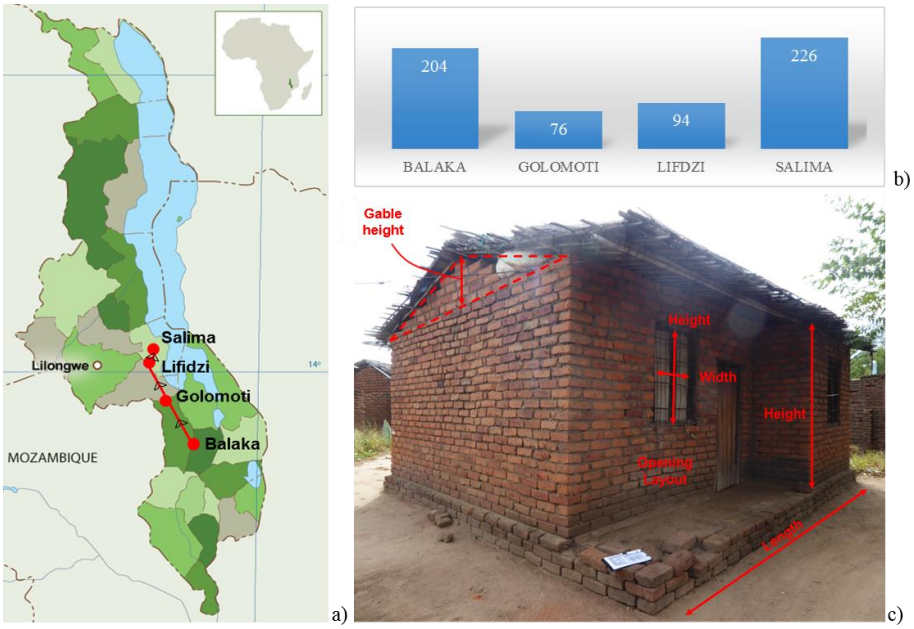

Figure 1: a) Building survey locations, Balaka, Golomoti, Lifidzi, and Salima; b) number of façades collected for each site c) geometrical measurments collected for each inspected façade

4. BUILDIGN CLASSIFICATION

Data collected on site were used to classify the inspected buildings in typologies, which are adopted in Section 5 to derive the vulnerability of the Malawian constructions. In Table 1, the inspected buildings are classified according to material type (a: unfired bricks, b: unfired bricks), fabric quality (1: good, 2: medium; 3: poor), and roof type (thatched/metallic sheet roof). Main features of the inspected constructions are reported in Figure 2.

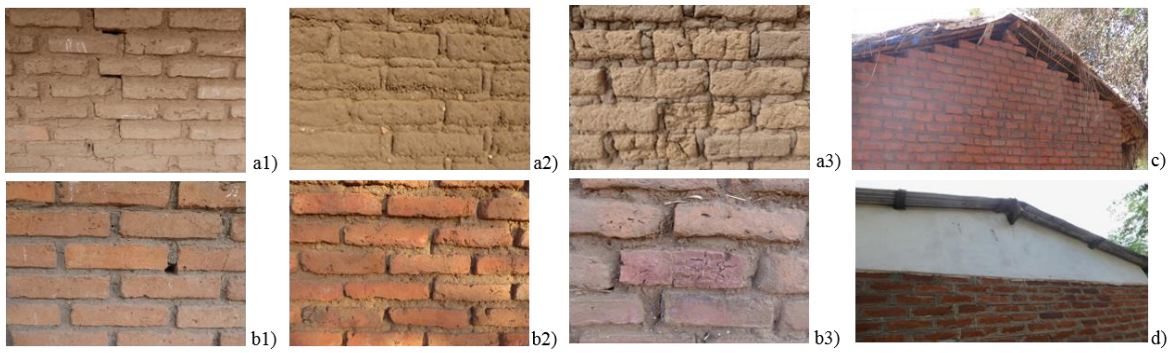

Figure 2: a1) and b1) good; a2) and b2) medium and a3) and b3) poor fabric quality of unfired and fired bricks, respectively c) thrached roof and d) metallic sheet roof

Most of the observed buildings (82%) were made of fired bricks, since these are affordable materials to be sourced on-site, and they do not require high construction skills. Mud mortar was identified for 76% of the inspected buildings, while cement mortar, observed for the remaining inspected houses, is gradually being adopted. Fabric quality varies considerably from poor to good and underlines the need of assessing the building performance by defining mechanical properties which reflect the actual masonry strength according to the different fabric quality identified on site (see Section 5.1).

The majority of the inspected houses (55%) were built with single-skin walls with thickness varying from 100 mm to 160 mm. For these constructions, the connections between adjacent walls were assumed poor, while for the remaining inspected houses with double-skin walls and thickness varying from 210 mm to 260 mm, the connections between walls were assumed stronger only if cement mortar was employed. Regarding building roofs, these were made of timber rafters supporting thatch for 21% of the inspected buildings or light metallic corrugated sheets for the remaining ones. Both roof types were inspected on site and classified as light systems, as they are not rigid along the entire plane do not act as rigid diaphragm.

According to the collected data described above, inspected buildings, as illustrated in Table 1, are classified in three typologies: A, B, and C (shown in Figure 3) introduced in the World Housing Encyclopedia by the authors [9, 13] Typology A is representative for 20% of the inspected buildings, characterized by low seismic vulnerability (Figure 3 (a)). These buildings were made of mud mortar combined with fired bricks of poor fabric quality (see Figure 2(b3)) and unfired bricks from poor to high fabric quality (see Figure 2(a1), (a2), and (a3)). Generally, these houses have smaller building footprints than the typical floor plan of 8 m × 6 m. Most of these houses (17%) have thatch supported by light timber elements, while the remaining are made with metallic sheet roof. Roof structures are characterized by a poor structural detailing (e.g. lack of connection between walls and between the walls and roof).

	Thatched roof				
	Unfired bricks + mud mortar			Fired bricks +mud mortar	
	a1	a2	a3	b2	b3
	1.2%	11.3%	1.8%	4.6%	2.5%
typology	A			B	A

	Metallic sheet roof							
	Unfired bricks + cement mortar			Fired bricks +mud mortar			Fired bricks + cement mortar	
	a1	a2	a3	b1	b2	b3	b1	b2
	0.3%	2.5%	0.6%	3.7%	41.4%	6.4%	11.7%	12.0%
typology	A			B			C	

Table 1: Building distribution with reference to material type (a: unfired brick, b: fired brick), fabric quality (1: good; 2: medium and 3: poor), and roof type (thatched or metallic sheet roof).

The most common typology observed in Malawi, B, representing 52 % of the buildings, is rated as medium seismic vulnerability (see Figure 3(b)). These buildings were made of fired bricks characterized from poor to a good quality fabric (Figure 2(b1), (b2), and (b3)). Due to the presence of mud mortar in these houses, the bonding between bricks is considered poor, therefore connections between walls were assumed weak. The construction details varied significantly, as well as maintenance levels.

a) b) c)

Figure 3: Typical one-story masonry building in Malawi. a) typology A; b) typology B; c) typology C

Typology C covers 28% of the inspected houses (see Figure 3(c)). These were made of fired bricks from poor to good quality fabric (Figure 2(b1), (b2), and (b3)) and cement mortar. Generally, these houses had a larger floor plan than the typical plan. Due to the extended plan

size, irregularities were likely to occur (e.g. portico and re-entrant corner). Most of these houses had corrugated metallic sheets supported by timber elements or truss, and good structural detailing (e.g. adjacent walls and walls/roof are connected). The good structural quality of these houses can be also attributed to the presence of strengthening elements (e.g. ring beams).

5. DERIVATION OF SEISMIC PERFORMANCE FOR BUILDING TYPOLOGIES

In this work, results are shown for two locations: Lifidzi and Balaka, classified as a rural and an urban area, respectively. These sites are adopted in this study with the scope of illustrating that buildings with the same construction material types and roof structures, classified in the same typologies (i.e. A, B and C), they may have a different seismic response. This is stated because, during the on-site survey, it was observed that buildings of the same typology are often characterized by a different geometry (i.e. plan size, height, and opening layouts) or a different fabric quality (dimensions of the bricks, bonding between brick-mortar in terms of friction and cohesion) or a different level of structural conditions (connections between orthogonal walls, and between the walls and roof). Therefore, there is a high possibility that the different observed parameters could impact on the behaviour of the individual building and consequently, on the vulnerability of the specific typology.

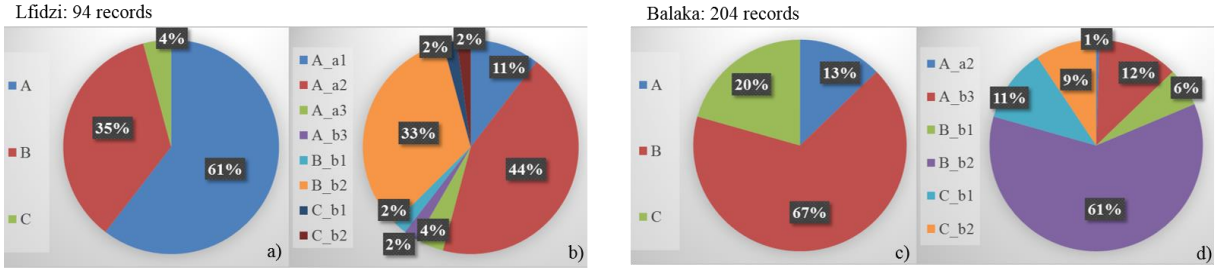

Figure 4: a) and c) Building typology distribution (A, B and C) identified in Lifidzi and Balaka; b) and c) each identified building typology is associated to inspected material type and fabric quality, where a1 and b1 is good; a2 and b2 is medium and a3 and b3 poor fabric quality for unfired and fired bricks.

Before discussing the results obtained for the two different sites, Figure 4(a) and 4(c) are presented to illustrate the building distributions identified for building typologies A, B and C for Lifidzi and Balaka, respectively. As expected, the weakest typologies A, built with unfired bricks and low low-quality of fired bricks, has a higher concentration in Lifidzi, where houses are constructed in rural communities by local builders/artisans in absence of technical guidance. Building typologies B and C are more concentrated in Balaka, where houses are built using materials with better mechanical properties than the ones in rural areas. Figure 4(b) and 4(d) present the fabric quality observed in the three typologies, underlining, as expected, that materials adopted in Balaka have better fabric quality than the ones observed in Lifidzi. This can be underlined by typology A, where 79% of the houses belonging to this class for Lifidzi are made of unfired bricks of medium/poor fabric quality against the 4% in Balaka, where houses are mainly made of fired bricks of poor fabric quality. For typology B, 16% of the houses in Balaka are made with bricks of high fabric quality compared to 6% identified in Lifidzi, while the remaining houses for both sites are made of bricks with medium fabric quality. For typology C, houses belonging to this class, cover only 4% of the inspected houses in Lifidzi, whereas 20% observed in Balaka. Mechanical properties defined for the different material types are indicated in Section 5.1. As discussed in Section 4, roofs are made in thatch or metallic corrugated sheets supported by timber elements, therefore in both cases it is assumed

that the roof structures behave as flexible horizontal systems. Furthermore, for the classes A and B, it is assumed that the roof structure is completely detached from the walls, in order to be consistent with the observations on site. As for the connections between walls, they are assumed absent for houses constructed with single-skin walls, features belonging to 63% of the inspected houses in Lifidzi and Balaka.

5.1 Strength of local masonry in Malawi

Strength properties of masonry materials commonly used for housing construction in formal and informal settlements in Malawi, were investigated by means of laboratory testing, conducted on masonry prisms and panels [14]. The tests were conducted with the scope at reproducing actual field conditions and construction practices in the country. Based on the observations from the on-site structural surveys, specimens were prepared by local artisans using local commercial production of brick batch and mortar types in mud and cement, which were cured in uncontrolled conditions. The results revealed that the behaviour of the masonry in compression is governed by the low compressive strength of the brick units. It was also found that the quality of the brick-mortar bonding governs the in-plane shear and out-of-plane flexural behaviour, which are the critical parameters of the resistance to horizontal loading, such as earthquake action. These are directly related to the quality of the brick-mortar interface bonding and the thickness of the walls. Values for interface cohesion, measured by means of standard triplet shear testing, vary between 0.01-0.02 MPa for mud mortar and between 0.2-0.25 MPa for cement mortar configurations. Friction angles were measured at around 32 degrees.

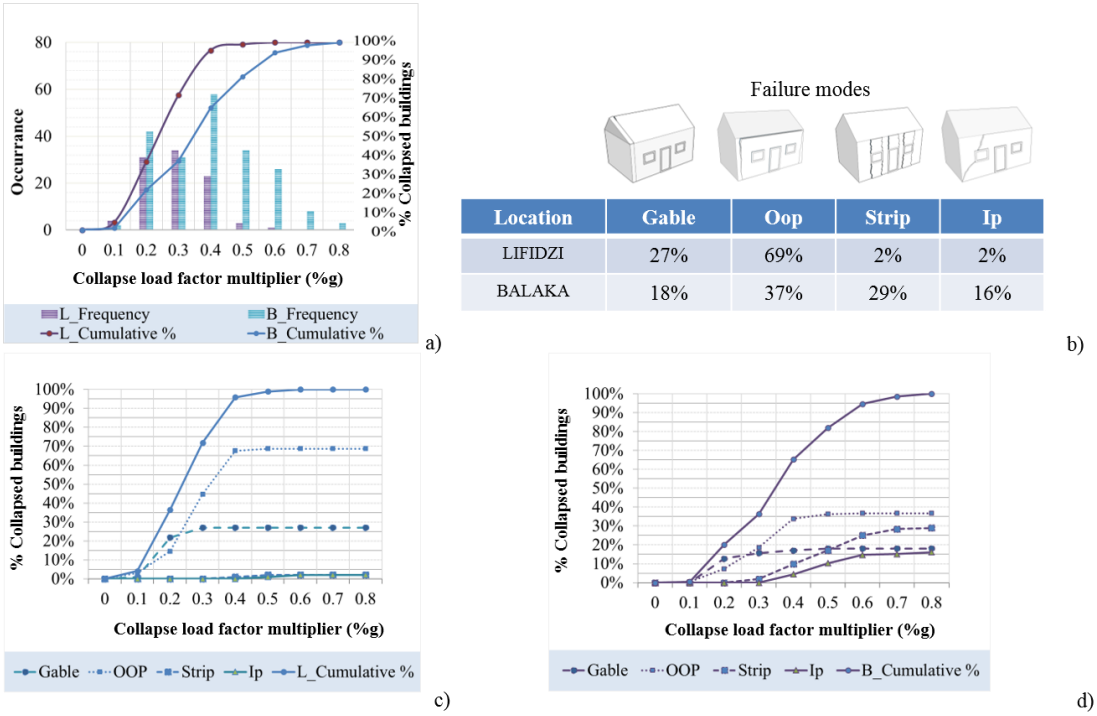
With reference to these measured values, they are used to define the mechanical properties of the observed fired bricks with mud and cement mortar with a good fabric quality. In evaluating seismic vulnerability of the houses based on FaMIVE, typologies with poor/medium structural features are penalized by considering that their fabric quality and brick-mortar bonding are inferior compared to the ones derived from the tested materials [11].

5.2 Estimation of load factor multipliers and failure mode distribution

The seismic performance of the buildings inspected in Lifidzi and Balaka is assessed using FaMIVE [10, 11, 15, 16]. The approach is based on a mechanical procedure, relying on the assumption that buildings behave as an assemblage of macro elements, held together by compressive forces. Analyses are performed using equilibrium equations, where earthquake actions are simulated as a horizontal static force, proportional to the mass of the single inspected façade. The analysis is static equivalent and aims to predict the horizontal static actions, quantified by means of collapse load factor multipliers (λ), corresponding to a percentage of gravity acceleration, g [10, 11]. The factor λ is calculated for each of the failure modes, which are defined as all possible collapse mechanisms that can occur for a masonry building subjected to earthquake shaking. The estimated values of λ indicate the lower bounds of the level of shaking which trigger the identified failure modes. Among the computed collapse load factor multipliers, the failure mode with the smallest multiplier is considered to occur on a façade (as the weak link). In implementing the FaMIVE method, geometrical/structural features described in Sections 3 and 4 for the inspected houses in Malawi are used as input of the proposed approach. Furthermore, since masonry type, fabric quality, and connection level between walls have a considerable impact on the building responses, both angle of friction and cohesion taken from Section 5.1, and relative dimensions of bricks and walls taken from the survey carried on site were adopted to assess the capacity of the inspected buildings.

The occurrence of λ, evaluated for the selected building stocks in Lifidzi and Balaka are illustrated in Figure 5(a). The median of λ, being 0.24g and 0.38g for Lifidzi and Balaka re-

spectively, underlines that the buildings inspected in Lifidzi are weaker than the ones inspected in Balaka, as they fail for lower values of λ. This is also highlighted by the slope of the cumulative curve: the one derived for Lifidzi has a higher slope than the one derived for Balaka (i.e. for λ = 0.35g, 72% and 35% of the inspected buildings fail in Lifidzi and Balaka, respectively).



Location	Gable	Oop	Strip	Ip
LIFIDZI	27%	69%	2%	2%
BALAKA	18%	37%	29%	16%

Figure 5: a) Collapse load factor multiplier distribution in the selected building stocks in Lifidzi (L) and Balaka (B); b) failure modes distribution; c) collapse load factor multiplier distribution for the failure modes identified in Lifidzi (L) and d) collapse load factor multiplier distribution for failure modes identified in Balaka (B)

The failure modes associated with the identified collapse load factor multipliers are illustrated in Figure 5(b). These are classified into four categories: 1) *Gable*: predominantly occurs on walls with gables which are not connected to roofs, and therefore fail in overturning; 2) *Oop*: Out of plane, predominantly occurs on single-skin walls with a low-quality material and poor connection with orthogonal walls and roof, causing overturning of a single façade; 3) *Strip*: predominantly occurs on single-/double-skin walls with a medium-quality material and a good connection with orthogonal walls and roof; causing overturning of a strip of piers and spandrels; and 4) *Ip*: In-plane, predominantly occurs on single/double-skin walls with a medium-quality material and a good-quality connection with orthogonal walls and roof; causing shear failure of a single façade.

As expected from the on-site surveys, since a lack of connections between the walls and roof and low-quality construction materials were frequently observed in the inspected buildings in Lifidzi, *Oop* is the most likely failure mode with a percentage of 69%. By contrast in Balaka, there is a smaller percentage of buildings failing in *Oop* (37%), and a higher percentage of buildings failing for *Strip* (29%), where the latest occurs on buildings with stronger connections, belonging to typologies B or C. Only a small percentage of the inspected buildings fail for *Ip* (16%), emphasizing that even buildings of typology C, built with double-skin walls, fired bricks of better quality and cement mortar, mostly fail due to overturning of ga-

bles, walls, and spandrels and piers, due to use of poor construction materials and construction practice details.

Figure 5(c) and 5(d) show the distribution of collapse load factor multipliers for the failure modes identified in Lifidzi and Balaka, respectively. *Gable* failure modes occur for the lowest values of λ (smaller than 0.3g) for inspected buildings with tall gables, resulting in separation of their roofs. Buildings in classes B and C, classified in a medium high-quality class, mostly fail for *Strip* and *Ip* failure modes with the highest values λ, (greater than 0.3g). Regarding *Oop*, λ varies from a minimum value of 0.1, values identified for buildings belonging to typology A, to 0.4, values identified for buildings belonging to typologies B and C.

5.3 Derivation of capacity curves

In this section, capacity curves are derived for the building typologies identified in Lifidzi and Balaka with reference to [10, 11, 16, 17, 18]. Derived capacities strictly correspond to the parameters defining the geometry, structural conditions, connection level between walls, material types and fabric quality of the inspected buildings in the case study. Multiple capacity curves, one for each analysed façade, are derived for a single building. This is because capacity curves are directly developed from the load factor multipliers, which are also calculated for each inspected façade, as illustrated in Section 5.2.

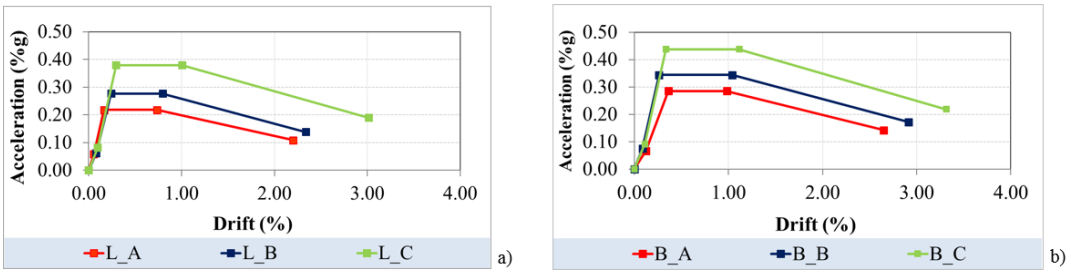


Figure 6: Median capacity curves for a) the building typologies: A, B and C for Lifidzi and Balaka, respectively

The maximum strength or maximum acceleration (g) in a capacity curve is taken equal to the minimum collapse load factor estimated by FaMIVE for each inspected façade. The elastic limit displacement of each façade is calculated as a function of the elastic stiffness and the mass of the façade, involved in the identified failure mode. The ultimate displacement is defined as the displacement identifying the geometrical instability of the façade and hence its collapse. Computed these displacements, these are divided by the height of the single inspected façade to derive the drift.

Figure 6 shows the different capacity curves derived for the building typologies A, B, and C identified in Lifidzi and Balaka, respectively. As expected from the definition of the three typologies, it is noticeable that the building typology A (class of buildings characterized by low-quality materials and construction details) has the lowest values of acceleration and drift compared to B and C. Clearly, the derived capacity curves are capable of capturing the different performances for the single typology. Furthermore, they underline that classifying buildings according to structural conditions and differentiating mechanical properties with respect to the fabric quality improve the reliability of the vulnerability obtained for the single typology. This can be observed particularly for the different values of acceleration obtained for typologies B (maximum acceleration is 0.29g, and 0.35g for Lifidzi and Balaka, respectively), and C (maximum acceleration is 0.38g, and 0.43g for Lifidzi and Balaka, respectively) which point out that buildings of the same typology (same construction materials and roof

types) located at different sites and subjected to different levels of quality control are likely to behave differently under seismic events. Conversely for the typology A, the values of maximum acceleration are the same (0.21g), underlining that the two classes in the two sites have same vulnerability, as they are constructed using poor materials with same mechanical properties.

6. CONCLUSIONS

This paper has shown the results derived from a seismic vulnerability study carried out for representative non-engineered masonry buildings in Central-Southern Malawi. The presented work integrates an effective methodology for collecting data, classifying non-engineered masonry buildings in main typologies, correlating observed masonry types to their strength measured experimentally, and assessing vulnerability. The data collected during the structural investigations and presented in this paper have enhanced the available information related to building distribution and typologies compared with local/global datasets that were previously available for the Malawian constructions (Ngoma & Sassu, 2002; National Statistical Office of Malawi, 2008; Bureau TNM, 2016). Furthermore, this work illustrates the importance of gathering detailed structural information, including masonry type, fabric quality, bonding between masonry and mortar, and connection levels between walls. Moreover, the vulnerability calculated for this work can offer notable advantages to identify failure modes and derive capacity curves for non-engineered masonry buildings which could be further implemented in a risk assessment tool together with enhanced local data.

Abstract

In nuclear applications, fragility curves are an essential element of the seismic probabilistic safety assessment that is performed at the level of the power plant. They are required to account for the aleatory randomness and the epistemic uncertainty generated by various sources of variability, such as the representation of the seismic input by intensity measures, the assumptions in the structural model (e.g., mechanical or geometrical parameters) and the confidence in the statistical estimation of the fragility parameters (i.e., related to number of data points used). Therefore, this study investigates the relative contributions of such variables to the dispersion of the resulting fragility functions, while ensuring the separation between aleatory and epistemic uncertainty sources, as advocated by the standards in effect in the nuclear industry. To this end, vector-valued fragility functions, based on two intensity measures, are also investigated: it appears that they allow for a partial transfer from the record-to-record variability to an epistemic uncertainty component that is related to the description of the seismic loading given the hazard at the studied site.
The proposed uncertainty decomposition is applied to the fragility assessment of the main steam line of a nuclear reactor: the total dispersion of the resulting fragility models is then decomposed into different aleatory and epistemic components. Although it is found that vector-valued intensity measures contribute to a significant part of the total dispersion, the uncertainty due to the variability of mechanical and geometrical parameters appears to be even larger.

Keywords: Fragility curves, intensity measures, dynamic analysis, epistemic uncertainty.

1 INTRODUCTION

The quantification of the vulnerability of structures and equipment constitute a crucial step of the seismic Probability Safety Assessment (PSA) of a Nuclear Power Plant (NPP). To this end, fragility curves are common tools developed in the nuclear industry. The vulnerability of a component may then be represented by the so-called High Confidence Probability of Failure (HCLPF) capacity, which corresponds to the value of the intensity measure (IM) leading to a failure probability of 5% on the 95% confidence interval of the fragility curve (EPRI, 2003). Therefore a rigorous distinction between aleatory and epistemic uncertainty sources is required, following for instance the decomposition proposed by Kennedy et al. (1980): the total dispersion β of the fragility curve is decomposed into a term β_R representing aleatory randomness (i.e., the "slope" of the curve) and a term β_U representing epistemic uncertainty (i.e., the width of the confidence interval).

$$P_f(im) = \Phi\left(\frac{\ln im - \ln \alpha + \beta_U \Phi^{-1}(Q)}{\beta_R}\right) \quad (1)$$

where P_f is the conditional probability of reaching or exceeding a given damage state, Φ is the normal cumulative distribution function, α is the median of the fragility function, and Q is the confidence level

Due to the complexity of a ground-motion time history, the description of the seismic loading through a single IM is acknowledged as a significant source of uncertainty, usually referred to as the record-to-record variability. Several studies have addressed this issue, either by searching for adequate IMs (Luco & Cornell, 2007; Padgett et al., 2008) or by deriving vector-IM fragility functions or surfaces (Baker & Cornell, 2005; Seyedi et al., 2010; Modica & Stafford, 2014). Generally, a decrease in the dispersion of the fragility functions is observed, however its interpretation in terms of uncertainty transfer remains to be clarified. Therefore, the aim of this study is to quantify the various uncertainty sources that may contribute the total dispersion of the derived fragility models. In particular, the comparison between single-IM fragility curves and vector-IM fragility functions should offer insight on the treatment of record-to-record variability and on its impact on the aleatory uncertainty component.

The proposed analysis will be demonstrated on the fragility assessment of the main steam line of a pressurizer water reactor (Rahni et al., 2017), using a set of nonlinear time-history analyses (Section 2). Then, several criteria for the selection of IMs will be investigated (Section 3), before deriving vector-IM fragility functions with multivariate regression models (Section 4). Finally, in Section 5, three main types of uncertainty will be compared thanks to different fragility formulations: *(i)* the aleatory uncertainty due to the record-to-record variability, *(ii)* the epistemic uncertainty due to the number of simulations (data points) used, and *(iii)* the epistemic uncertainty due to the variability of mechanical and geometrical parameters. As a result, this work will allow to decompose the total dispersion into several components, thus identifying the terms that deserve the most attention when computing the HCPLF.

2 NUMERICAL MODEL AND ANALYSES

This section details the modelling assumptions for the main steam line of the reactor, as well as the design of experiment for the dynamic analyses.

2.1 Modelling assumptions

The coupled model of a supporting structure and a secondary system is considered here, corresponding to the main steam line of a pressurised water reactor. The model, built and

computed with the CAST3M finite-element software (Combescure et al., 1982), is taken from Rahni et al. (2017). Structural elements, representing the containment building, are modelled with multi-degree-of-freedom stick formulations. The containment building has a double-wall structure, with an inner reinforced prestressed concrete wall and an outer reinforced concrete wall (see Figure 1). The steel steam line is modelled by means of beam elements, representing pipe segments and elbows, as well as several valves, supporting devices and stops at different elevations of the supporting structure. The stick models, which have the benefit of enabling fast computations, have been calibrated from detailed finite-element 3D models of the containment building (Rahni et al., 2017).

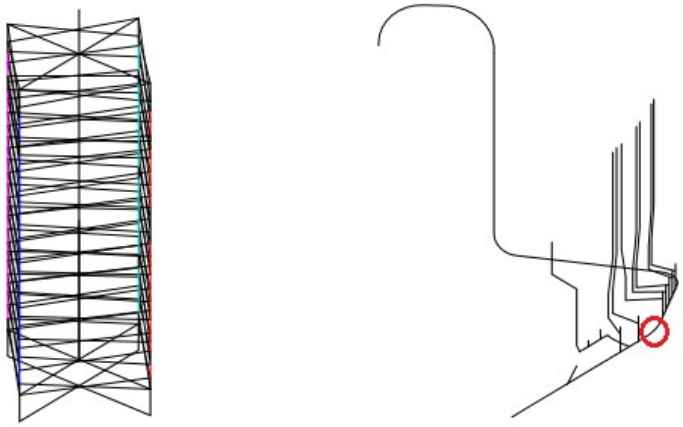

Figure 1:Left: stick model of the containment building (inner wall, outer wall and internal structures); Right: steam line beam model, where the red circle points to the location of the vertical stop.

Dynamic analyses are performed in two successive steps: first, the seismic loading is applied at the base of the building; and the resulting time history of structural displacements is then applied to the steam line model in order to estimate the induced strains and stresses on the beam elements. Rahni et al. (2017) have proposed several mechanical failure criteria for the verification of the steam pipe line integrity, such as the equivalent stress at any point of the pipe line (conservative assumption), the total plastic deformation at the pipe location corresponding to the containment penetration (i.e., accounting for the non-linear behaviour of the steel material), and the effort calculated at the beam model's node corresponding to a vertical stop (see Figure 1). For simplicity purposes, the latter failure criterion is considered here for the fragility analysis. The threshold for the occurrence of the damage state considered (i.e., failure at the vertical stop) is arbitrarily set at EDP_{th} = 400 kN for the maximum transient effort: this choice is made in order to obtain a relatively good balance between data points corresponding to intact or damaged states, for demonstration purposes.

As a preliminary to the non-linear time-history analyses, a modal analysis of the supporting structure is carried out, in order to identify the main vibration modes (see Table 1).

Mode #	Period [s]	3D mass participation factor [%]
1	0.38	61
2	0.38	65
3	0.15	35
4	0.14	97

5	0.14	31

Table 1: Modal analysis of the model of the containment building.

Modes #1 and #2 correspond to the excitation of the structure in the *Y*- and *X*-direction, respectively: due the almost symmetrical properties of the building, they are almost identical. Therefore, the fundamental period of the structure is taken as $T_1 = 0.38$s, while the second one is taken as $T_2 = 0.15$s (i.e., cluster of modes #3, #4 and #5).

In order to integrate the epistemic uncertainties due to the identification of some mechanical and geometrical parameters, ten variables are sampled within a Latin Hypercube Sampling design (see Table 2), following the values provided by Rahni et al. (2017).

Variable	Description	Uniform distribution interval
E_{IC}	Young's Modulus – Inner containment	[27700 – 45556] MPa
ξ_{RPC}	Damping ratio – reinforced prestressed concrete	[4 – 6] %
ξ_{RC}	Damping ratio – reinforced concrete	[6 – 8] %
e_1	Pipe thickness – Segment #1	[29.8 – 38.3] mm
e_2	Pipe thickness – Segment #2	[33.3 – 42.8] mm
e_3	Pipe thickness – Segment #3	[34.1 – 43.9] mm
e_4	Pipe thickness – Segment #4	[33.3 – 42.8] mm
e_5	Pipe thickness – Segment #5	[53.4 – 68.6] mm
e_6	Pipe thickness – Segment #6	[34.1 – 43.9] mm
ξ_{SL}	Damping ratio – steam line	[1 – 4] %

Table 2: Range of variation of the ten uncertain parameters considered, based on Rahni et al. (2017). A uniform distribution is assumed.

2.2 Selection of input ground-motion records

The conditional spectrum method (Lin et al., 2013) is used here for the selection of the input ground motions, for subsequent dynamic analyses. This approach has the benefit of enabling a light scaling of a set of natural records, while saving the consistency of the associated response spectra. Therefore, it is especially suited for the use of spectral values, such as *SA* (spectral acceleration) at various periods. The main steps of this procedure are the following:

- *Probabilistic hazard assessment of the studied site*: here, an arbitrary location in Southern Europe is selected. Hazard curves are generated with the OpenQuake platform (www.globalquakemodel.org), accounting for 13 seismogenic areas which have been characterized in the SHARE project (Woessner et al., 2013).

- *Selection of a period of interest and of scaling levels*: here, the response spectrum is chosen to be conditioned on $SA(T_1=0.38\text{s})$, with 6 scaling levels ranging from 0.185g to 3.882g, corresponding to return periods from 20 years to 20 000 years.

- *Identification of reference earthquakes*: for the studied site, the OpenQuake software performs a hazard disaggregation for each scaling level in order to identify a reference earthquake scenario.

• *Generation of the target response spectrum* and *selection of spectrum-compatible ground-motion records* (Jayaram et al., 2011). The final selection from the PEER database (PEER, 2013) consists of 30 records for each of the 6 scaling levels (i.e., 180 ground-motion records in total), as shown in Figure 2.

The ground-motion selection using conditional spectrum implies the evaluation of the seismic hazard at a given site, along with the identification of reference earthquakes at various return periods: as a result, this approach leads to site-specific fragility functions, which are well suited to the context of NPPs.

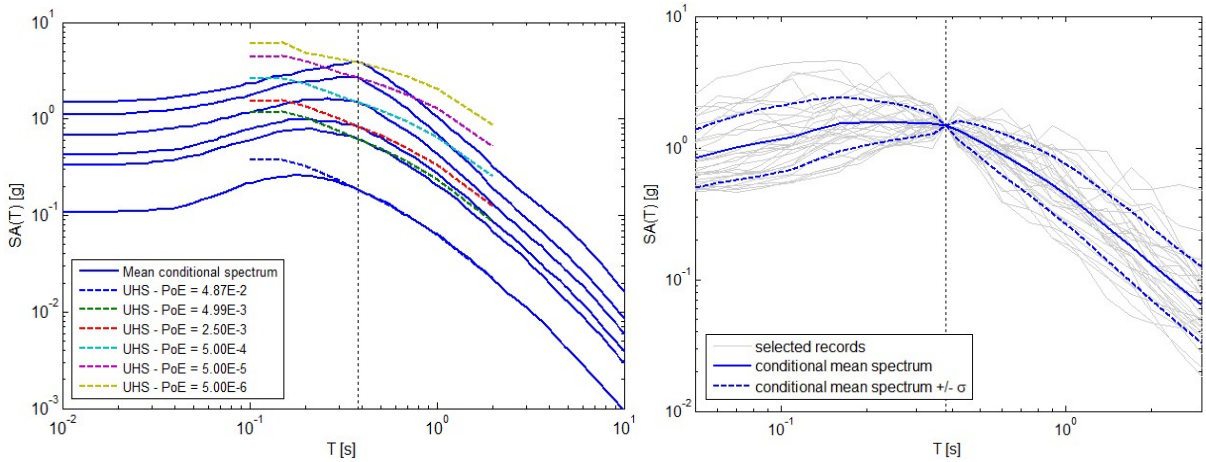

Figure 2: Left: conditional mean spectra and uniform hazard spectra for the 6 scaling levels; Right: conditional spectrum for scaling level #4 and corresponding set of 30 selected ground-motion records.

2.3 Non-linear time-history analyses

The 180 ground-motion records are applied to the base of the 3D model of the containment building, in the form of a 3-component loading. In total, 360 models of the PWR structure are built in the CAST3M environment, so that each ground-motion record may be applied to two different models, with the objective of generating enough data points. As an example, some simulation outcomes are presented in Figure 3, with PGA and SA(0.5s).

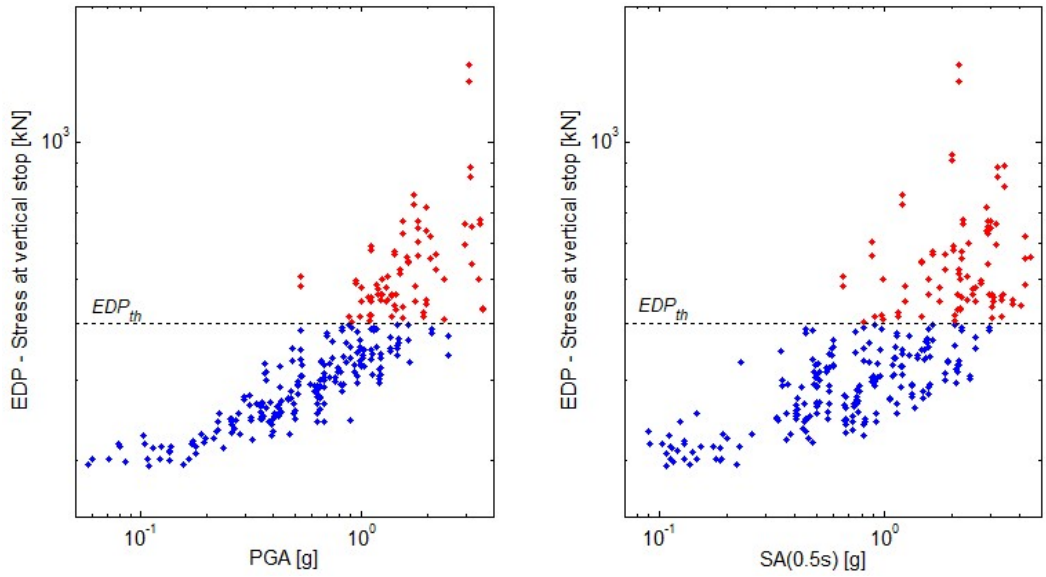

Figure 3: IM-EDP data points, with respect to PGA (left) and SA(0.5s) (right).

3 SELECTION OF SCALAR IMS

From Figure 3, it may be observed that a linear fit between the logarithms of IM and EDP is not justified for this specific case study: it is proposed here to apply the maximum estimation approach (MLE – cf. Shinozuka et al., 2000) approach, which only requires a separation between the intact and damaged states (i.e., respectively blue and red points in Figure 3). To this end, a large number of ground-motion parameters is evaluated as potential IMs:

- Spectral acceleration at various periods: *SA*(*T*)
- Peak parameters (acceleration, velocity and displacement): *PGA*, *PGV*, *PGD*
- Arias Intensity parameters: *AI* (Arias Intensity), *A95*[1], *SL75-95*[2]
- Spectral intensities: *SI* (Housner Intensity), *ASI* (Acceleration Spectral Intensity)
- Duration parameters: *RSD75-95*[3]
- Cyclic parameters: *NCy* (number of effective cycles), *DCy* (cyclic damage parameter)
- Energy-related parameters: *NED* (Normalised Energy Density)
- Parameters related to time-integrated acceleration: *CAV* (Cumulative Absolute Velocity), *ARMS* (Root-Mean-Square Acceleration)

The adequacy of IMs for the derivation of fragility curves has been addressed by many studies, using efficiency and sufficiency indicators (Luco & Cornell, 2007), statistical classifiers (Lancieri et al., 2015) or the concept of hazard compatibility (Hariri-Ardebili & Saouma, 2016). Based on these previous works, it is proposed to use three performance metrics in order to estimate the adequacy of the considered IMs:

1. **Standard-deviation β of the fragility curve:** although the MLE approach is used here, the estimated dispersion parameter β may be interpreted as the quantity described by Padgett et al. (2008) as the *proficiency* measure (i.e. combination of efficiency and practicability measures).
2. **Akaike Information Criterion (AIC):** this criterion quantitatively assesses the goodness-of-fit of a given model. The AIC accounts for the number of parameters used in a model through the variable k, in order to penalize the over-parametrization of some models. In the case of scalar-IM fragility curves, $k = 2$ (i.e., parameters α and β). The AIC is then expressed as follows:

$$AIC = 2k - 2\ln L \tag{2}$$

   where L is the likelihood function of the fragility model, which is computed as a product of the 360 conditional probabilities corresponding to the 360 simulation outputs. Therefore, a small AIC value implies a great statistical fit given the data.
3. **Area under the ROC curve (AUC):** the ROC curve is a possible representation of a ROC analysis, where the ability of a given model to be both specific and sensitive is evaluated by plotting the true positive rate versus the false positive rate. This approach has been applied by Gehl et al. (2013) to the evaluation of fragility curves (i.e. ability of the model to accurately predict the damage state or not, given an IM taken as a predictor). Therefore, the AUC provides a quantification of how well the fragility model

[1] Level of acceleration that contains 95% of the Arias Intensity

[2] Slope of the Husid plot (cumulative *AI* over time) between 5% and 75% (or 95%) of the total *AI*

[3] Relative Significant Duration: length of time interval between when *AI* first exceeds 5% of total value and when *AI* first exceeds 75% (or 95%) of total value

works as a classifier: a large AUC value (i.e., area close to 1) implies a model that works significantly better than a random classifier (i.e., the 1:1 diagonal).

These three criteria are first estimated for *SA* at various periods, ranging from 0.05s to 2s (see Figure 4). The curves reveal an optimum at T = 0.29s, whatever the metric considered. Local optima are also found at periods equal to 0.14s and 0.50s. The three identified periods are close to the periods that corresponding to the first two vibration modes (i.e., T_1 = 0.38s and T_2 = 0.15s). However, they are not exactly identical, and these differences may be explained by two factors, i.e. *(i)* the combination of superior modes that may be excited by some ground motions and *(ii)* the lengthening of the fundamental period due to the loss of elasticity of the structural components.

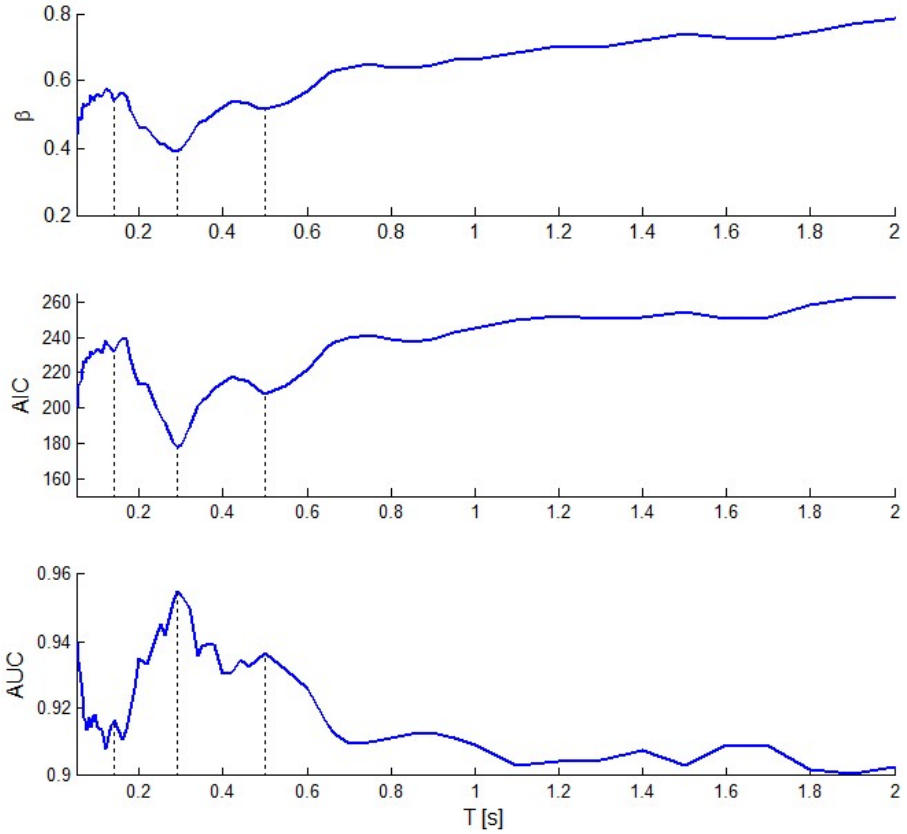

Figure 4: Evolution of the three performance metrics considered, with SA at different periods.

As a result, *SA* at the three identified periods (0.14s, 0.29s and 0.50s) are considered as potential IMs; and their performance is compared to other ground-motion parameters (see Table 3).

IM	β	AIC	AUC
SA(0.14s)	0.5415	229.91	0.9166
SA(0.29s)	0.3898	175.82	0.9547
SA(0.50s)	0.5144	206.12	0.9363
PGA	0.4403	198.45	0.9399
PGV	0.4928	205.73	0.9381
PGD	1.2622	308.93	0.8469

AI	0.7674	182.13	0.9485
A95	0.4041	192.88	0.9389
SL75	0.9471	206.91	0.9325
SL95	0.7681	176.59	0.9508
SI	0.5293	213.94	0.9347
ASI	0.3775	176.23	0.9519
RSD75	-	-	-
RSD95	-	-	-
NCy	-	-	-
DCy	0.8123	191.58	0.9412
NED	1.4284	259.27	0.8968
CAV	0.6012	247.15	0.8951
ARMS	0.5728	240.45	0.9073

Table 3: Estimated values of the three performance metrics, for different potential IMs. The gray cells indicate the five best performing IMs, for each metric.

It is found that the parameters *SA*(0.29s) and *ASI* are the most consistent, since they show a satisfying performance across the three metrics. Other well performing parameters are *PGA*, *PGV*, *AI*, *A95*, *SL95* and *DCy*. However, it should be noted that *DCy*, *SL95* and *A95* may not be easily computed from current GMPEs (see **Erreur ! Source du renvoi introuvable.**). The metrics cannot be evaluated for some parameters (*RSD75*, *RSD95*, *NCy*) because the fragility estimation has not converged due the poor IM-EDP correlation: these parameters may still be used as secondary IMs when deriving fragility surfaces, if the right IM combination is found.

4 DERIVATION OF VECTOR-IM FRAGILITY FUNCTIONS

In order to improve the predictive power of the fragility curves and to reduce the dispersion due to the record-to-record variability, it is proposed to combine two IMs and to use this vector-valued predictor for the derivation of the fragility functions. To this end, the following functional form for the damage probability is assumed:

$$\begin{aligned} P_f(im_1, im_2) &= P(ds \geq DS | IM_1 = im_1, IM_2 = im_2) \\ &= \frac{1}{2}[1 + erf(c_1 + c_2 \ln im_1 + c_3 \ln im_2)] \end{aligned} \quad (3)$$

where *erf* is the error function and c_1, c_2 and c_3 are the coefficients to be estimated (i.e., fragility parameters).

A composite variable im_V may then be introduced as follows:

$$\mathrm{im_V} = \mathrm{im_1}^{\frac{c_2}{c_2+c_3}} \cdot \mathrm{im_2}^{\frac{c_3}{c_2+c_3}} \quad (4)$$

Using im_V as the IM, the functional form in Eq. 3 is expressed as:

$$
\begin{aligned}
P_f(im_V) &= P(ds \geq DS|IM_V = im_V) = P(ds \geq DS|IM_1 = im_1, IM_2 = im_2) \\
&= \frac{1}{2}[1 + \mathrm{erf}(c_1 + c_2 \ln im_1 + c_3 \ln im_2)] \\
&= \frac{1}{2}\left[1 + \mathrm{erf}\left(\frac{\frac{c_1}{c_2+c_3} + \ln im_1^{\frac{c_2}{c_2+c_3}} + \ln im_2^{\frac{c_3}{c_2+c_3}}}{\frac{1}{c_2+c_3}}\right)\right] \\
&= \frac{1}{2}\left[1 + \mathrm{erf}\left(\frac{\ln im_V + \frac{c_1}{c_2+c_3}}{\frac{1}{c_2+c_3}}\right)\right] \\
&= \frac{1}{2}\left[1 + \mathrm{erf}\left(\frac{\ln im_V - \ln a_V}{\beta_V\sqrt{2}}\right)\right]
\end{aligned}
\tag{5}
$$

where α_V and β_V are the "fragility parameters" of the composite IM im_V, which are finally identified as follows:

$$
\begin{cases}
\alpha_V = exp\left(-\frac{c_1}{c_2+c_3}\right) \\
\beta_V = \frac{1}{(c_2+c_3)\sqrt{2}}
\end{cases}
\tag{6}
$$

The coefficients c_1, c_2 and c_3 are estimated with a MLE approach, using the same likelihood function as for scalar-IM fragility curves (expect that there are now three parameters to find, instead of two).

Thanks to the identification of the "composite" dispersion parameter β_V, it is possible to compute the same three of types of performance metrics, as for the case of scalar-IM fragility curves. More than sixty combinations of vector-valued IMs are tested, and the results for the most promising couples of IMs are detailed in Table 4.

IM_1	IM_2	β_V	AIC	AUC
SA(0.14s)	*SA*(0.29s)	0.3724	173.71	0.9568
SA(0.14s)	*SI*	0.3464	167.19	0.9508
SA(0.29s)	*SA*(0.50s)	0.3834	173.74	0.9571
SA(0.29s)	*PGA*	0.3370	161.33	0.9424
SA(0.29s)	*PGV*	0.3718	171.22	0.9591
SA(0.29s)	*AI*	0.4687	171.69	0.9530
SA(0.29s)	*SI*	0.3659	167.43	0.9610
SA(0.29s)	*RSD95*	0.4371	174.11	0.9559
SA(0.50s)	*PGA*	0.3348	158.25	0.9439
PGA	*PGV*	0.3389	166.18	0.9532
PGA	*AI*	0.5027	170.79	0.9468
PGA	*SI*	0.3225	155.43	0.9339
PGA	*ASI*	0.3447	169.06	0.9416
PGV	*ASI*	0.3668	173.61	0.9526

Table 4: Estimation values of the three performance metrics, for different vector-valued IMs. The gray cells indicate the three best performing couples of IMs, for each metric.

It is found that the vector-valued IMs tend to perform slightly better than the scalar IMs, judging from the values of the three metrics. Some scalar IMs that were not identified as ade-

quate (e.g., *RSD95*) become much more efficient when combined together. Some examples of vector-valued fragility functions are displayed in Figure 5, for selected combinations of IMs.

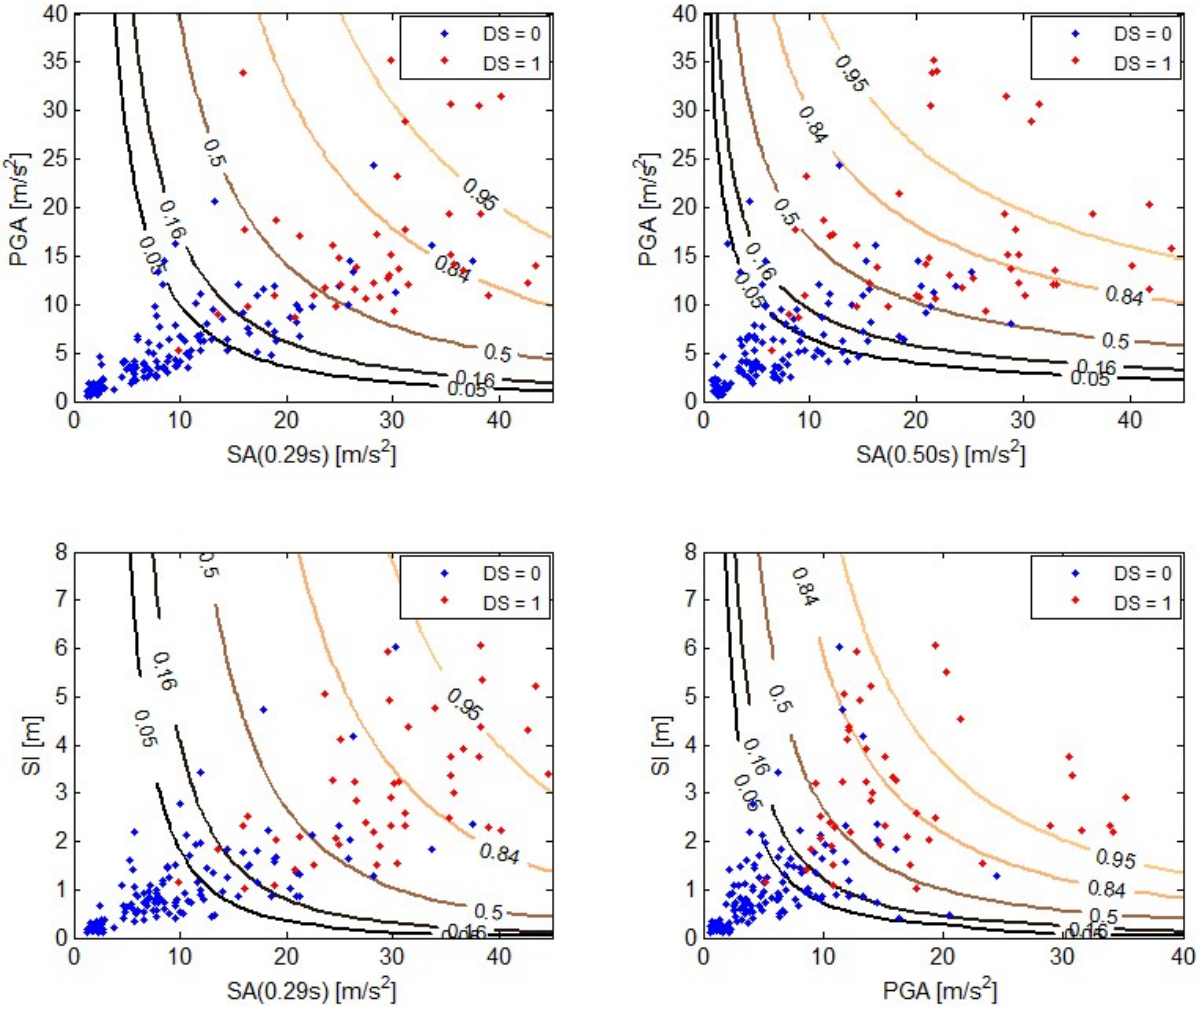

Figure 5: Iso-probability lines corresponding to some examples of vector-valued fragility function (i.e., probabilities of 0.05, 0.16, 0.5 0.84 and 0.95). The dots represent the outcomes of the NLTHAs in the vector-IM space.

5 COMPARATIVE ANALYSIS OF UNCERTAINTY SOURCES

This section discusses a set of procedures for the quantitative estimation of some uncertain components, namely the record-to-record variability, the uncertainty due to the number of data points, and the in-situ variability due to the variability of mechanical and geometrical parameters

5.1 Decomposition of the record-to-record variability

The contribution of the record-to-record variability to the global uncertainty structure may be estimated thanks to the comparison between scalar-IM fragility curves and vector-IM fragility surfaces. To this end, as an example, it is proposed to reduce the fragility surface w.r.t. [*PGA* ; *SA*(0.29s)] (see top left plot in Figure 5) into a fragility curve w.r.t. *SA*(0.29s) only. This operation should consider the correlation between the two IMs, in order to preserve the hazard consistency of the applied loading. Therefore, a first step consists in estimating the distribution of the secondary IM (i.e, *PGA*) w.r.t. *SA*(0.29s), using the dataset of the input ground-motion records: a median line and its 16%-84% confidence intervals are then plotted

(see Figure 6, left). The space delimited by this interval provides also practical guidance on the validity domain of the fragility surface, in the sense that it identifies the IM combinations that are very unlikely.

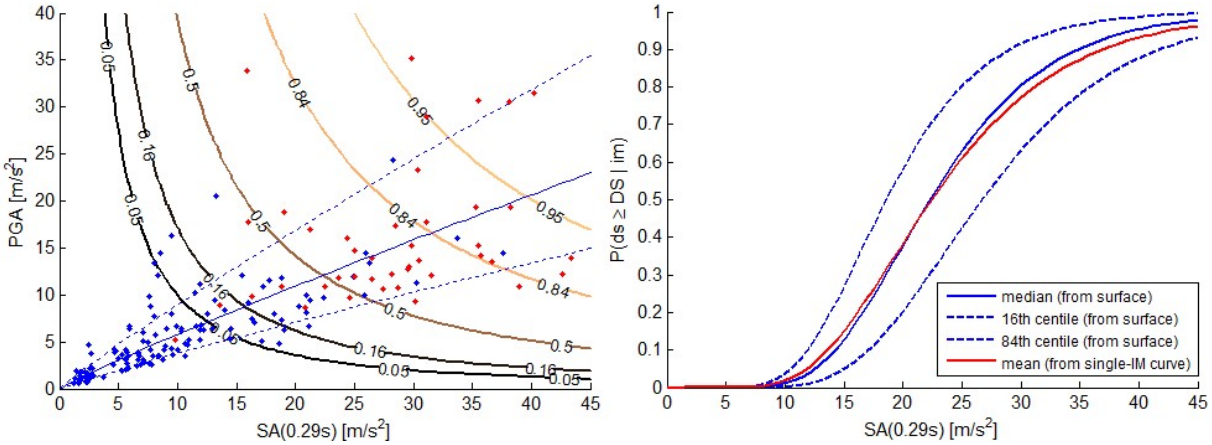

Figure 6: Left: fragility surface w.r.t. PGA and SA(0.29s), the solid blue line represents the median of the PGA-SA(0.29s) distribution and the dashed blue lines the 16%-84% confidence intervals; Right: equivalent fragility curves w.r.t. SA(0.29s).

It is then proposed to generate "slices" of the fragility surfaces by following the distribution of *PGA* as a function of *SA*(0.29s) (i.e., solid and dashed lines in Figure 6, left). As a result, the "slices", now represented as a function of the single IM *SA*(0.29s), may be compared to the original scalar-IM fragility curve. The fragility curves in Figure 6, right, are identified as follows:

- *Solid red line*: "mean" fragility curve corresponding to the scalar-IM fragility curve, derived w.r.t. *SA*(0.29s) only;
- *Solid blue line*: median fragility curve corresponding to the "median" slice of the fragility surface;
- *Dashed blue lines*: 16%-84% confidence intervals around the median fragility, corresponding to the lower and upper bounds of the slices of the fragility surfaces.

Finally, this family of fragility functions corresponds to the probabilistic framework by Kennedy et al. (1980), where the identification of aleatory and epistemic uncertainties (β_R and β_U, respectively), as introduced in Eq. 1. The mean fragility curve, w.r.t. to *SA*(0.29s), has a total standard deviation $\beta_{tot} = (\beta_R^2 + \beta_U^2)^{1/2} = 0.390$. Meanwhile, the median fragility curve, obtained from the fragility surface w.r.t. *PGA* and *SA*(0.29s), has a standard deviation of 0.349, which actually corresponds to the aleatory randomness term only (i.e., β_R). The confidence intervals obtained from the graphical construction in Figure 6 are then used to estimate the epistemic uncertainty term, i.e. $\beta_U \approx 0.174$.

It may be concluded that the vector-IM fragility functions lead to the transfer of a part of the record-to-record variability into a form of epistemic uncertainty, which is related to the description of the seismic loading given the hazard at the specific site.

5.2 Uncertainty due to the number of data points

The epistemic uncertainty due to the number of data points in the simulations, i.e. related to the quality of the statistical estimation of the fragility parameters, may also be evaluated in the case of vector-IM fragility functions. To this end, a bootstrap sampling approach is ap-

plied to the fragility surface w.r.t. of *PGA* and *SA*(0.29s). The outcomes of the bootstrap sampling are displayed in Figure 7, in the case of 16%-84% confidence intervals.

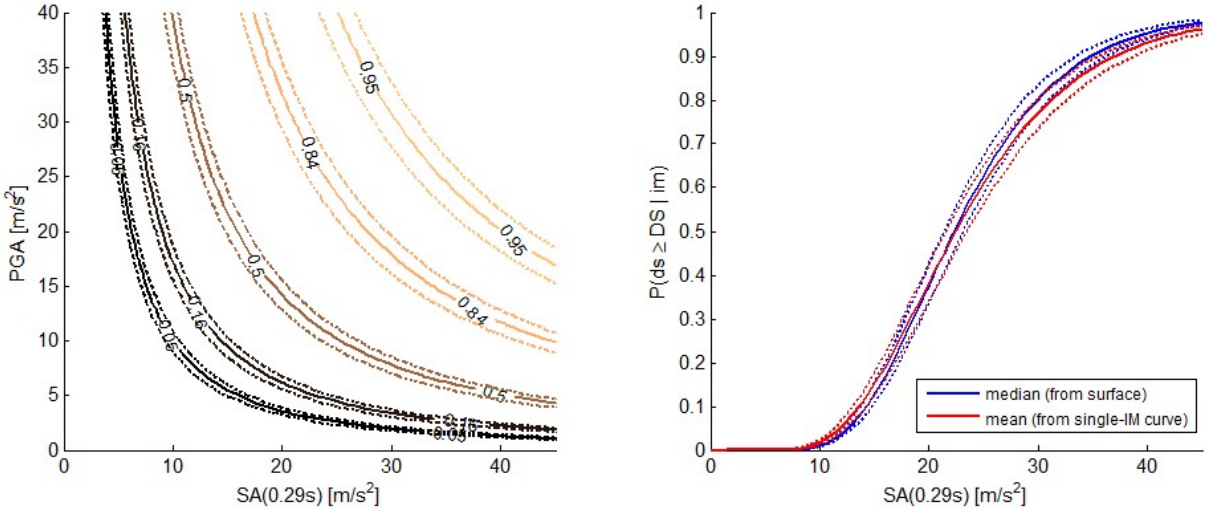

Figure 7: Left: fragility surface w.r.t. PGA and SA(0.29s), with the 16%-84% confidence intervals (dashed lines) due to the statistical estimation; Right: equivalent fragility curves w.r.t. SA(0.29s) and related 16%-84% confidence intervals due to the statistical estimation.

In order to compare these confidence intervals with the ones estimated for the corresponding scalar-IM fragility curves, the fragility surface is reduced to a scalar case w.r.t. *SA*(0.29s) only, following the same approach as before (i.e., use of a "median" slice of the fragility surface). The curves in Figure 7, right, reveal a similar order of magnitude for the confidence intervals due to the amount of data points, both for the single-IM fragility curve ($\beta_U = 0.043$) and for the vector-IM fragility function ($\beta_U = 0.048$).

5.3 Uncertainty due to the variability of mechanical and geometrical parameters

Based on the 360 randomly generated structures, a new vector-IM fragility curve is derived by incorporating the effect of the epistemic uncertainties related to the $p = 10$ mechanical and geometrical parameters (described in Table 2). This is done by adding linear terms in Eq. 3 as:

$$\frac{1}{2}\left[1 + \mathrm{erf}(c_1 + c_2 ln\, im_1 + c_3 ln\, im_2 + \sum_{i=1}^{p} c_{x_i} x_i)\right] \tag{7}$$

where x_i is the i^{th} uncertain parameter and c_{x_i} the corresponding regression coefficient.

When the ten parameters are considered at the same time, it is found that the MLE-based regression cannot converge, due to the limited number of data points. Therefore, partial combinations of parameters are tested until the most influent parameters are identified. As a result, the MLE regression on Eq. 7 has been carried out with three geometrical parameters, namely the thicknesses e_2, e_4 and e_6 (see Table 5). The analysis by the *p*-value of the Wald test has been used to decide whether the corresponding parameter is significant or not, using a significance threshold at 5%. Interestingly, the mechanical parameters barely affect the mean of the vector-IM fragility function (at 5% significance).

Parameter	Regression coefficient	Std. Error	*p*-value (Wald statistic)
c_1 - Intercept	-22.008	4.030	4.73e-8
c_2 - *SA*(0.29s)	1.991	0.359	2.98e-8

c_3 - *PGA*	1.284	0.342	1.75e-4
c_4 - Thickness e_2	95.504	46.303	0.0392
c_5 - Thickness e_4	135.553	46.184	0.0033
c_6 - Thickness e_6	98.819	44.217	0.0254

Table 5: Regression coefficients, standard error and *p*-value of the Wald statistic of the vector-IM fragility function.

On this basis, a new vector-IM fragility function is plotted in Figure 8, left, by incorporating only the significant geometrical parameters. The median surface is obtained by setting the thickness parameters at the median of their uniform distribution interval (cf. Table 2), while its 16%-84% confidence bounds account for the corresponding variations of these parameters. The same approach is applied to the construction of the single-IM fragility curve, enabling the comparison between the two approaches (see Figure 8, right).

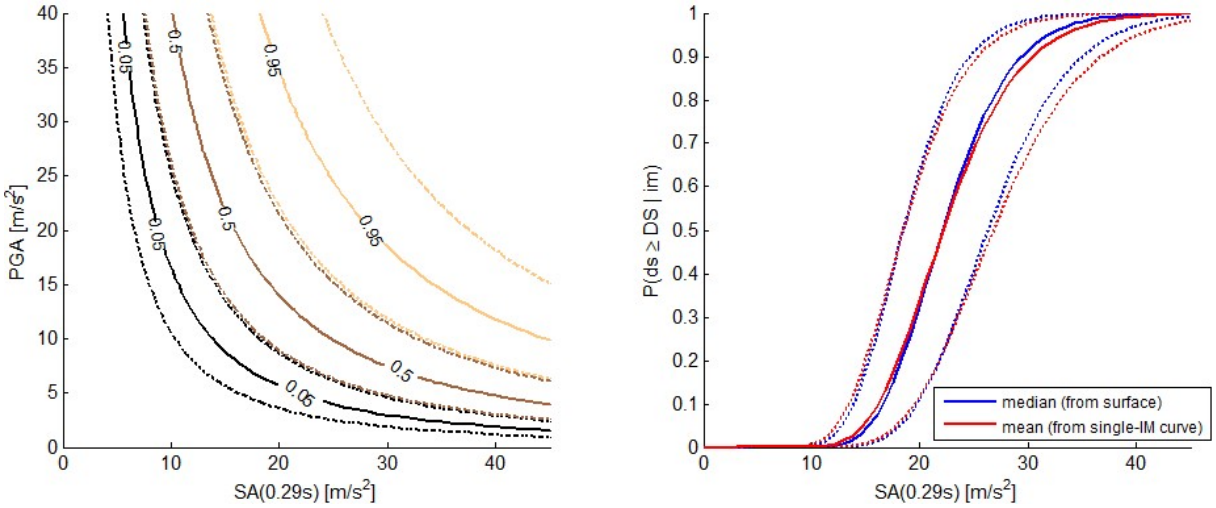

Figure 8: Left: fragility surface w.r.t. PGA and SA(0.29s) with the 16%-84% confidence intervals (dashed lines) due to variability in the parameters; Right: equivalent fragility curves w.r.t. SA(0.29s) and related 16%-84% confidence intervals due to variability in the parameters.

These fragility models, based on the disaggregation of the variability of some mechanical or geometrical, show a significantly reduced dispersion, when compared to the ones that do not use these parameters as input variables (i.e., models in Figures 6 and 7). However, it should be noted that some regression coefficients have been estimated with a significant standard error (see Table 5), which implies that much more data points from simulations should be necessary in order to get stable estimates.

5.4 Discussion on the respective contribution of uncertainty sources

The previous statistical analyses have helped identifying the uncertainty sources at play in different fragility modelling strategies (see Figure 9):

- *Single-IM fragility curve*: the aleatory dispersion β_R includes most of the variability, with a very small contribution of the epistemic uncertainty due to the number of data points.

- *Vector-IM fragility function*: a part of the record-to-record variability may be interpreted as an epistemic uncertainty term. The uncertainty term due to the number of data points is slightly larger, without becoming significant.
- *Vector-IM fragility function accounting for mechanical and geometrical parameters*: a multivariate MLE-based regression has allowed to explicitly account for the most influent mechanical and geometrical, further reducing the aleatory dispersion.

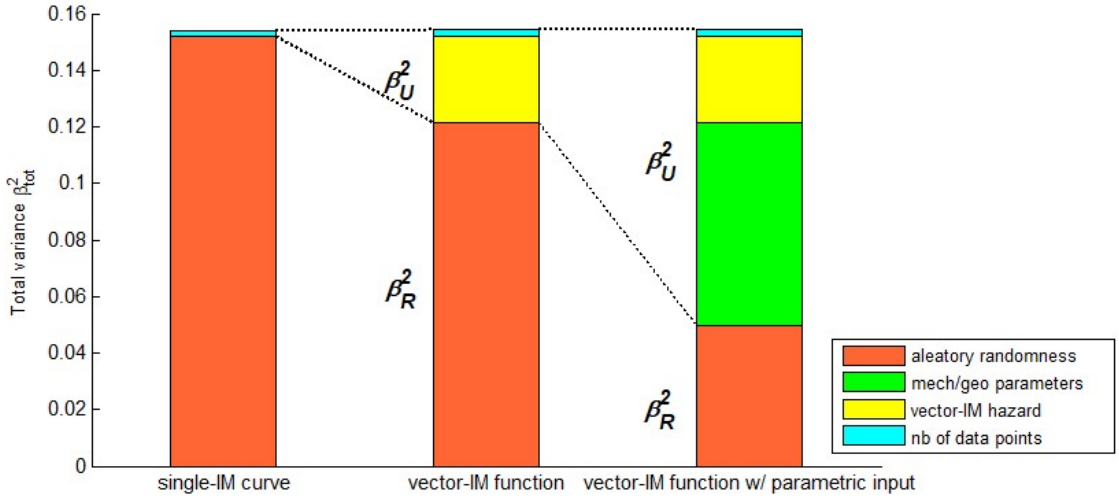

Figure 9: Decomposition of the uncertainty sources in terms β_R (aleatory) and β_U (epistemic), depending on the modelling strategy used.

It may be noted that, for the considered application, the use of vector-IMs contributes to a significant part of the total dispersion, although the uncertainty due to the variability of mechanical and geometrical parameters appears to be much larger. When computing the HCLPF, the uncertainty decomposition from Figure 9 is preserved, according to the following equation derived from Eq. 1:

$$SA(0.29s)_{HCLPF} = \alpha_{SA} \cdot exp[-(\beta_R + \beta_U) \cdot \Phi^{-1}(0.95)] \quad (8)$$

Therefore, when assessing a given element from an NPP, its HPCLPF may be gradually reduced if the following measures are taken to lower the epistemic uncertainty term:

- Reduction of β_U due to the number of data points, by performing more simulations (i.e., increased confidence in the statistical estimation);
- Reduction of β_U due to the description of the seismic loading, by performing a vector probabilistic hazard assessment of the considered site (i.e., more accurate knowledge of the excepted vector-IM distribution);
- Reduction of β_U due to the variability of mechanical and geometrical parameters, by testing or qualifying the materials used (i.e., increase of knowledge).

6 CONCLUSIONS

This study has confronted the concept of vector-IM fragility functions to the probabilistic framework commonly employed in nuclear applications. This exercise has then allowed for a systematic analysis of various sources of aleatory or epistemic uncertainty.

Regarding the selection of IMs, carefully selected vector-IMs make excellent candidates in terms of IM sufficiency and efficiency, when compared to scalar IMs. As a result, vector-IM

fragility functions tend to generate less dispersion (i.e., aleatory uncertainty due to record-to-record variability) than single-IM fragility curves: this difference may be interpreted as a partial transfer from the record-to-record variability to an epistemic uncertainty component that is related to the description of the seismic loading given the hazard at the studied site. However, in the present example, it appears that the epistemic uncertainty due to the variability of mechanical and geometrical parameters is still much larger.

Although a wide range of statistical tools are available for the quantification and propagation of sources of uncertainties, it appears that all the epistemic uncertainties usually cannot be adequately covered and accounted for (e.g., much more simulations would be required in order to accurately model the variability of the mechanical and geometrical parameters). In most cases, expert judgment would be necessary in order to constrain the assumptions and to interpret the simulation results.

Finally, the present study has followed the lognormal assumption for the functional form of the fragility functions. This constraint, while convenient for the combination of nested uncertainty terms, is bound to introduce significant biases in the statistical estimates (i.e., the outcomes of the MLE-based regression). A similar analysis based on undefined functional forms would also be able to deliver valuable lessons.

7 ACKNOWLEDGEMENT

This study has been carried out within the NARSIS project, which has received funding from the European Union's H2020-Euratom Program under grant agreement N° 755439. The Pacific Earthquake Engineering Research Center is gratefully acknowledged for providing access to their database of ground-motion records.

Abstract

The city of Florence, famous all over the world for its historical and artistic heritage, experienced public housing interventions since the XIX century. They consist both in RC and masonry constructions developed during several interventions in the external areas around the historical centre. Florence has been classified "seismic zone" just in 1982 so, most part of the considered population of buildings have been built without seismic criteria. Masonry buildings represent the most significant part of public housing population, characterized by the oldest constructions. This work deals with the vulnerability assessment of masonry public housing interventions at urban scale in Florence. A meaningful database with a large number of selected buildings has been made. Every construction has been investigated adopting an empirical approach based on geometrical and mechanical parameters; houses have been divided into typological classes in function of geometrical and architectonical features. This information has been collected on a GIS platform into a geo-referred system. This allowed a ranking of the public housing population that defines a vulnerability index for different classes of buildings. Further studies will be developed to mix vulnerability features with seismic microzonations of soils and to combine the proposed empirical approach to numerical one in order to investigate representative case-studies adopting mechanical models.

Keywords: Urban Scale, Public Housing Intervention, Pre-normative Buildings, Masonry Buildings, Seismic Assessment.

1 INTRODUCTION

The seismic assessment of existing buildings plays a crucial role in the evaluation - and mitigation - of the seismic risk. Italy joints a high seismic hazard to rich and complex monumental goods and constructive tradition. A huge number of historical buildings, in Italy, needs to be preserved, retrofitted and improved in order to assure the required safety standards, and to preserve the National and local history and traditions.

The earthquakes occurred during the last century (L'Aquila, Emilia Romagna, Central Italy) remarked the vulnerability of stocks where people live [1-3]; the majority of existing buildings has been realized before the introduction of seismic codes and without anti-seismic criteria. This vulnerability affects all types of buildings; masonry buildings, however, for their number and age, deserve a special attention. Nowadays, indeed, masonry structures still represent a large percentage of urban fabric.

The most studied masonry structures consist of monumental historical buildings; indeed, they have a special value for their cultural and architectural importance and collected the most part of the research efforts and contributions. However, most part of masonry buildings is represented by residential ones; the assessment of these buildings is usually left to the will of the single owners, since they are too many to be faced by the Government. For this reason, the researchers are facing their assessment at the urban scale, in order to provide some general and useful benchmark for the assessment of single cases [4-6].

Since the last century, many different studies (empirical, analytical and hybrid methods) have been carried on for a vulnerability assessment of urban stocks at urban scale [7-10]. Empirical methods are the most basic ones; they reduce computational costs analyzing the vulnerability based on statistic damage examinations of past earthquakes, achieving a consequent typological classification. They use macroseismic scales (MSK and MCS scales are the most used); even if these methodologies cannot be considered as advanced approaches they are important to connect vulnerability assessment with historic seismology of places since historical documentaries are based on damage testimonies [11]. Analytical methods assess the damage with numerical analysis performing mechanical computational models; they demand an adequate knowledge of the structure and usually they refer to individual structural units or specific building classes. They are based on simplified tuning of the Capacity Spectrum Method [12-13] and they lead to acceleration-displacement response spectra evaluated in terms of damage limit states [14]. Finally, hybrid methods start from the definition of buildings-types which are representative of different constructions, combining empirical and analytical techniques for an implementation of the empirical typological classifications with specific mechanical analysis. Computational costs of the assessment at urban scale are then limited to the evaluation of selected case-studies [15].

The research project deals with the vulnerability assessment of the residential buildings of Florence. In this work the empirical approach is applied to a relevant database, consisting of almost 300 buildings. In this area of interest, different studies have been carried out during the last years [16-17] combining typological features of buildings with the soil specification investigated such as amplification factors or period ground motions. In this paper, seismic assessment of part of the Florentine residential stock has been evaluated in a systematic way. Public Housing Interventions have been selected as a scattered homogeneous database, more trackable. For a relevant database of buildings referred into a GIS system the GNDT second level approach has been used. Buildings have been divided according to their architectonical and typological features into nine classes. Vulnerability indices have been then expressed in terms of macroseismic intensities and related to the historical seismology of the city. Finally, the expected damage of the nine classes of buildings have been defined.

2 FLORENCE: RESIDENTIAL VULNERABILITY AND SEISMIC RISK

2.1 The residential stock of Florence

The city of Florence is characterized by important architectures and monuments famous all over the world. Since December 1982 the centre is considered UNESCO World Heritage Centre and it concerns both the copious number of Medieval and Renaissance buildings, and the historic urban pattern of the districts. However, external areas of the city centre have grown just in a recent period. Starting with the demolition of the city walls in the XIX century and the support at the urbanization of a multitude of different new districts and areas, the contemporary face of the city has been defined. Perimetral zones of Florence are mainly composed by residential buildings which have been designed according to the zoning theories of the last centuries; they were settled far from the other functions and supported by urbanistic regulations [18]. The most significant part of this residential stock (and the most ancient) has been realized through masonry buildings.

Nowadays, in the city of Florence, 24308 residential buildings of the total residential stock (31070 buildings) are composed by masonry structures (78,2%), while just 4840 are composed by RC (15,5%) and 1110 with different technologies (6,3%). From a legislative point of view, the city is classified as "seismic zone" just since 1982 so, most part of the residential heritage has been made without anti-seismic criteria. Furthermore, the last important Florentine earthquake is dated 1895, before the main development of satellite stocks; seismic performance of most part of pre-modern buildings has never been checked by relevant ground motions, and their vulnerability never been assessed.

Together with the grow of the city, many Public Housing Interventions have been promoted. Starting from the XIX century different institutions built several buildings. These houses are characterized both for masonry and RC structures. During more than a century, according to Pierini [19], more than 20000 apartments have been realized. In this paper, Public Interventions have been selected to assess the seismic vulnerability of a relevant percentage of the residential buildings of Florence. Social houses interventions have been made by few institutions, which provide private archives with technical information and, if still of public domain, they are accessible to in-depth studies and more specific analysis.

2.2 History of Public Housing Intervention in Florence

Public housing interventions in Florence started in 1848 with the institution of SAE (Società Anonima Edificatrice). The society dealt with the construction of houses for the working class in the external areas of the historical centre. In the years between 1885 and 1911, the *"Comitato per le Case ad uso degli indigenti"*, built 342 houses for needy people divided into 14 different interventions. Since 1912, Railway Society built other new residential buildings for their workers. The "*Istituto Autonomo per le Case Popolari*" (*IACP*) was established in 1909. It represented the main promoter of the last century. Starting from the oldest interventions, IACP adopted different architectonical typologies, realizing both "ring" large buildings with internal courtyards and line-type having different spatial configurations. Many different interventions were constructed from 20's by *IACP* and *ENCEP* ("*Ente Nazionale Combattenti Edilizia Popolare*") during the fascist period. It concerned small urban villages like the stock in *via Carlo del Prete*, modern architectures like the residential buildings of *via Erbosa* or public housing interventions for middle classes like the district of *Romito*. Constructions arrested during the Second World War; as a consequence of its destructions, many reconstruction projects were planned in Florence and in the entire peninsula. The "*INA-Casa*" plan, financed by state fundings, represents the most meaningful project. In the 50s it supported dif-

ferent large interventions of which the *Isolotto* district, projected by important architects or Italian modernism (such as Michelucci, Tiezzi, Pastorini, Pellegrini, Fagnoni, Gamberini) is the most important one. In 1956 a further important public housing intervention, *Sorgane*, had been built in reinforce concrete buildings. After *INA-Casa* and its continuation with "*Gescal*" (*Gestione Case per Lavoratori*), in the 60s the residential building constructions got slower, while, from 70s they had been mostly characterized by RC structures. During the last decays most part of these public housing interventions has been privatized with hire-purchase procedures, so nowadays social houses heritage follows private regulations and is not fully available to the will of institutions.

This research, besides regarding a large number of residential buildings in Florence, could present an higher effectiveness, since many further interventions have been made even in other cities according to the *INA-Casa* standards.

2.3 Technological information of the investigated stock

A meaningful archive research has been made. It concerned different catalogues in Florence (*Archivio Ater/Casa SPA*, *Archivio Storico del Comune di Firenze*, *Archivio delle Ferrovie dello Stato*) and has found a relevant number of projects of residential buildings. For each project has been founded the final design and the related technical specifications and quantity surveying of materials. The detail level of the achieved information is not always the same, depending on the catalogue, the contractor society, the years of constructions, the researched intervention. *Ferrovie dello Stato* records represent the most precious source of information for the quantity and the quality of specifications and details.

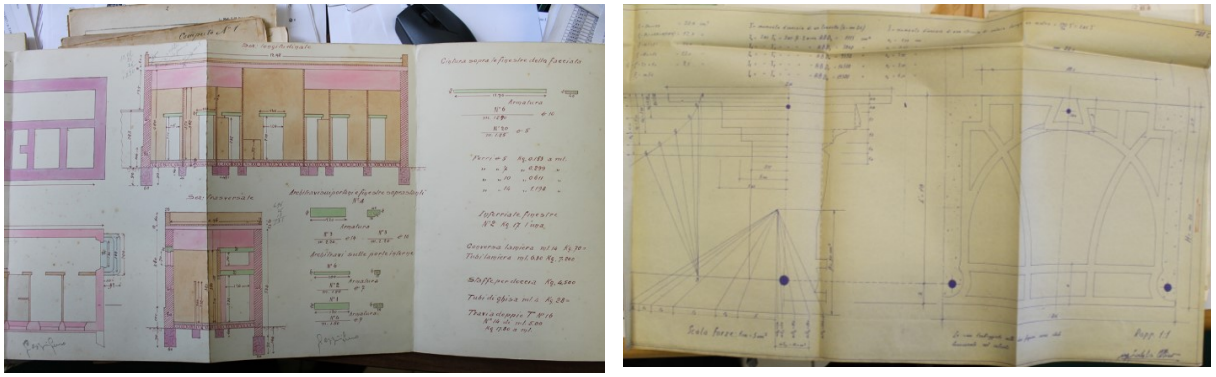

Fig. 1. From left to right: Details of masonry structures; particular of slabs in hollow bricks and RC joists.

The collected database allowed a technical characterisation of residential modern buildings in Florence. They are composed by bearing walls in coursed rubble stone masonry and plain bricks. The coursed rubble masonry is generally made of irregular stones of various dimensions subdivided by horizontal courses, 1 meter spaced, made of clay bricks. It is usually adopted in the largest walls of the perimeter at the lower floors. The plain brick masonries, instead, are made with lime mortar.

The floors are made of RC joists alternated to hollow bricks, topped by a 4-cm concrete slab, and they have a thickness of 20 cm. The hollow bricks can have different shapes that can lead at different distances between the joists. The top storey floors, used for crawl spaces where there are not live loads, in some cases have the same technology but lower (12/16 cm) depths, while in other examples are composed by steel beams alternated to

hollow tiles generally without concrete slab. Roofs are generally made with wooden beams covered by wooden planks and roof tiles; otherwise, they are composed by prefabricated RC joists, hollow tiles and finally hollow roof tiles. Generally, the crawl space has the concrete kerb over the perimeter of the building and it is joined with the level floor, while the roof structure is not linked with the concrete ring.

2.4 Seismic history of Florence

During the last years many studies on the soil stratigraphy and the consequent classification have been conducted. Florentine area has a sedimentary base originated by the Late Pliocene activities [20]. According to the geological history, deposits can be divided into three typologies: the Synthem of the Basin, the Ancient Arno River Deposits and Recent Arno River Deposits [21].

The area is characterized by a moderate telluric activity; historical earthquakes has been estimated at 5 ML and their epicenter were located around Florence (Mugello 1542 and 1919, Impruneta 1456 and 1895, Valdarno 1770). Historical seismology is the main source of information to define the hazard of a place. Historical records show that the most severe earthquakes were occurred in 09/28/1453 and 05/18/1895, both estimated at VII-VIII MCS level.

During the last years more than 2000 drillings of the soil have been made, implemented by 52 downhole tests. These works have permitted the definition of a mapped grid with the main subsoil information such as Fundamental Period of the soil, Amplification Factor, bedrock depth and its stratigraphy.

3 VULNERABILITY ASSESSMENT OF THE RESIDENTIAL STOCK

3.1 GIS Database

A GIS database of public housing interventions in Florence has been made. It concerns a large number of selected buildings. Preliminarily they have been distinguished in three categories, depending on their structure: masonry buildings, RC buildings and mixed typologies. Masonry interventions have been amply recorded. Each single project has been identified with an *ID* number and geo-referred; using the archive drawings, they have been re-drawn in CAD and related to the GIS identification number. Actually, the main part of the masonry database consists of 286 buildings.

3.2 The GNDT 2nd level approach

The collected interventions have been classified according to the GNDT second level vulnerability assessment method, and a vulnerability index, *Iv*, for every building has been found. The assessment is composed of 11 parameters, which are listed in Table 1. They concern many different types of information, and they are "weighted" through proper coefficients, ranging from 0.25 to 1.5, on the basis of their importance and influence. The Vulnerability Index, *Iv*, can be found on the basis of the assumed classification, through the following expression:

$$I_v = \sum P_i \, x \, w_i \tag{1}$$

Finally, the vulnerability index is normalized between 0 and 100.

Parameter	P_i				w_i
	A	B	C	D	
P1 Type of resisting system	0	5	20	45	1,5
P2 Quality of resisting system	0	5	25	45	0,25
P3 Conventional strength	0	5	25	45	1,5
P4 Location and soil condition	0	5	25	45	0,75
P5 Horizontal diaphragms	0	5	15	45	variable
P6 Planimetric configuration	0	5	25	45	0,5
P7 Regularity in height	0	5	25	45	variable
P8 Maximum distance between masonries	0	5	25	45	0,25
P9 Roofing system	0	15	25	45	variable
P10 Non-structural elements	0	0	25	45	0,25
P11 conservation state	0	5	25	45	1

Table 1: GNDT Vulnerability Index.

3.3 The data-base classification

Each building of the database has been classified according to the GNDT criteria, and a Vulnerability Index ranging between 13% and 39% has been found, with a *mean* value equal to 29%. Figure 2 and Table 2 show the database classification. As can be noted, some parameters do not seem to be sensitive to the database features, since almost all buildings present the same classification. In particular, the parameters most sensitive to the database features are parameters #3, #6, #7, #8 and #9.

	1	2	3	4	5	6	7	8	9	10	11
A	0	286	0	286	286	0	216	19	6	246	259
B	286	0	6	0	0	9	23	56	0	36	27
C	0	0	24	0	0	128	16	100	280	0	0
D	0	0	256	0	0	149	31	111	0	4	0

Fig. 2. Distribution of GNDT parameters applied to the database.

Parameter P3 is based on geometrical and mechanical data like: the resistant area along x and y directions, the total area, the number of storeys and some non-investigated mechanical features, like density of materials ρ and tangential resistance τ_k as well live loads. Because of the lack of detailed studies for this type of buildings, mechanical characteristics have been chosen following normative guidelines considering their values constant, so, variability of parameter P3 is given mainly by geometrical features such as height, number of storeys, plan area and resistant areas. Resistant area varies in a range from 8 to 22 % of the total area of

buildings. It is usually not equi-distributed between *x* and *y* directions depending on typological and architectonical features.

	A	B	C	D
P1	0%	100%	0%	0%
P2	100%	0%	0%	0%
P3	0%	2%	8%	90%
P4	0%	3%	45%	52%
P7	76%	8%	6%	11%
P8	7%	20%	35%	39%
P9	2%	0%	98%	0%
P10	86%	13%	0%	1%
P11	91%	9%	0%	0%

Table 2: GNDT Vulnerability Index.

P7 is one of the most sensible parameters to the quality of considered drawings projects. It is referred to "elevated configuration of buildings" and concerns the percentage decrease of resistant area along the height of the fabric. Masonries setback are typical of historic masonry buildings in which flexible wooden slabs are wedge into bearing walls; anyway, modern pre-normative buildings are characterized by clear-cut interruptions of masonry due to the presence of the perimetral RC kerb. In the database of buildings, there is some variability of results; it is mainly given by the change of material in the making of the walls. If the lowest levels of the buildings are composed by rubble stone masonries with larger depths, while upper level are generally made with hollow bricks and lower thicknesses. In some case the top floors are composed by perforated bricks with the drillings along the horizontal set.

P8 parameter provides better scores to buildings with bearing walls disposed along two directions, while it penalizes houses with walls along one direction. Each building of the database can be considered to have a box-behavior with concrete rings and rigid slabs. However, when the distance between two consecutive bearing walls is excessive, undesirable torsional effects can occur.

Finally, parameter P9 concerns the roof type of buildings through a quality assessment; most part of the considered buildings resulted to have the same classification.

3.4 Macroseismic methodology assessment

In order to find the damage level which the building could experience at the occurring of a ground motion, the GNDT vulnerability index I_v presented in § 3.3 has been transformed in a macroseismic vulnerability index, V, assuming different levels of seismic intensity according with the EMS-98 [22].

Macroseismic methodology allows to determine the expected damage μ_D for different levels of intensity, I. For each building, vulnerability curves have been found with the following expression:

$$\mu_D = 2.5\left[1+\tanh\left(\frac{I+6.25V-13.1}{Q}\right)\right] \quad ; \quad 0 \le \mu_D \le 5 \tag{2}$$

where Q is the ductility factor. Recent studies have provided different values for Q; in this work Q has been assumed equal to 3, according to the Sandi and Floricel [23] suggestion. The

macroseismic vulnerability index V has been determined through the relationship proposed by Vicente et al. [7]:

$$V = 0.58 + 0.0064\, I_v \tag{3}$$

Seismic intensity can be related to the historical seismology of Florence. The definition of EMS-98 intensity applied in a specific area is related to the vulnerability of buildings that suffered earthquakes in past centuries; so, the comparison of this parameter with "more recent" buildings that never experienced seismic shocks can be not so proper. Seismic intensity of Florence can be estimated between grade VI and grade VIII MCS scale; for each expected measure it is possible to define the respective damage level. The definition of damage according the EMS-98 defines five levels of increasing damage, from D_0 (No damage) to D_5 (Collapse). The damage distribution has been evaluated according to the macroseismic approach through a binomial function based on the damage collection of Italian earthquakes [24]. The probability to have a certain level of damage corresponding to a specific intensity has been assessed according to the probability mass function of the binomial distribution:

$$PMF: \; p_k = \frac{n!}{k!(n-k)!} \times d^k \times (1-d)^{n-k} \quad n \geq 0; \tag{4}$$

where p_k ranges between 0 and 1 and it expresses, in terms of percentage, the continuous damage level for each value of μ_D. Finally, expected damage of the database for different levels of macroseismic intensity can be defined.

In the technical literature there are many formulas to convert the macroseismic intensity measure in PGA. In this work the correlation defined by Giovinazzi and Lagomarsino [24] has been used:

$$a_g = c_1 c_2^{(I-5)} \tag{5}$$

where C_1 is the value of the vulnerability curve for macroseismic intensity I, and C_2 represents the slope of the correlation curve. In this work correlation factors C_1 and C_2 have been estimated respectively equal to 0.03 and 2.05 according to Margottini et al. [25] and traced back on MCS macroseismic scale by Bernardini et al. [26]. PGA of Florence is equal to 0.131 g [27]. Considering the latest soil information about the area of Florence, the amplification factor induced by the soil stratigraphy can vary between 0.7 and 1.7. In this paper only amplification factors greater than 1 have been considered, generating a range of g between 0.131 g and 0.223 g. Fig. 3 shows the *minimum*, *mean* and *maximum* values presented in the database and correlated to the seismic action expressed in terms of macroseismic intensity and PGA.

3.5 Building classification

Building database has been classified in order to determine more specific analyses on buildings. In this work buildings have been divided from a typological point of view into nine building-types, depending on the global shape of their plans. Buildings with a rectangular plan are named "stairs-building-type", and they are further distinguished on the basis of the number of stairs (i.e. their slenderness in plan) in: one-stairs-building-type (1SBT), two-stairs-building-type (2SBT), three-stairs-building-type (3SBT), four/five-stairs-building-type (4SBT). Moreover, there are buildings with a different plan shape: L-buildings (LBT), C-buildings (CBT), T-buildings (TBT), and two further classes: terraced-houses (TH) and irregular buildings (XBT). SBT-types are characterized by central stairwells that serve two apartments for each story. Terraced houses are low buildings aggregated one after the other in a

continuous structural unit. Their vulnerability is most estimable from the length of the construction and the number of unities repetitions than for other parameters. Finally, XBT includes all the interventions not clearly identifiable in the previous classification.

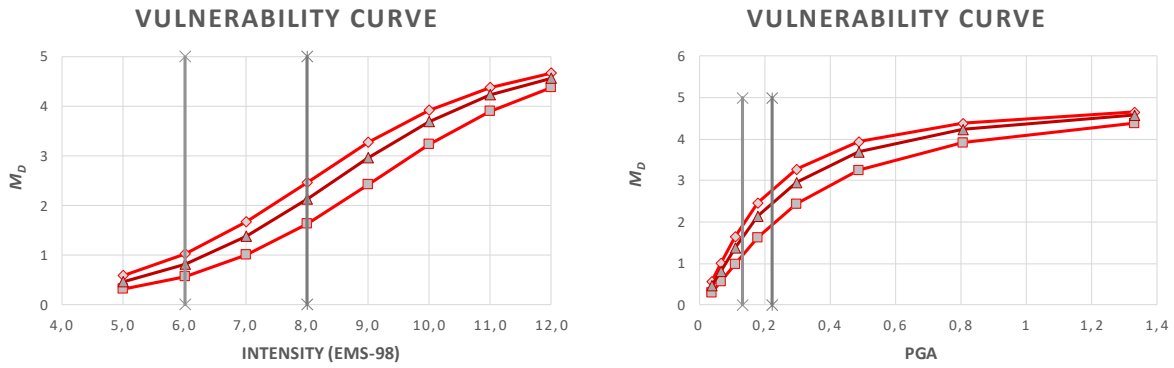

Fig. 3. Vulnerability curves of the database expressed in terms of macroseismic scale (EMS-98) and in PGA (*g*).

The proposed classification (presented in Table 4) can be finally assessed for the expected level of damage for the assumed seismic intensities. According with (4) for each building-type the probability to achieve a certain level of damage for intensities VI, VII and VIII has been assessed. Fig. 4 shows, for each building typology, some examples of real buildings belonging to the database.

Damage distributions of building-types according to the probability mass function of the binomial distribution are finally presented in Fig. 5. Results are very similar from each other because of the lack of variability in terms of Vulnerability Index and, consequently, of macroseismic intensity *I*.

Type	n.	%	I_v range	I_v mean	dev. St.
1SBT	131	43%	21-38	29,72	0,0430
2SBT	58	19%	12-37	28,23	0,0634
3SBT	22	7%	20-32	28,07	0,0344
4SBT	8	3%	29-32	28,13	0,0432
TH	30	10%	22-33	29,14	0,0451
LBT	28	9%	22-32	29,83	0,0209
TBT	12	4%	22-33	29,14	0,0300
XBT	15	5%	20-34	30,03	0,0347
CBT	3	1%	28	28,99	0

Table 4: The proposed classification of buildings.

For seismic intensity equal to VI the probability to have a damage between D_0 and D_1 holds the 80% of the full sample, almost equally distributed. Percentages descend significantly for the other damage levels. Intensity VII leads more scattered results, with the peak of probability (*mean* value 37%) for D_1. D_2 value settles at 29%, while D_0 obtains 20% of the total. Finally, for the most severe intensity expected in the area, VIII, D_2 is the most possible damage configuration of the database (34%), with D_3 at 26% and D_1 at 2 % of probability.

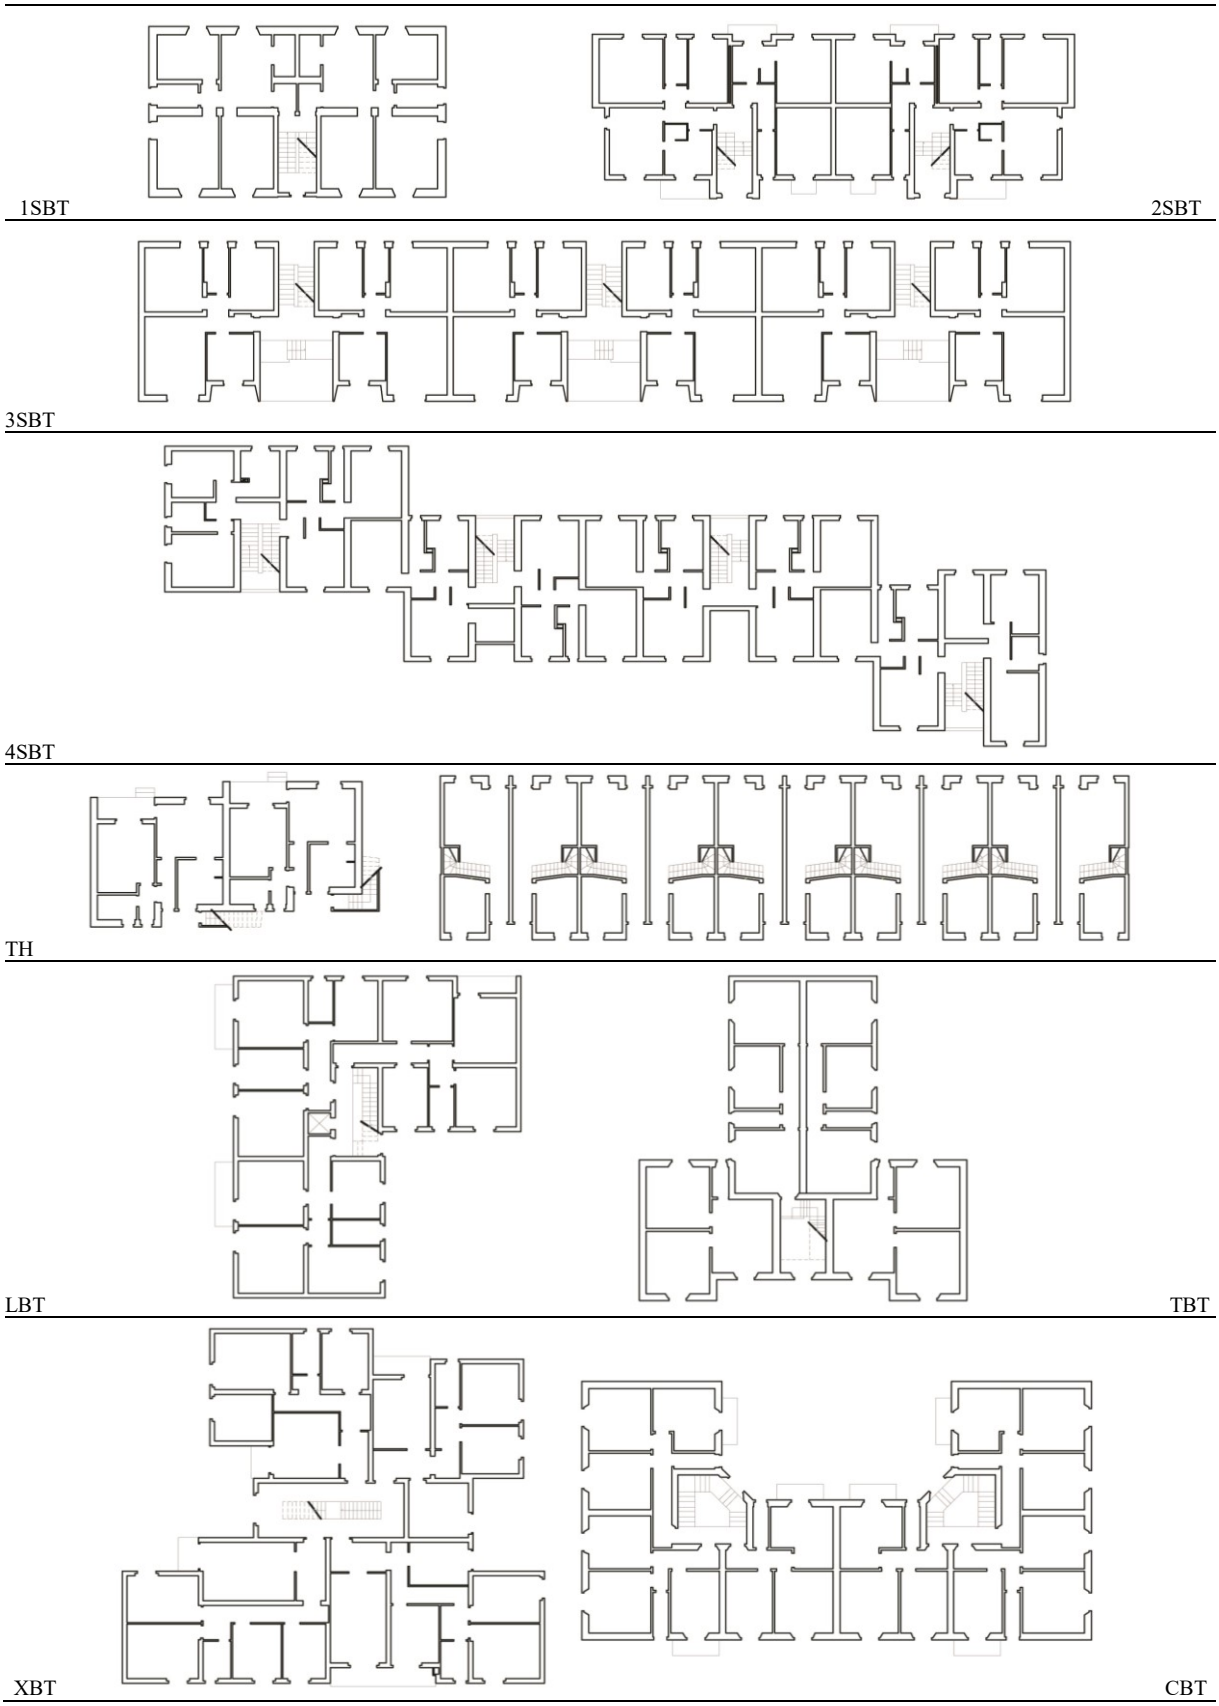

Fig. 4: Examples of buildings selected by the database and classified according the proposed specifications.

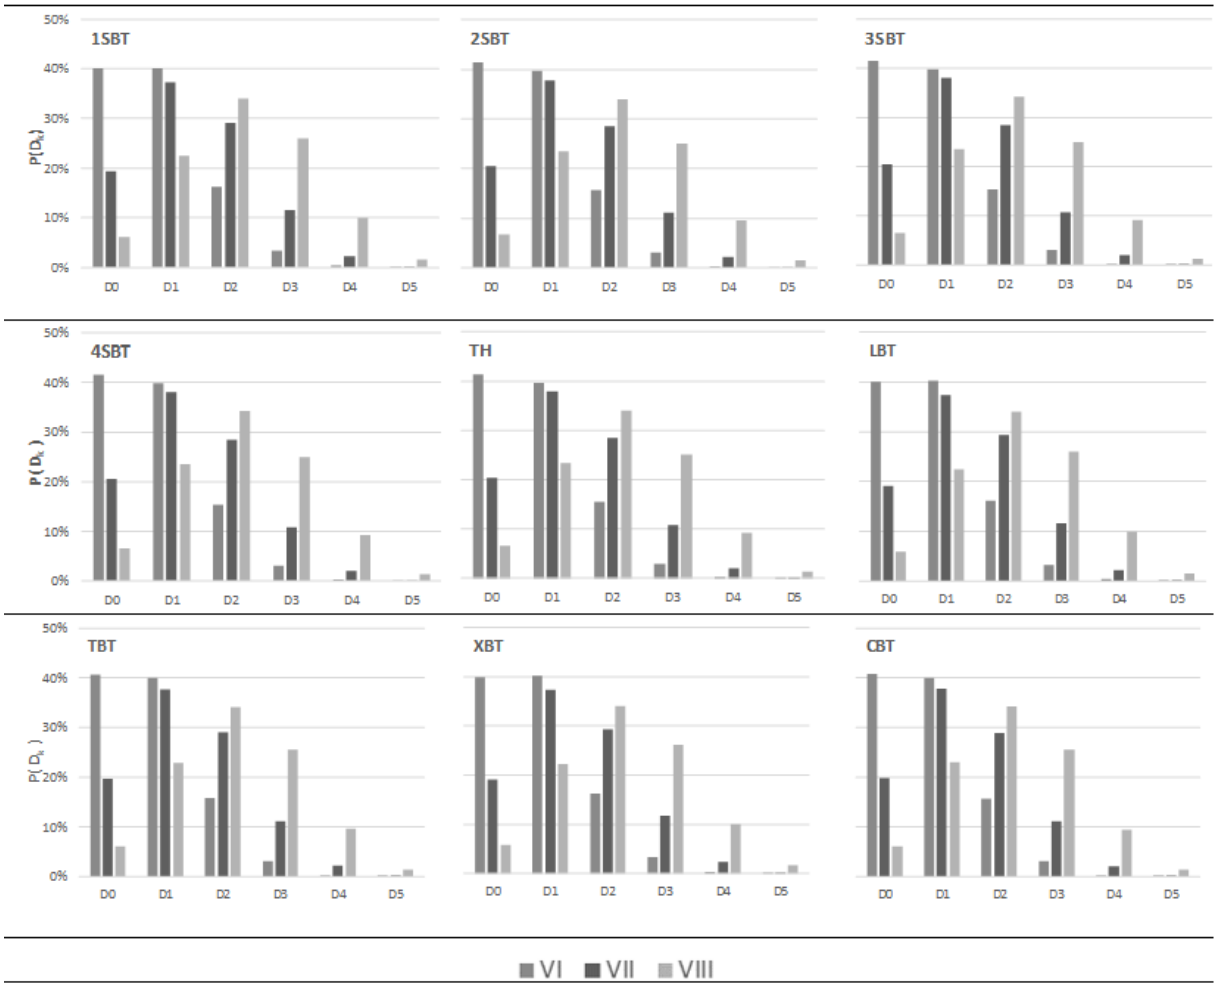

Fig. 5: Probability damage distributions for the three levels of seismic intensity expected in the considered area.

4 CONCLUSIONS

In this paper a systematic assessment of the residential buildings of Florence has been made. Public Housing Interventions have been chosen like representative of the residential stock because of their numerosity and scattered localization. Information about buildings have been collected through an extensive archive research. Finally, each building has been gathered into a geo-referred system. The GNDT second level method has been applied and a vulnerability index I_v for each building has been found. Through expressions presented in literature and based on statistical seismic damage observations, the seismic vulnerability has then been converted in terms of vulnerability curves. The database has been then expressed in terms of macroseismic intensity and peak ground accelerations. The building database has been divided into nine classes, as a function of typological parameters. Finally, the probability of damage for different levels of seismic intensity has been defined for each different class. Seismic scenarios for the residential stock are not dramatic; for Intensity VIII the most expected damage levels is D_2 with the 34% of probability of occurrence and D_3 with the 26% of probability of occurrence.

The results are sensitive to the quality of the vulnerability assessment. Since the database is related to modern homogeneous buildings, the GNDT second level approach, is probably too much broad to catch the database variability. Previous works [28] have shown through analytical analyses the sensitivity of the seismic performance of one-stairwell-building-type to dif-

ferent parameters. A calibration of the presented empirical methodology is expected, to quantify the effects related to single parameters through hybrid approaches, such as analytical models based on performance-based assessments and mechanical characteristics by *in-situ* tests and dynamic identifications.

Abstract

The Garisenda Tower, built in the XI century in Bologna (Italy) is a tilted Tower of 48 m high, with a square cross section, that represent the cultural symbol of the city. From the date of its construction, the tower was subjected to various accidents (such as fires, lightings and earthquakes) and interventions of consolidation. Nevertheless its structural configuration and the natural decay of the materials during the years, makes the tower inherently vulnerable to static and seismic actions, thus requiring a constant evolution of its structural health. The purpose of the study is to evaluate the current structural health of the Garisenda tower, through the development of a number of Finite Element models, in order to account for the influence of the geometrical configuration (actual inclination, cross section variability), peculiar construction techniques ("a sacco" masonry) and potential material degradation. To this aim, it has been of fundamental importance to integrate information related to both the actual geometrical configuration from data provided through static and dynamic monitoring and masonry texture, quality and material mechanical properties. In particular, to evaluate the effects caused by an eventual reduction in the material properties at the base, composed by selenitic stones, on the structural behavior, Three Dimensional Finite Element models with brick elements have been developed. The results of the FE analyses indicate that a material degradation at the base of the Tower could lead to local increase of stress levels close to material strength. Moreover, the analyses results also allow to better interpret some trends of behavior as resulted from the monitoring data.

Keywords: Masonry tower, Structural Health Monitoring, Three Dimensional Finite Element Methods

1 INTRODUCTION

The correct management of the historical buildings is a matter of crucial importance that passes through a deep knowledge of their present state and its eventual evolutions during the centuries. The availability of only partial information regarding the original project and the construction techniques, together with strong limitations in the number and extent of in-situ tests for materials characterizations (related to preservation issues), make the assessment of the actual safety level of a monumental building of extreme difficulty [1]. For this reason, data acquired from a structural health monitoring system become of fundamental importance since their proper interpretation may help in increasing the knowledge and better understanding the structural behavior of the monument. The aim of the present study is the analysis of the current structural health of the Garisenda tower. The Garisenda tower is a masonry tilt tower built in the XI century in Bologna (Italy). Although several studies and strengthening interventions have been carried out in the last decades, a continuous attention should be payed on the evaluation of the structural health and on the consequences of the natural decay of material properties in terms of safety and stability [2]. In the present work, the assessment of the current structural behavior of the Garisenda tower is conducted through different Finite Element (FE) models able to take into account the actual geometrical state and variation of inclination as detected from the monitoring system as well potential material degradation at the base. First, the available knowledges related to the tower geometrical configuration and material properties are illustrated and correlated/integrated with the information obtained from the static and dynamic monitoring. Then, the results of structural analysis carried out by mean of FE models with different levels of complexity and accuracy are presented. In particular, to evaluate the effects caused by a material degradation at the base on the structural behavior, Three Dimensional Elements models were performed.

2 GARISENDA TOWER

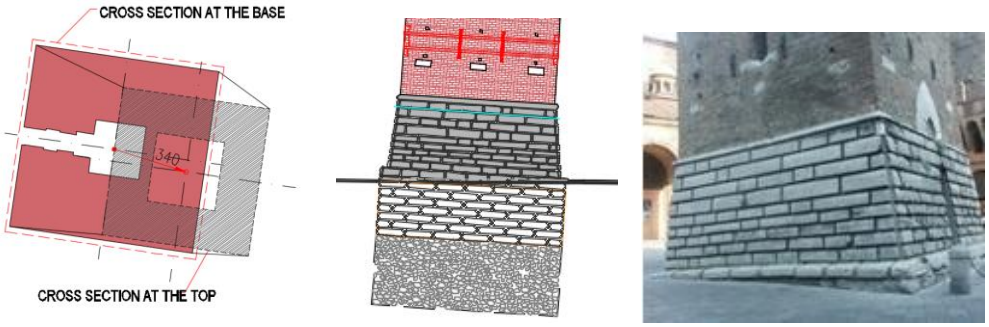
The Garisenda tower, built in the heart of the city of Bologna in the 11th century, together with its nearby Asinelli tower, is known as one of the “The Two Towers”, that are the main cultural symbol of the city (Fig.1a)[3]. It has a height of 48 m and with an overhang of 3.4 m towards South-East. It is one of the most leaning Tower in Italy.

a) b)

Figure 1-a) The Two Towers of Bologna (Asinelli and Garisenda towers). b) The Garisenda tower

2.1 Geometrical configuration and material proprieties

The cross section of the tower, approximately square, is composed by two external skins and an internal infill. Its thickness decreases with the height as shown in Figure 2a. Starting from the foundation, the first few meters of the tower are composed by an external and internal perimeter of selenitic stones (thickness of around 50-60 cm). In 1889, another external selenitic layer was added to cover the heterogeneous and unsightly portion of the wall in the first 3.5 m (Figure 2b) [4].The properties of the material, summarized in Table 1, have been characterized through in situ tests (both destructive and non-destructive) [5].



(a) (b) (c)

Material	Specific Weight γ	υ	Elastic Modulus E_m	Compressive strength f_m	Shear strength $f_{v,m}$
	[KN/m^3]		[MPa]	[MPa]	[MPa]
Masonry bricks	18	0.2	3000	4	0.5
Selenitic stone	24	0.2	5000	7	0.7
infill	17	0.2	2500	4	0.5

Table 1: Material properties

2.2 The Static Structural Health Monitoring (SHM) results

A static SHM system was installed on the Garisenda tower at the beginning of 2011. This system allows monitoring: movements of the main cracks, deformations of critical portions of masonry, inclination, strains along the steel ties (installed on the height of the tower to provide a lateral confinement to the masonry) and environmental parameter (such as temperature, wind speed). Additional details on the monitoring system are available in previous work developed by some of the authors [6], [7]. The results obtained from the analyses of the data recorded by the SHM system highlighted a slight evolutionary trend especially in relation to the inclination. Six inclinometers are installed in the East and South fronts at different levels (13.20 m, 30.65m and 43.3m). The data recorded show an increase in the Tower inclination toward East of around 1.3 mm/year and also a slight inclination northwards.

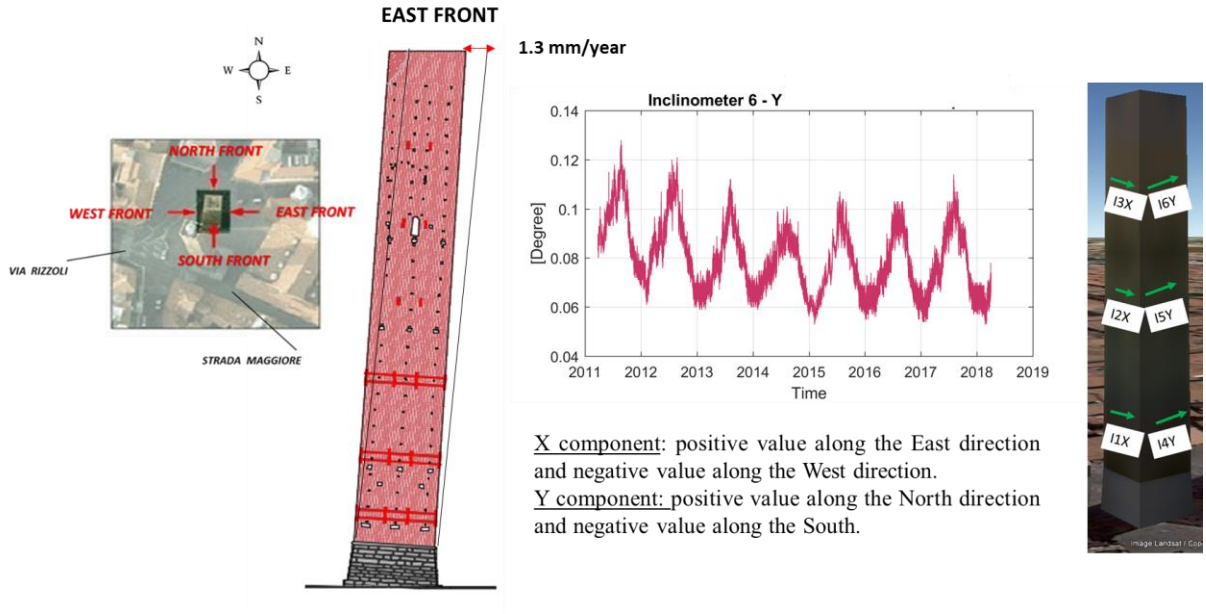

Figure 3-(a) Inclination detected toward East from the X-component of the inclinometers. (b)Inclination detected towards North Y-component of the inclinometers

2.3 Actual state of degradation

Over the last year, some surveys and visual inspections revealed that small portions of the selenitic layer are degrading and becoming chalk, with a significant reduction of the mechanical characteristics of the original stone. This phenomenon is observed at the base in the corner under slope, both on the outside and in the inner side (Figure 4a). Externally the selenitic blocks, that cover the first meters of the tower, have suffered relative displacements mainly concentrated on the East front (Figure 4b). The internal selenitic stones, on the other hand, show the presence of a deterioration process underway due to chemical processes linked to humidity. This phenomenon is particularly pronounced in the South-East corner (Figure 4c).

Figure 4-(a) Corner mainly affected by the degradation phenomenon. (b) Displacements of the selenitic blocks of the East front (c) Degradation of the internal selenite basement

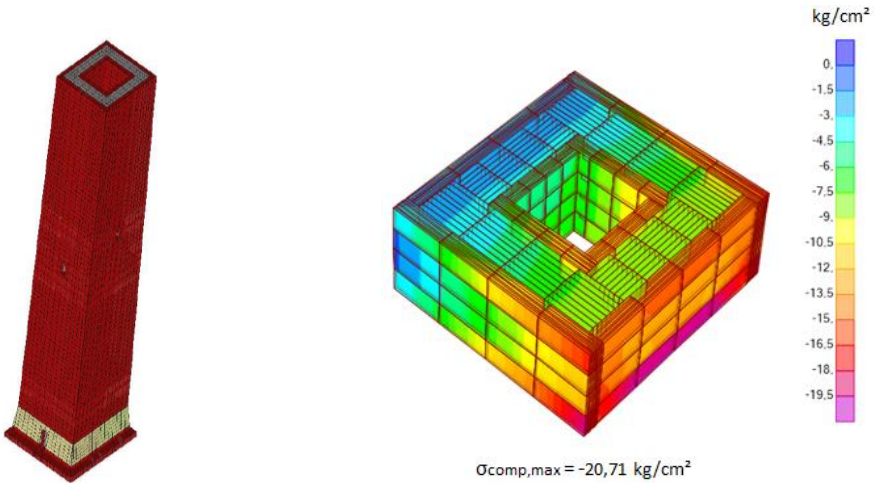
3 NUMERICAL ANALYSES

Structural analyses have been carried out on 3D FE models of the tower in order to assess (i) the effect of static loads and wind accounting for the tower inclination and thermal variations, (ii) the dynamic properties through comparisons with data from SHM, (iii) behavior under earthquake loadings, (iv) the influence of the material degradation at the basement on the structural behavior, (v) possible cause of specific trend detected through the SHM [2]. In

this section, for sake of conciseness, the attention is focused only on the study of the variation of the stress levels due to the material degradation at the base of the tower by means of a Three-Dimensional Finite Element Model (Figure 5a). In detail, the following models/limit cases have been considered:

1) UNDmodel: model with materials having full strengths and elastic moduli according to values provided in Table1,
2) DEGmodel_1: model with a portion of the external and internal selenitic stones having reduced values of elastic moduli (Figure 6a);
3) DEGmodel_2: model with a portion of the entire wall (including the internal infill) with reduced elastic moduli,
4) DEGmodel_3: model with the entire East side with the external selenitic stones having reduced values of elastic moduli.

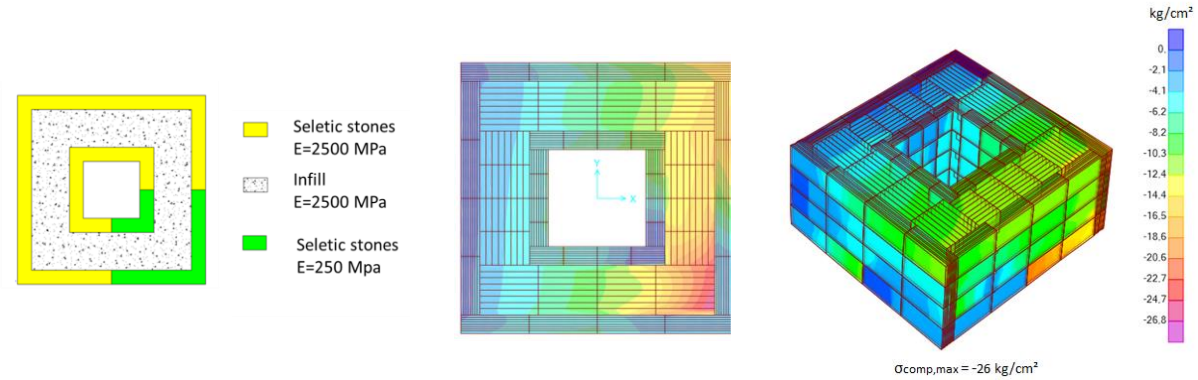
First, the stress levels as obtained from UNDmodel are reported in figure 5b. It can be noted that the maximum compressive stresses accumulates on the external selenitic blocks concentrated on the South-East corner (around 2 MPa), while the internal infill achieves compressive stresses of the order of 1 MPa.



(a) (b)

Figure 5-(a) Three-Dimensional Finite Element Model of the Garisenda Tower. (b)Stress levels at the base of the tower considering the material not degraded.

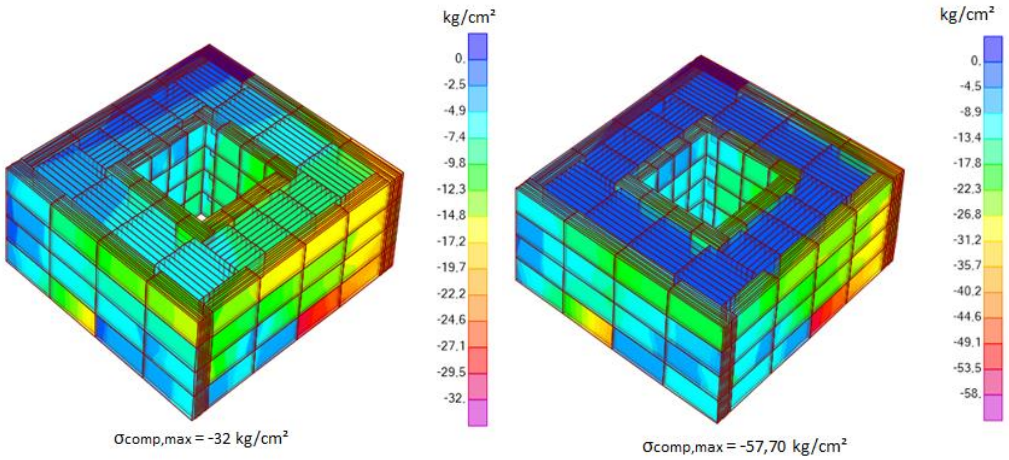
In model DEGmodel_1, the degradation detected in the external and internal perimeter constituted by blocks of selenite has been simulated progressively decreasing the elastic modulus of the material in the South-East corner, evidenced in green in Figure 6a (in particular several analyses have been carried out reducing the elastic moduli from 2500 to 250 MPa). The analyses have been conducted considering only the self-weight. The results obtained in terms of contour maps, considering an elastic modulus of the corner equal to 250 MPa, are presented in figure 6b. It can be noticed that the maximum value of the compressive stress in selenitic blocks remains of the same order of magnitude whilst increase in the infill (reaching values of the order of 2.6 MPa).



(a) (b)

Figure 6-(a) Identification of the areas interested by the reduction of the Elastic modulus. (b) Contour maps, considering an elastic modulus of the corner equal to 250 MPa

DEGmodel_2 includes the effect of a possible deterioration in the infill material through 2 reductions in the elastic moduli: (i) from 3000 MPa (initial value) to 1500 MPa, (ii) from 3000 MPa (initial value) to 300 MPa. Figure 7 displays the contour maps of the stresses levels in the selenitic stones and infill for the two cases. It can be noticed that the degradation of the infill causes a redistribution of the tension moving the maximum stresses in the selenitic stones close to the deteriorate corner (peaks of the order of 3.2 MPa and 5.7 MPa).



(a) (b)

Figure 7-(a) Contour maps of the stress level at the base section obtained reducing the infill Elastic modulus by: (a) 50% and (b) 90%

DEGmodel_3 investigates the possible cause of the inclination detected by the inclinometers in the North direction of the tower. In this model, the properties of the selenic stone for all the external portion of the East side were reduced to 250 MPa. This phenomenon could be related to the results obtained by recent investigations that detect a small cavity on the Eastern front towards the edge opposite to the one actually under slope, causing a weakening of the section. From this latter case, it can be inferred that if all the side under slope as well as the internal infill would become completely deteriorated, there would be peaks of tension in the infill of the order of 3.5 MPa and close to material strength. Analysing the displacements in the Y-direction of this model (corresponding to North direction of the tower), it has been possible noticed that the presence of a degradation in all the side under slope actually provokes a displacement, although of the order of tenths of millimetres, in North direction.

4 CONCLUSIONS

The main conclusion of the present work can be summarized as follows:

- The structural health of the Garisenda tower has been investigated with a particular attention to the effects of the potential material degradation detected at the base of the tower. First, the present state of the tower has been studied through survey and non-destructive tests correlated to the data obtained by a static and dynamic monitoring system.
- The effects caused by a reduction in the material properties at the base, composed by selenitic stones, on the structural behavior, has been investigated by means of Three Dimensional Finite Element models with brick elements.
- Considering the degradation only in the selenitic stone and with a concentration in the South-East front, the results obtained reveal that the maximum compression value in the selenite blocks remains substantially unchanged but creates a sort of arc effect that leads to the loading of the first blocks alongside the deteriorated ones.
- A deterioration of the infill material would cause tensions that could reach the limit of the material strength with a considerable reduction of the safety levels of the building.
- In addition, it has been confirmed that the tower is undergoing a slight displacement northwards due to a deterioration of the coating portion on the North-East front.

ACKNOWLEDGEMENT

The authors gratefully acknowledge Dott. Ing. Gilberto Dallavalle who provided valuable information related to geometrical and material properties.

UNCERTAINTY OF PROPERTIES AND FAILURE LOAD IN COMPOSITE MATERIALS

Piotr Kędziora

Cracow University of Technology
31-155 Kraków, ul. Warszawska 24, Poland
e-mail: piotr.kedziora@mech.pk.edu.pl

Abstract

The impreciseness (uncertainty) of the experimentally obtained data can be described using fuzzy sets theory. It is proposed the fuzzy set method for the correct and concise evaluation of various geometrical and mechanical properties or final failure load. The variability (understood as the fuzziness) of the fiber and matrix properties is described by a membership function. Based on experimental results it is possible to determine the effect of the fuzziness of the mechanical properties. The fuzzy sets theory allows to build the lower and upper bounds of the failure envelopes for the Tsai-Wu criterion. The linear qualifier function is applied to analyze the composite structure subjected to the load.

Keywords: Composite Materials, Fuzzy Set, Fuzzy Logic, Material Uncertainty.

1 INTRODUCTION

The use of fiber-reinforced composite materials in modern engineering structural design has become a common practice. However, since more design variables typically exist when composite materials are employed and the manufacturing processes for producing composites are more complex, more variability can exist in a design procedures with composites compared to conventional (isotropic) materials [1]. Thus, the variability of properties that occurs in composite structures leads directly to a random field of variables describing constructions. A scatter of properties has a different origin including geometrical and mechanical properties, environmental effects and the influence of the applied technology or existence of the internal defects of flaws, see e.g. papers [2-5]. Therefore, there is a fundamental question: how many and which of the above factors can (or should) be incorporated in the design process and how can we manage to take into account the existing variability of parameters. A broader discussion of those problems can be found in reference [6].

The majority of available references in literature discussing design problems of composite structures is devoted to the analysis conducted in a pure deterministic way. However, the random field of parameters describing composites may be taken into account by the standard use of different variants of the statistical analysis or by the application of non-stochastic methods – a fuzzy set approach.

Referring to composite materials the origin and the source of imprecision (or uncertainty) lies mainly in the lack of information dealing with their microstructure, mechanical properties, behavior and the number of factors responsible for gradual degradation of their properties and final failure. Commonly, the theoretical (deterministic) analysis of composites is based on the homogenization theories that may include an increasing number of different parameters [7, 8]. However, it is unknown in advance what number of parameters is sufficient to describe satisfactorily the problem considered. On the other hand, the material parameters are evaluated in the experimental way being the source of randomness in the traditional (deterministic) analysis or impreciseness or vagueness in the fuzzy set approach. The imprecise, vague, qualitative, linguistic or incomplete information may be present in geometry, material properties, degradation of properties, applied loads or boundary conditions.

Different kinds of methods are investigated for different types of uncertainties. Oskay and Fish [9] calibrated material properties in a deterministic fashion with the aid of genetic algorithms and gradient-based techniques. Jiang et al. [10] proposed the deterministic model to identify the uncertain elastic modulus of braided composites using modal data. Mustafa et al. [11] presented a probabilistic model for estimating the fatigue life of composite laminates using a high fidelity, multi-scale approach called M-LaF (Micromechanics based approach for Fatigue Life Failure). They developed a unified framework for the representation and quantification of uncertainty present in the fiber and matrix properties with the use of the Bayesian inference approach in order to calculate probabilistic composite fatigue failure. Chandrashekhar and Ganguli [12] performed probabilistic analysis using the Monte Carlo Simulation on a refined composite plate finite element model to calculate the statistical properties of the variation in modal parameters of a cantilever composite plate due to structural damage and material uncertainty.

If the system parameters are described in imprecise or linguistic terms the fuzzy theory can be implemented to predict the structural response in the sense of evaluation of its upper and lower bounds, respectively. Various problems connected with fundamentals and concepts used in the fuzzy set theory are presented in a few representative monographs: McNeill and Thro [13], Cox [14], Tsoukalas and Uhrig [15], Dubois and Prade [16], Zadeh et al. [17], Kosko [18].

Fuzzy concepts are used in various areas of mechanics. Moens and Hanss [19] presented an overview of the research activities on non-probabilistic finite element analysis and its application in the representation of parametric uncertainty in applied mechanics. Sodoke et al. [20] used a fuzzy logic model to obtain a simplified view of linguistic variables representing the modulus of elasticity and to reconcile different modules by including the uncertainty inherent to the different measuring techniques. Altmann et al. [21] introduced a fuzzy-probabilistic approach to assess the durability of strain-hardening cement-based composites. Karbhari and Stein [22] described the application of a fuzzy probabilistic approach to reflect the impact of the inherent uncertainty in determining the reinforcing fibers of polymer jackets for the seismic retrofit of columns. Bohlooli et al. [23] presented a suitable model based on fuzzy logic to predict the compressive strength of inorganic polymers with seeded fly ash and rice husk bark ash. Syamsiah et al. [24] proposed the role of input selection using a neuro-fuzzy approach to predict the physical properties of degradable composites, namely the melt flow index and density. Rassbach and Lehnert [25] developed a model based on the mathematical methods of fuzzy-logic which can describe the plasto-mechanical behavior of functionally gradient materials during the deformation process. Muc and Kędziora [26] employed a fuzzy-set based approach in conjunction with a finite element analysis and fracture mechanics. In the numerical analysis four parameters were considered to be fuzzy, namely, three mechanical parameters (Young's moduli, Kirchhoff's modulus) and one geometrical parameter describing the position of the crack center. Kędziora and Muc [27-29] proposed the fuzzy set analysis in order to estimate the uncertainty in the evaluation of critical number of cycles corresponding to the final fatigue damage. Experimental data obtained during fatigue tests conducted for tension and compression were represented by the lower and upper bounds of the stiffness degradation, i.e., as stiffness versus the number of cycles relationships [28, 29].

Therefore, in this way the impreciseness (uncertainty) of the experimentally obtained data can be described using fuzzy sets theory. In this paper, it is proposed the fuzzy set method for the correct and concise evaluation of various mechanical properties or final failure load. The variability (understood as the fuzziness) of the fiber and matrix properties is described by a membership function. Based on experimental results it is possible to determine the effect of the fuzziness of the mechanical properties. The fuzzy sets theory allows to build the lower and upper bounds of the failure envelopes for the Tsai-Wu criterion. The linear qualifier function is applied to analyze the composite structure subjected to the load.

2 FUNDAMENTAL DEFINITIONS

2.1 Representations of Fuzzy Sets

The data "integer less than 10" is the definition of characteristic function Π_A and is represented in the following way:

$$\Pi_A : IN \rightarrow \{0,1\}$$
$$\Pi_A(\eta) = \begin{cases} 1, & \text{if less than } 10 \\ 0, & \text{otherwise} \end{cases} \tag{1}$$

that yields a value 1 for each element of space IN that belongs to set A and a value 0 for each element that does not. The above representation is commonly called a crisp set. However, this concept cannot be used directly as we intend to characterize the typical property for composite materials, e.g. the failure of carbon fiber reinforced polymer under tension occurring as tensile strain ε_x is equal to the ultimate value of 0.015. The characteristic function of this set is depicted in Figure 1a. For the three-dimensional analysis, all the components of the strain ten-

sor can be evaluated in a similar manner. A problem arises if the linguistic term “failure under tension” has to be described. The value of a failure strain in composites depends on various parameters such as the fiber and matrix materials, loading conditions, porosity, environmental effects, etc. It is well-known that from the micromechanical point of view that failure starts from microcracks in the matrix for strain values much lower than the value 0.015. In addition, the value 0.015 is usually an average value characterizing rather a scatter of a random values of macrocracks appearing at the strain level 0.015. Therefore, for some specimens one can observe the final (macroscale) failure as ε_x is equal to 0.0159 or to 0.0141. A possible solution to this problem is to generalize the definition of the characteristic function in a way that it yields values from interval [0, 1] and not just the two values of the {0, 1}. This leads to the notion of a fuzzy set.

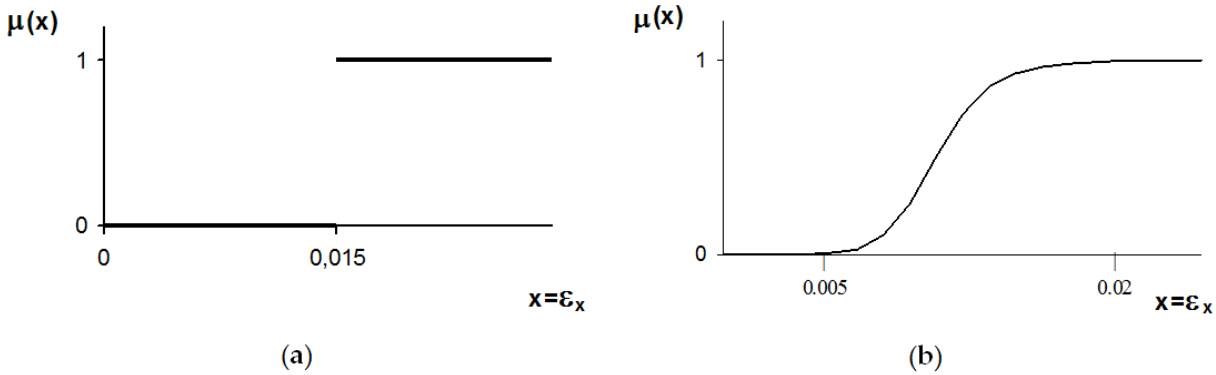

Figure 1: Representation of term “failure under tension”: (a) crisp set; (b) fuzzy set.

Fuzzy set μ of X is a function that maps space X into the unit interval, i.e.:

$$\mu : X \rightarrow [0,1] \tag{2}$$

Value μ(x) denotes the membership function of x to fuzzy set μ. Figure 1b shows (subjectively defined) a membership function of fuzzy set μ describing the linguistic meaning of the term “failure under tension”. The use of fuzzy sets to formally represent vague data is often done in an intuitive way because in many applications there is no model that provides a clear interpretation of the membership degrees, though we want or we try to base it on various experimental data.

The application of fuzzy methodologies requires the knowledge of the membership functions of fuzzy quantities. In general, fuzzy numbers are sets that represent numeric quantity. It can be done in a variety of ways. Of course, there are different possibilities to determine and represent membership functions characterizing a fuzzy set. If subspace S contains only a finite number of elements, a fuzzy set μ of X will be defined by specifying for each element $x \in X$ its membership degree μ(x). If the number of elements is very large or a continuum is chosen for X, then μ(x) can be better defined by a function that can use parameters which are adapted to the actual modeling problem. For instance, if we want to represent the term “Young’s modulus is equal to 200 GPa” in the sense of a fuzzy set having a finite amount of experimental data, we can select one of the different representations given in Figure 2.

The determination of the membership functions is difficult. There are different forms of them and in the description of the fuzzy numbers the triangular, trapezoidal, Π, B, Gaussian or Weibull curves are commonly used, whereas in the case of fuzzy qualifiers – the sigmodal or linear curves – see reference [3]. However, the first attempt or trial in building the membership functions can be based on the statistical data – see e.g. the description of failure.

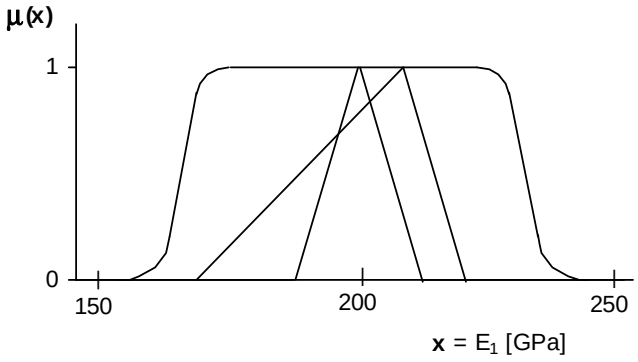

Figure 2: The used descriptions of uncertainty.

One of the possible fuzzy set representations was presented there. Another approach is the so-called horizontal representation of fuzzy sets. This is introduced by using their α-cuts instead of membership functions μ(x) which are called vertical representations.

Let $\mu \in F(x)$ and $\alpha \in [0, 1]$. The set is called the α-cuts of μ:

$$[\mu]_\alpha = \{x \in X | \mu(x) \geq \alpha\} \tag{3}$$

Let μ be the triangular function on IR given in Figure 3. The α-cuts of μ are in this case defined as follows:

$$[\mu]_\alpha = \begin{cases} [a + \alpha \cdot (m-a), b - a \cdot (b-m)] & \text{if } 0 < \alpha \leq 1 \\ IR & \text{if } \alpha = 0 \end{cases} \tag{4}$$

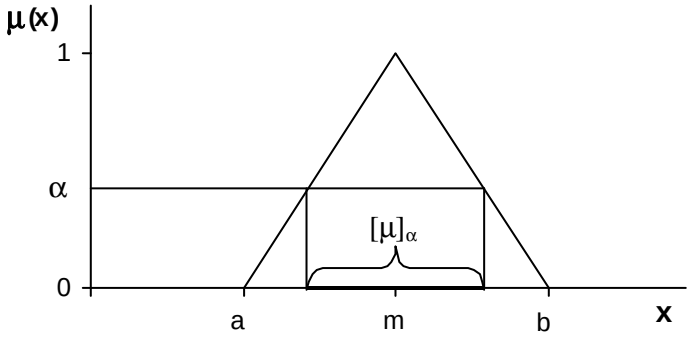

Figure 3: Definition of α-cuts.

There are, generally, two kinds of fuzzy sets:

- numbers that represent an approximate numeric quantity; those values can represent uncertainty (impreciseness, fuzziness) of Young's (see Figure 2) or Kirchhoff's moduli, geometric properties of structures (dimensions, fiber orientations) or allowable strengths/strains in appropriate directions;
- qualifiers that characterize open-ended concepts; these sets provide the framework for describing unbounded concepts (or concepts that are theoretically unbounded), e.g. qualifiers of failure or constraints in various optimization problems – see e.g. Rao [30].

2.2 Vertex Method

Let us introduce N fuzzy parameters describing the material or geometric parameters of the considered composite structure. The membership functions are discretized using several α-cuts – Equation (4). Considering the left and right end points of the α-cut s intervals $[\mu]_\alpha$ (see Figure 3) for all the fuzzy parameters, one can find the total number of combinations $N_{c/\alpha}$ per α-cut in the following form:

$$N_{c/\alpha} = \begin{cases} 2^N & for\ 0 \le \alpha < 1 \\ 1 & \text{for } \alpha = 1 \end{cases} \tag{5}$$

An output response denoted by p is an unknown function of input fuzzy parameters x_i (i=1, 2, …, N), so that:

$$p = f(x_1,...,x_N) \tag{6}$$

Using the α-cut concept combined with binary representation (5) of fuzzy parameters x_i (i=1,2,…,N) relation (6) can be rewritten in the abbreviated form:

$$p = f(C_{\lambda,j}); \quad j = 1, 2, ..., N_{c/\alpha} \tag{7}$$

Since output response p as a function of fuzzy parameters is a fuzzy set, the corresponding interval in p is obtained from relation (6):

$$[p_\alpha^L, p_\alpha^R] = [\min_{\lambda,j} f(C_{\lambda,j}), \max_{\lambda,j} f(C_{\lambda,j}); \ \lambda \ge \alpha, \ j = 1, 2, ..., N_{c/\alpha} \tag{8}$$

As may be seen, relation (8) allows one to obtain a scatter of the output parameters and then to build the appropriate probability distributions and reliability functions by a sweep of α-cut at different possibility levels.

In order to conduct the computations and to evaluate the upper and lower boundaries of output response (8), it is necessary to outline the deterministic method of the definition of function f given in Equation (6). It can be defined in a purely analytical way or alternatively in a purely numerical way. As may be noticed, the vertex method resembles here the Monte Carlo simulation method where the output response also has a deterministic, and therefore unique form.

Function f existing in Equation (6) may describe an arbitrary failure criterion for composites, e.g. buckling, delamination, first-ply-failure (FPF) etc., whereas symbol p denotes the corresponding value of the failure load.

3 FUZZY SET ANALYSIS

The origin and source of imprecision (or uncertainty) can result from the lack of information dealing with their microstructure, mechanical properties, behavior and the number of factors responsible for gradual degradation of their properties and final failure of composite materials.

3.1 Mechanical Properties

Commonly, the theoretical (deterministic) analysis of composites is based on homogenization theories. In the micromechanics analysis the development of the model of repeating unit cells is based on the assumption that the unidirectional composite is represented by fibers which are aligned in the x_1–direction and distributed regularly in the matrix and finally the components form a doubly periodic array in the x_2 and x_3 directions – see Figure 4. In Figure

4 the fibers have a circular cross-section and the same diameter d and are arranged at distances h, l apart. The unit cell is showed in Figure 4b.

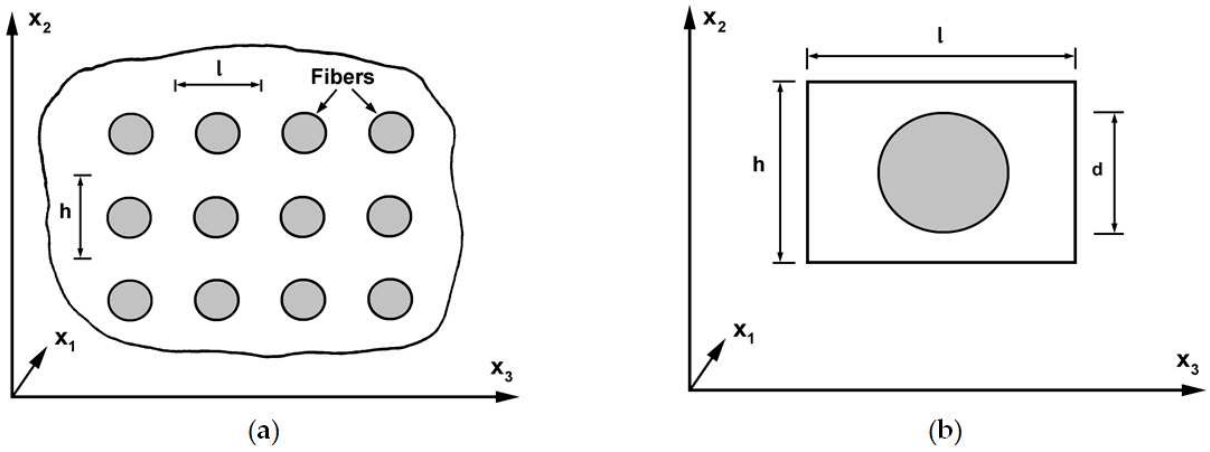

Figure 4: Micromechanics unit cell geometry: (a) periodic array of circular fibers extending in the x_1 direction; (b) representative cell.

At the micromechanics level, the transversely isotropic material is expressed in terms of the five engineering constants. They are functions of the material variables, i.e. of the fiber and the matrix properties E_{f1}, E_{f2}, G_{f12}, ν_{f12}, ν_{f13}, E_m, ν_m, V_f, where f denotes fiber property, m – a matrix property, E – the Young's modulus, G – the Kirchhoff's modulus, ν – Poisson's ratio and V_f is the fiber volume fraction (assuming $V_f + V_m = 1$, where V_m is the matrix volume fraction).

The impreciseness in the modeling is obvious: the ideal forms of the constituents and of representative cells, an influence of the interface is completely eliminated – there are two components in the model fibers and matrices, the matrix and fibers have constant values (there is no defects inside them) etc.

Now, let us assume that the variables characterizing the fiber and matrix properties are fuzzy variables and their fuzziness is described by a triangular membership function – see Figure 3. It is assumed that the variability (understood as the fuzziness) of material parameters is taken to be equal to ±10 %. The nominal (average) values correspond to α=1 (see Figure 3) whereas the parameters of the triangular membership function given by Equation (4) are following :

$$m = \frac{a+b}{2}, \quad a = 0.9 \cdot m \quad b = 1.1 \cdot m \tag{9}$$

Having the Halpin–Tsai model equations of the relation (6) and using the procedure proposed in the Section 2 for a given α-cut one can evaluate the upper (the right end point of the interval (8)) and lower bounds (the left end point of the interval (8)) of the effective longitudinal and transverse Young moduli. The results are evaluated for the unidirectional long glass fibers/epoxy resin, i.e. the nominal properties (denoted by m in relation (10) and Figure 3) E_{f1}=73GPa, E_m=3.5GPa from [31]. The results of computations are plotted in Figure 5. As it may be seen, the nominal curve denoted by the value α=1 (the solid red line in Figure 5) is obtained for nominal values of E_{f1} and E_m. The lower and upper bounds of the curves denoted by the value α=0 plotted in Figure 5 (denoted by the superscripts L and R), are evaluated with the use of Equation (8). As it may be observed the biggest effect of fuzziness is for the maximal values of the fiber volume fraction.

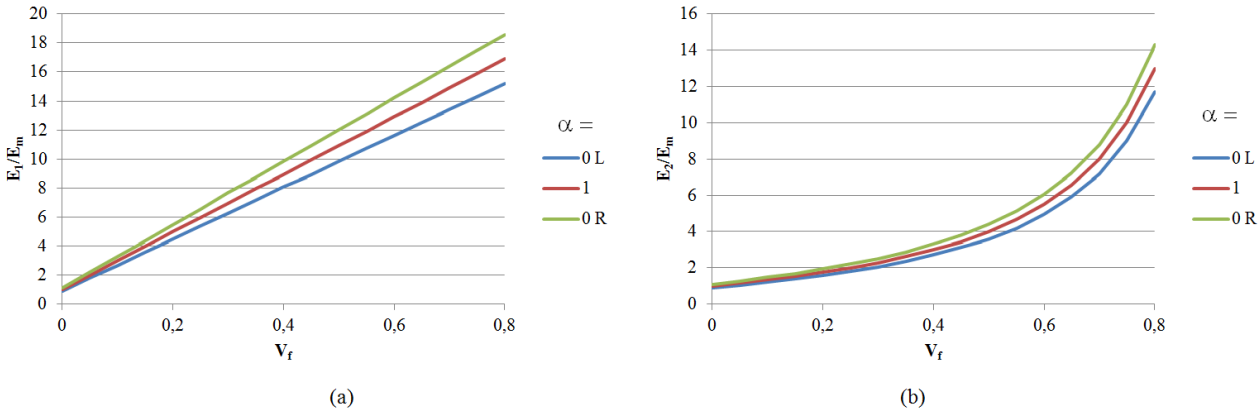

Figure 5: Distributions of the effective longitudinal E_1 (a) and transverse E_2 (b) Young moduli at α= 0 and 1 (L – lower bound, R – upper bound).

3.2 First-ply-failure

One of failure criterion in order to consider these uncertain material properties is applied to the calculation. For example, uncertainties in elastic moduli of laminates are due to several factors, such as e.g. the misalignment of fibers or imperfect bonding between fibers and matrix.

The classical first-ply-failure (FPF) envelopes (e.g. the Tsai-Wu criterion) are described with the aid of variety of material constants characterizing different modes of failures (tension, compression etc.). Those values may be treated as fuzzy ones and in this way the fuzzy set theory allows us to build the lower and upper bounds of the failure envelopes for each fiber orientations of plies in the laminate. Assuming that five strength constants are fuzzy parameters such envelopes have been built and the plot is presented in Figure 6. For compressive deformations the uncertainty of failure locations (at plies having fibers oriented at 0° or 45°) is the characteristic feature of the resulting curves.

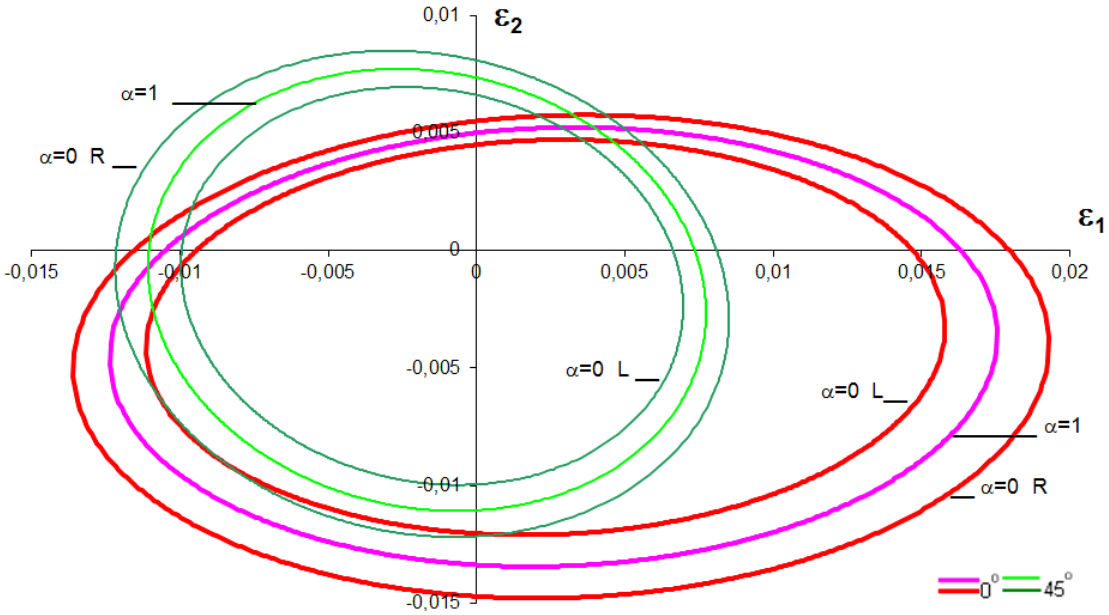

Figure 6: Upper and lower bounds of FPF envelopes – the Tsai-Wu criterion (plies having fibers oriented at 0° or 45°; L – lower bound, R – upper bound).

The results demonstrate evidently that the classical deterministic approach to the FPF analysis can lead to the inconsistency and incorrectness with experimental data. For compression in both directions it is possible to obtain experimentally the FPF initiation at plies oriented both at 0° and 45°. They show simply the limitations of the classical global elastic approach since the matrix cracking associated with the FPF is connected with inelastic deformations (in the global sense), especially for fibers oriented at 45° or with the appearance of intralaminar cracks (a micromechanical approach).

3.3 Fuzzy Constrains

The deformation of composite structure subjected to in-plane and/or bending loads can be considered using fuzzy maximum strain criteria. Fuzzy constrains are defined by maximum strain criteria in the following way:

$$\begin{aligned} \varepsilon_{1c}^{ult} - \Delta\varepsilon_{1c} \le \varepsilon_1^{\pm}(\theta_k) \le \varepsilon_{1t}^{ult} + \Delta\varepsilon_{1t} \\ \varepsilon_{2c}^{ult} - \Delta\varepsilon_{2c} \le \varepsilon_2^{\pm}(\theta_k) \le \varepsilon_{2t}^{ult} + \Delta\varepsilon_{2t} \\ \left|\varepsilon_6^{\pm}(\theta_k)\right| \le \varepsilon_{6t}^{ult} + \Delta\varepsilon_{6t} \end{aligned} \tag{10}$$

where ± denotes upper and lower surface of k-th layer, respectively. t designates tension and c – compression. θ denotes fiber orientation. Ultimate strain strengths (maximum) ε^{ult} are dealt with as fuzzy numbers by using $\Delta\varepsilon$ and β in the following manner:

$$\Delta\varepsilon_{ij} = \beta \cdot \varepsilon_{ij}^{ult} \quad i = 1,2,6 \quad j = t, c \tag{11}$$

The value of the parameter β denotes the level of fuzziness in the problem. When β is equal to 0% it denotes a crisp optimization problem. The degree of satisfaction of constraint is determined using the membership functions $\mu_\varepsilon(\varepsilon(\theta))$ (see reference [3]) which are represented by linear qualifier function in the form of asymmetrically trapezium. For the positive value of strain $\varepsilon(\theta)$, the membership functions $\mu_\varepsilon(\varepsilon(\theta))$ is given by

$$\mu_{\varepsilon_t}(\varepsilon(\theta_k)) = \begin{cases} 1 & \varepsilon(\theta_k) < \varepsilon_t^{ult} - \Delta\varepsilon_t \\ \alpha_t & \varepsilon_t^{ult} - \Delta\varepsilon_t \le \varepsilon(\theta_k) \le \varepsilon_t^{ult} + \Delta\varepsilon_t \\ 0 & \varepsilon(\theta_k) > \varepsilon_t^{ult} + \Delta\varepsilon_t \end{cases} \tag{12}$$

where

$$\alpha_t = 1 - \frac{\varepsilon(\theta_k) - \left(\varepsilon_t^{ult} - \Delta\varepsilon_t\right)}{\varepsilon_t^{ult} + \Delta\varepsilon_t - \left(\varepsilon_t^{ult} - \Delta\varepsilon_t\right)} \in [0,1] \tag{13}$$

and presented in Figure 7a. For the negative value of strain $\varepsilon(\theta)$, the membership functions $\mu_\varepsilon(\varepsilon(\theta))$ is showed in Figure 7b.

The maximum stress criterion has a similar form. Then, in Equations (10)-(13), the notation σ is used in place of ε.

CONCLUSIONS

The present study is a practical tool for engineering activities dealing with evaluating the degradation of real material structure. As it remains an open problem, it is connected with the total number of uncertain parameters that should be considered in order to describe the real

behavior of engineering structures with an acceptable accuracy. However, it can be solved for each individual problem only.

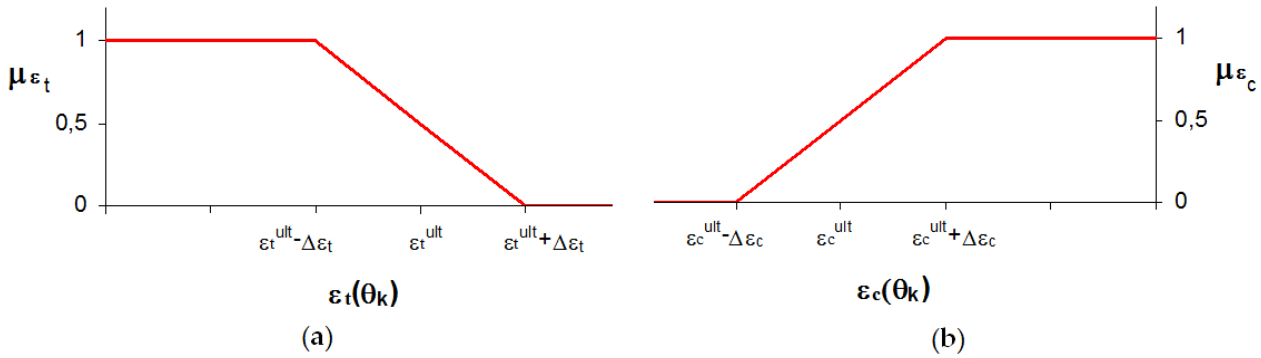

Figure 7: The membership functions for: (a) the positive value of strain; (b) the negative value of strain.

The presented method allows one to build the appropriate membership functions for the evaluated values of the Young moduli.

The fuzzy set theory allows us to build the lower and upper bounds of the failure envelopes for FPF and the linear qualifier function (in the form of asymmetrically trapezium for maximum strains criteria). Fuzziness of failure strain has a great influence on a surface of limit load values. The above conclusions depend on structural geometry and load parameters.

Abstract. *The implementation of methods which belong to the field of Artificial Intelligence such as the Artificial Neural Networks (ANN) based methods is continuously increased in many scientific and technological applications. As regards the civil engineering applications, the investigation for the utilization of these methods has led to very promising results. More specifically, the experimental application of ANN-based methods for the seismic vulnerability assessment of structures has proved that they can be utilized as alternative methods in parallel of the well-documented existing methods. However, despite their promising results there is no wide acceptance of ANNs as computational tools for the prediction of the seismic damage level of structures. This can possibly be attributed mainly to the fact that the vast majority of civil engineers who investigate methods for structures' seismic vulnerability assessment has no the minimum required background about the abilities and the utilization of the ANN-based methods. The current paper attempts to present a different point of view of the ANN-based methods and to prove that the research for their further implementation can be approachable by civil engineers provided that the corresponding formulation is defined in certain stages. In the framework of the current paper it is also proved that by the utilization of ANNs the definition of relatively simple equations for the preliminary estimation of the seismic damage level of R/C buildings in near-real time is possible.*

---

1 INTRODUCTION

The utilization of the Artificial Neural Networks (ANNs) for the solution of civil engineering problems was examined for the first time at the end of eighties [1, 2]. Their alternative approach to these problems' solution as well as their very promising results led to a further study of them. More specifically, in the field of earthquake engineering the corresponding studies are enough but less than the studies which are focused on other scientific fields of civil engineering (see e.g. [3-9]). Thus, for the seismic vulnerability assessment of existing buildings at urban scale or at regional state, methods such as the seismic vulnerability curves were developed and widely used (e.g. [10, 11]). It must be noticed that, besides the fact that significant efforts have been done globally for the utilization of ANNs in the seismic vulnerability assessment of existing buildings, the correspondence of the civil engineering research community and the amount of the corresponding research was not sufficient. Among the possible reasons which led to this situation, perhaps the most significant according to the authors' opinion concerns the fact that the utilization of ANNs requires not only specialized software for their configuration (e.g. [12, 13]), training and evaluation, but also the corresponding knowledge. This knowledge is not given in the framework of the civil engineers' mandatory education. Thus, either the cooperation with scientists specialized on the ANNs or the post graduate education of civil engineers on the basic principles of ANNs is required. In order to fulfill this demand, the ANN based methods must be performed through specific stages:

(a) The stage of the problems' definition and the generation of the ANNs' training data-set. At this stage the civil engineer describes the computational problem to the ANN expert and collects the required data for its solution. Thus, significant problems such as the number and the types of ANNs' input and output parameters as well as the quality of the training data-set are initially detected and partly solved at this preliminary stage. The final solution of these issues is achieved in the following stage (b).

(b) The stage of the selection of problem's formulation in terms of ANNs' structure as well as the type, the configuration, the training and the optimization of ANNs' parameters. The available options for these selections are suggested by the ANN expert. In stage (b) final decisions about the selection of the input and output parameters of ANNs are made, perhaps through sensitivity analyses. This stage also includes the evaluation of the trained ANNs using data which were not used for their training (generalization tests).

(c) The final stage in which the most efficient trained networks must be encoded by the ANN expert in order to be produced a computer code ready for use by the civil engineer. It must be noted that it is possible to extract closed-form expressions which can be directly used for the problem's solution if specific conditions (e.g. small number of input parameters and small number of neurons) are valid.

The current paper attempts to prove that the ANN-based methods can have practical applications in a way which is more approachable to civil engineers, if the results which are extracted by them are appropriately processed. Thus, the present paper focuses on the detailed description of the stages of the r/c buildings' seismic vulnerability assessment using ANN-based procedures, and mainly on the final stage. It must me stressed that only Multilayer Feedforward Perceptron Networks (MFPN) are utilized. The problem is separated in the configuration and the training stage for which only a general description is presented, and the stage after the training for which a detailed formulation is given. Finally, closed-form equations which relate the seismic damage index MIDR (Maximum Interstorey Drift Ratio) with various seismic parameters (e.g. PGA, Arias Intensity, etc.) are developed. Thus, it is proved that the utilization of ANNs for the r/c buildings' seismic vulnerability assessment can lead to expressions which can be easily used by engineers.

2 THE STAGES FOR THE FORMULATION AND SOLUTION OF R/C BUILDINGS' SEISMIC VULNERABILITY ASSESSEMENT PROBLEM USING ANNS

The formulation and solution of the problem of R/C buildings' seismic vulnerability assessment using ANNs consists of three distinct stages. These stages are briefly presented in Figure 1. More detailed description of them will be given in the following subsections.

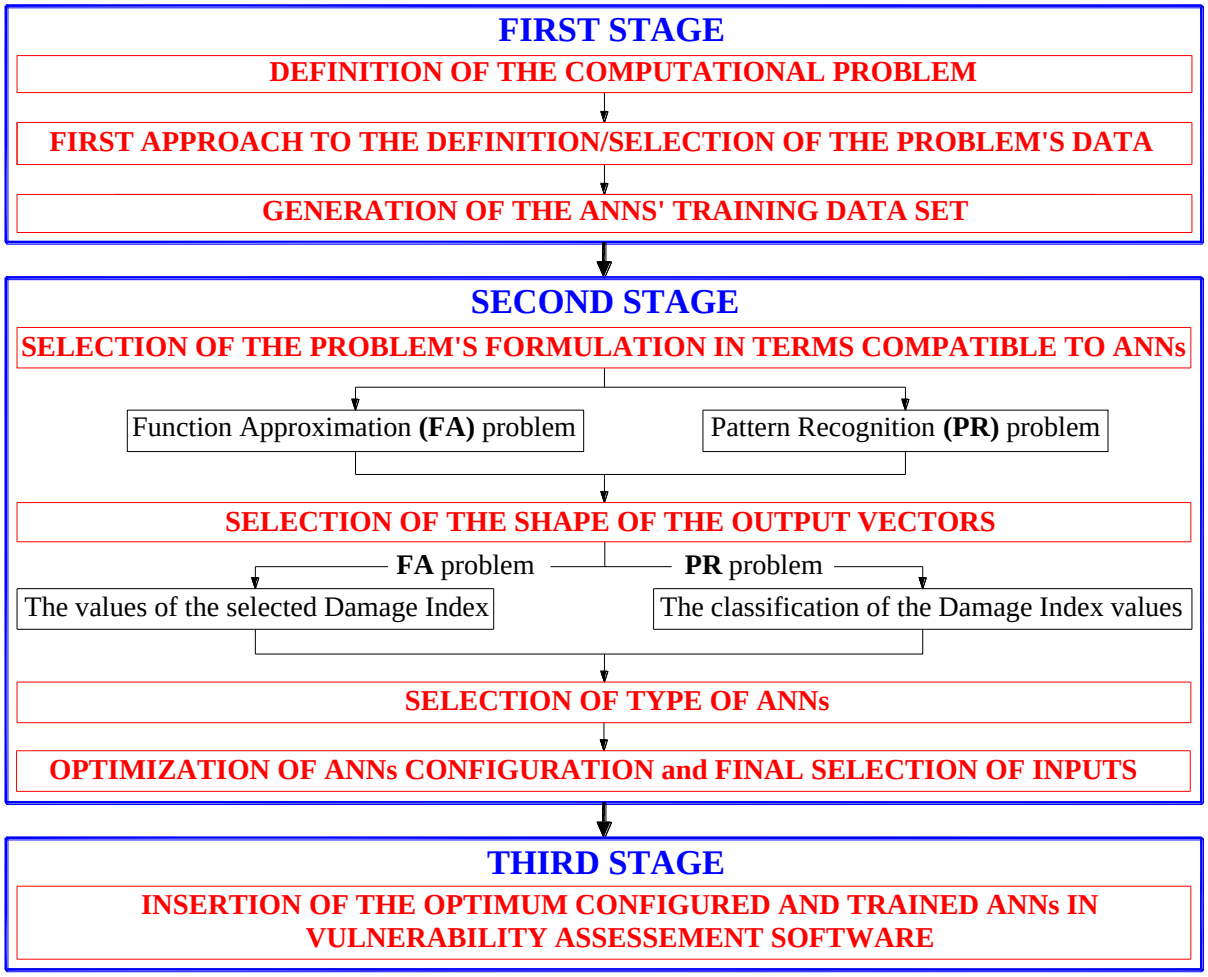

Figure 1: The three stages of problem's formulation and solution using ANNs

2.1 The first stage of problem's formulation

The first stage requires the cooperation between the civil engineer and the ANN expert. This stage consists of three individual steps as shown in Figure 1. These steps are explicitly described in Figure 2. In the first step the civil engineer describes the mathematical formulation of the problem to the ANN expert. This description contains the detailed presentation of the models and the methods which are used for the simulation of R/C buildings, earthquakes as well as their interaction. Thus, in this step the ANN expert receives the required knowledge about the problem's parameters in order to give instructions for the next step (Figure 2). In the framework of the next step (step two) the parameters which are considered as more suitable to be used as input and output parameters of ANNs are suggested. This suggestion is the result of the combination of the expertise of civil engineer and of the ANN expert. In particular, the civil engineer indicates the input parameters (structural, seismic and soil parameters) which widely used for the modeling of the seismic response of R/C buildings. It must be stressed

that this indication must be accompanied by the information about the type of input parameters (i.e. integers or real numbers) as well as the range in which they fluctuate. This information can be deployed by the ANN expert in order to give certain instructions about the effective composition of the input vectors at this (first) stage. Thus, combinations of input parameters which will cause problems to the efficient training of ANNs can be excluded at this early stage of the overall procedure.

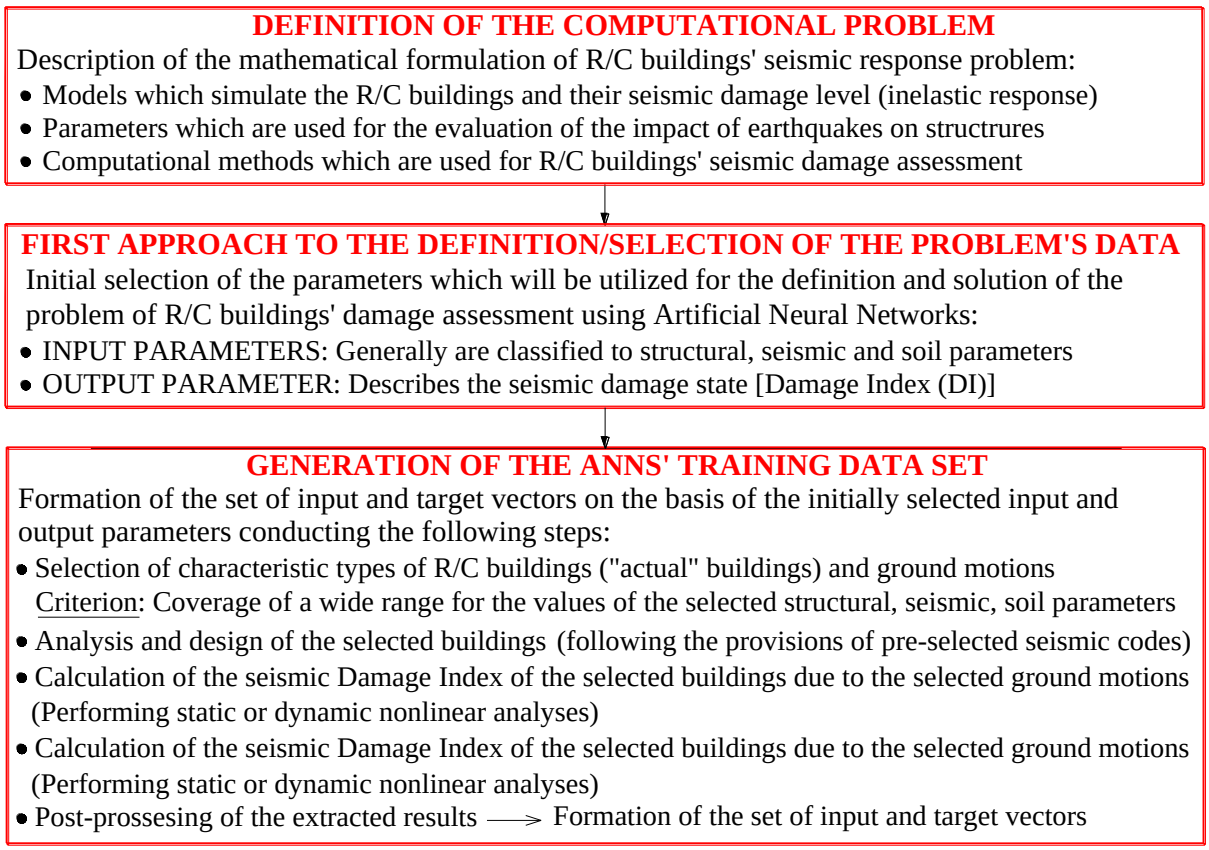

Figure 2: Detailed description of the steps of the first stage of problem's formulation

The third step of the first stage concerns the generation of the data-set (i.e. a set of samples) which is required for the training of ANNs (see e.g. [14]). The procedure of this generation for the problem of R/C buildings' vulnerability assessment is explicitly presented in [9, 15]. Having already available the information about the permissible choices for the input and the output parameters, the selection of the R/C buildings and the ground motions must correspond to a wide range of values of these parameters [for example in case of generation of training data-set which correspond to R/C buildings in Greece the height of the selected buildings must fluctuates between 3 meters (one storey buildings) and 30 meters (ten storey buildings)].

Finally, as regards the software packages which must be utilized for the accomplishment of the first stage it must be noted that only computer programs for the linear and the non-linear analysis and design of R/C buildings are required. The application of these software packages appertains to the scientific field of civil engineers. Thus, the role of the ANN expert in the first stage is limited to the instructions about the initial selection of the input and output parameters i.e. the parameters which will not cause significant malfunction to ANNs.

2.2 The second stage of problem's formulation

The second stage is mainly performed by the ANN expert. This stage consists of four individual steps as shown in Figure 1. First of all, a decision about the formulation of the problem in terms compatible to the ANNs function must be made. This decision is mainly based on the required application of the trained ANNs.

The formulation as a Function Approximation (FA) problem is intended if the prediction of the numerical value of the selected R/C buildings' Damage Index (DI) is required [9]. In the framework of this formulation, the DI is considered a (initially unknown) function of the selected structural, seismic and soil parameters:

$$DI = F\left(strP_1,...,strP_i,....,strP_n,seP_1,...,seP_j,...,seP_m,soP_1,...,soP_k,...,soP_l\right) \quad (1)$$

Where: $strP_i$ are the n selected structural parameters, seP_j are the m selected seismic parameters and soP_k are the l selected soil parameters. The Eq. (1) can be expressed in matrix form especially when a large number of input parameters is considered:

$$DI = F\left([StrP],[SeP],[SoP]\right) \quad (2)$$

Where: [StrP], [SeP] and [SoP] are the vectors which include the selected structural, seismic and soil parameters respectively.

The solution of the FA problem using ANNs leads to an approximation of the unknown function F by means of a combination of elementary linear or non-linear functions [14]. More specifically the approximate function F is also depended on a number of real numbers which are called synaptic weights and biases [14]. The calculation of these numbers is the object of the ANNs' training. The procedure for the development of function F by using the Eqs. (1), (2) as well as basic principles of the function of the trained Multilayer Feedforward Perceptron Networks (MFPN) will be explicitly presented in Section 3.

The formulation as a Pattern Recognition (PR) problem is intended if the prediction of the classification of R/C buildings to pre-defined seismic damage categories on the basis of the value of the selected DI is required (see e.g. [9, 16]). In this case, first of all the decision about the number of these categories is necessary. This is a decision which must be taken by the civil engineer. However, independently of this decision a significant difference between the FA and PR problems is the number of ANNs' outputs. In the solution of the FA problem the required output is a real number, i.e. the value of the selected DI. On the contrary, in the solution of the PR problem a mapping between the DI values and the pre-defined seismic damage classes is needed. Thus, in case of the formulation of the PR problem the required output is a vector. The dimension of this vector is (nx1), where n is the number of the pre-defined seismic damage classes. The description of the required mapping between the DI values and the seismic damage classes is presented in Figure 3.

DAMAGE CLASS	DI values	Output vector **o**
1	$0<DI\le DI_1$	$\longrightarrow o_1$
2	$DI_1<DI\le DI_2$	$\longrightarrow o_2$
⋮	⋮	⋮
i	$DI_i<DI\le DI_{i+1}$	$\longrightarrow o_i$
⋮	⋮	⋮
n	$DI_{n-1}<DI\le DI_n$	$\longrightarrow o_n$

$$\Rightarrow \text{ if } DI_i<DI\le DI_{i+1} \xrightarrow[\text{definition}]{\text{By}} \mathbf{o}=\begin{bmatrix}o_1\\o_2\\\vdots\\o_i\\\vdots\\o_n\end{bmatrix}=\begin{bmatrix}0\\0\\\vdots\\1\\\vdots\\0\end{bmatrix}$$

Figure 3: The mapping between the DI values and the pre-defined damage classes in case of PR formulation

The next step of the second stage is the selection of the type of ANNs' (Figure 1). This selection is based on the experience of the ANN expert. However, although several types of ANNs have been proposed (see e.g. [14, 17, 18]) the problem of R/C buildings' seismic vulnerability assessment is mainly approached using MFPN. This conclusion is based on the investigation of the relevant literature (see e.g. [3-9, 15]). More specifically, the choice of MFPN in the framework of the FA problem's formulation and solution is based on the fact that this type of networks can approach continuous functions with any desirable level of accuracy (e.g. [19, 20]). As regards the solution of the PR problem the MFPN are also a reliable option as it was presented in many references (see e.g. [8, 9, 21, 22, 23]).

The final (fourth) step of the second stage concerns the optimization of the networks' performance. This optimization consists of a parametric investigation with two components, namely the parametric investigation for the optimum configuration of networks as well as the parametric investigation for the optimum combination of their input parameters which were initially selected in the framework of the first stage (Figure 2). The target of the two aforementioned parametric investigations is the maximization of generalization ability of them. The generalization ability of the trained ANNs concerns their ability to extract reliable solutions for problems with data which are unknown to them. It must be stressed that in this step the contribution of the ANN expert is very critical because, as it was proved, a great danger during the ANNs' training is the so-called "overfitting" (see e.g. [24, 25]). The "overfitting" concerns the phenomenon of high performance of ANNs in problems with data which were used for their training and in parallel their poor performance in cases in which the data are unknown to them. Several techniques for the avoidance of the overfitting are available (for example the early stopping of the training procedure, the utilization of a part of the training data set for the generalization testing, the multiple trainings using different parts of the available training data set see etc., e.g. [12, 25]). In any case, the ANN expert is the most efficient to suggest the most proper technique to overcome this weakness.

The procedure for the above described parametric investigations is schematically presented in Figure 4. However, it must be stressed that this procedure is based on specific assumptions. The main assumption is the utilization of the Forward Stepwise Method (see e.g. [8, 15, 26]) for the parametric investigation for the optimum combination of input parameters. Thus, the procedure of Figure 4 is not a unique option for the accomplishment of the optimum performance of the utilized networks.

In the procedure which is described in Figure 4, the two components of the parametric investigation are not independent. The investigation for the optimum configuration of utilized MFPNs is included in the procedure for the investigation of the optimum combination of input parameters. Thus, in every step of the investigation of the optimum combination of input parameters a complete investigation procedure for the optimum configuration of the utilized networks is included. An additional comment which arises from the study of Figure 4 is the extremely big number of the required trainings in particular in cases of big number of initially selected input parameters and networks with more than one hidden layer. To overcome this problem – which can lead to time consuming procedures – the expertise of the civil engineer as well as of the ANN expert must be deployed. More specifically, the civil engineer can give advices about the input parameters which have significant influence on the seismic response of R/C buildings thus reducing the number of the initially selected input parameters and, as a result, the number of their different combinations. On the other hand, the ANN expert can give specific advices as regards the choices for parameters which must be defined for the MFPNs' configuration, thus reducing the number of the different configurations which must be evaluated (i.e. the restriction of the number of hidden layers, the exclusion of specific types of the activation functions, the optimum choice of training algorithms etc.).

STEP 1: Configuration of ***n*** MFPN [Each MFPN has as input one of the ***n*** examined parameters]

INDIVIDUAL STEPS: (For each one of the ***n*** MFPN)

(a) Parametric investigation for the optimum configured MFPN *

*(a1) Configuration of **m** MFPN with different configuration parameters***

*(a2) Multiple trainings of the **m** MFPN* (using the selected training algorithms)***

*(a3) Detection of the optimum configured MFPN (between the **m** configured networks) i.e. the network which exports the optimum results (i.e. the results with the smallest error)*****

(b) Ranking of the n MFPN on the basis of the error of their results

(This ranking leads to the network which exports results with the smallest error. This network indicates the most significant input parameter i.e. the input parameter which leads to the optimum performance between the examined input parameters)

STEP 2: Configuration of ***n-1*** MFPN

[Each MFPN has as input 2 of the ***n*** examined input parameters: The most significant parameter of the former step and one of the remaining ***n-1*** examined parameters]

INDIVIDUAL STEPS: (For each one of the ***n-1*** MFPN)

(a) Parametric investigation for the optimum configured MFPN * [Sub-steps (a1)-(a3)]

(b) Ranking of the n-1 MFPN on the basis of the error of their results

(This ranking leads to the network which exports results with the smallest error. This network indicates the combination of 2 input parameters which leads to the optimum performance between the examined input combinations of 2 parameters)

.....

STEP j: Configuration of ***n-(j-1)*** MFPN

[Each MFPN has as input j of the ***n*** examined input parameters: The most significant combination of the (j-1) parameters of the former step and one of the remaining ***n-(j-1)*** examined parameters]

INDIVIDUAL STEPS: (For each one of the ***n-(j-1)*** MFPN)

(a) Parametric investigation for the optimum configured MFPN * [Sub-steps (a1)-(a3)]

(b) Ranking of the n-(j-1) MFPN on the basis of the error of their results

(This ranking leads to the network which exports results with the smallest error. This network indicates the combination of j input parameters which leads to the optimum performance between the examined input combinations of j parameters)

.....

STEP n: Configuration of ***1*** MFPN

[This MFPN has as input all the ***n*** examined input parameters]

INDIVIDUAL STEPS:

(a) Parametric investigation for the optimum configured MFPN * [Sub-steps (a1)-(a3)]

STEP n+1: Comparison of values of the performance parameter of the ***n*** optimum MFPN which are exported from the ***n*** steps. The minimum of these values indicates the most significant (or optimum) combination of the examined parameters and the corresponding network

Notes

* After the completion of the individual step (a) networks with the same number of input parameters but with different combination of them are exported.

**These networks have the same number and the same combination of input parameters but different: number of hidden layers, number of neurons in hidden layers, types of activation functions partitioning ratios of the total training data set to training, validation and testing subsets.

*** Each one of the configured MFPN is trained several times using different part of the total training data set. The training which leads to the optimum results is selected.

**** The error is measured using ANNs' performance parameters such as the Mean Square Error (MSE)

Figure 4: Procedure for the detection of the optimum configured MFPN and the corresponding optimum combination of the input parameters by means of Forward Stepwise Method in case of a problem with n initially selected input parameters

Closing the description of the second stage, a special mention about the meaning of the term "training of MFPNs" must be given, because this is essential for the better understanding of the potential of separation of the second and third stage. In order to specify the MFPNs' training procedure using a simple and widely known terminology, we can describe it as an iterative procedure for the optimum definition of the values of the synaptic weights and biases of the neurons which are the structural units of MFPNs (Figure 5). The synaptic weights and the biases can be characterized as generalized "degrees of freedom" of networks in the sense that they give to networks the ability for the adaptation of their function to the problem's requirements. This optimum definition of the values of the synaptic weights and biases is the subject of the training algorithms which are complicated mathematical procedures (e.g. [14, 17, 24]). The criterion which is utilized for the optimum definition of the values of the synaptic weights and biases is the minimization of the error between the networks' outputs and the expected (known) outputs for a set of samples (i.e. a set of input vectors and output-target vectors) which comprise the training data set. Thus, after the completion of the training procedure the set of the values of the synaptic weights and biases which optimizes the generalization ability of the network on the basis of the available training data set is available. In other words, the training procedure leads to the calibration of the values of the synaptic weights and biases using the available input data having as target the optimum performance of the networks. Thus, the difference between a trained network and an untrained network with the same configuration parameters is only the set of the values of their synaptic weights and biases. Therefore, after the completion of the second stage is available (in matrix form) the optimum set of values of the synaptic weights and biases and the next challenge (in the framework of the third stage) is the simulation of the trained NFPN as it will be described in the next subsection. Furthermore (as it also can be extracted from the study of Figure 5) the process of the NFPNs leads to the expression of the Damage Index not only as a function of the input parameters (see Eq. 2) but also as a function of the matrices of values of the synaptic weights [W] and biases [B]. Thus the Eq. 2 can be rewritten as follows:

$$DI = \{ \underbrace{[StrP],[SeP],[SoP]}_{Input\ Parameters}, \underbrace{[W],[B]}_{Weights\ and\ Biases} \} \tag{3}$$

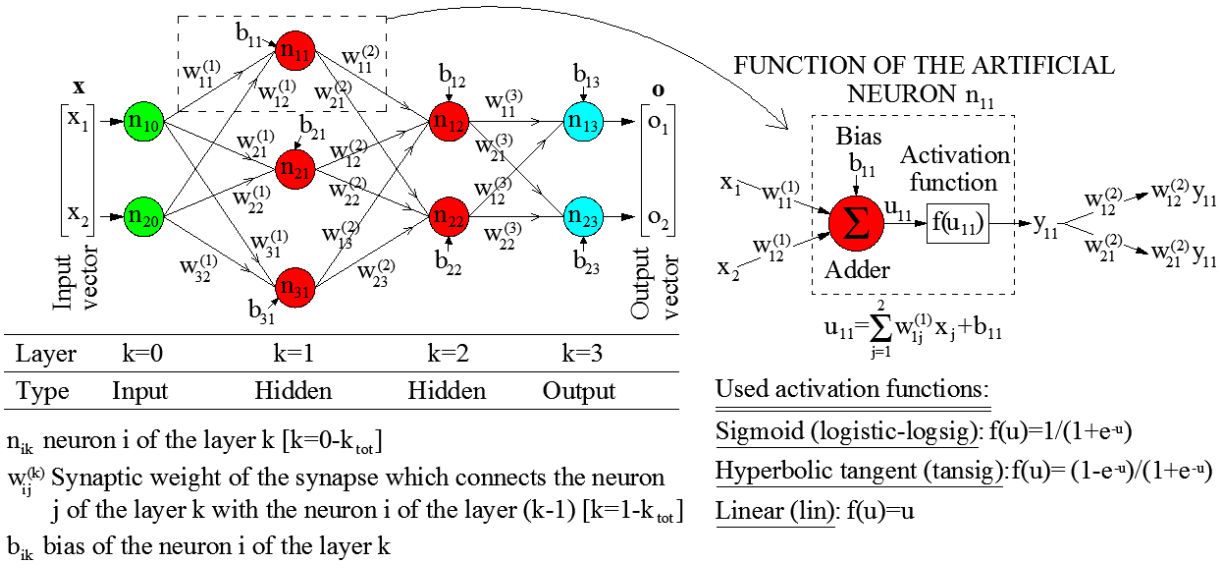

Figure 5: Description of the function of a MFPN and of the function of an artificial neuron as a unit

2.3 The third stage of problem's formulation

The third stage concerns the implementation of optimum configured and trained MFPN. In other words, in this stage the optimum configuration of the selected MFPN (i.e. number of hidden layers, number of neurons in the hidden layers, activation functions of neurons, number and combination of the input parameters), as well as the matrices with the values of synaptic weights and biases (Figure 5) which are best adapted to the utilized training data set (after the training procedure) are available. Thus, in this stage the unique target is the utilization of the optimum configured and trained MFPN in practical applications. This means that the MFPN will be implemented for the prediction of the seismic vulnerability of (known or unknown) R/C buildings which are subjected to (known or unknown) earthquakes. It must be stressed that the terms "known" and "unknown" in present case mean that the R/C buildings (or/and the earthquakes) have parameters which belong or not to the training data set's samples respectively. For example, the trained MFPN can be used for the prediction of the seismic damage state of a "known" R/C building (i.e. a building whose structural parameters have values which have been utilized as parts of at least one training vector) which is subjected to an "unknown" earthquake (i.e. an earthquake whose seismic parameters have values which have not been utilized as parts of at least one training vector).

The implementation of trained MFPNs for the solution of problems with unknown some or all of their data is called "network's simulation". The "network's simulation" requires the fully understanding of the MFPNs' function. This function can be formulated in matrix form. More specifically, it can be shown that the function of MFPNs is based on a matrix transformation of the input vector to the output vector with the aim of a sequence of matrices' operations. This sequence can be presented using a MFPN with n input parameters, p=1 output parameter and 1 hidden layer with m neurons (Figure 6).

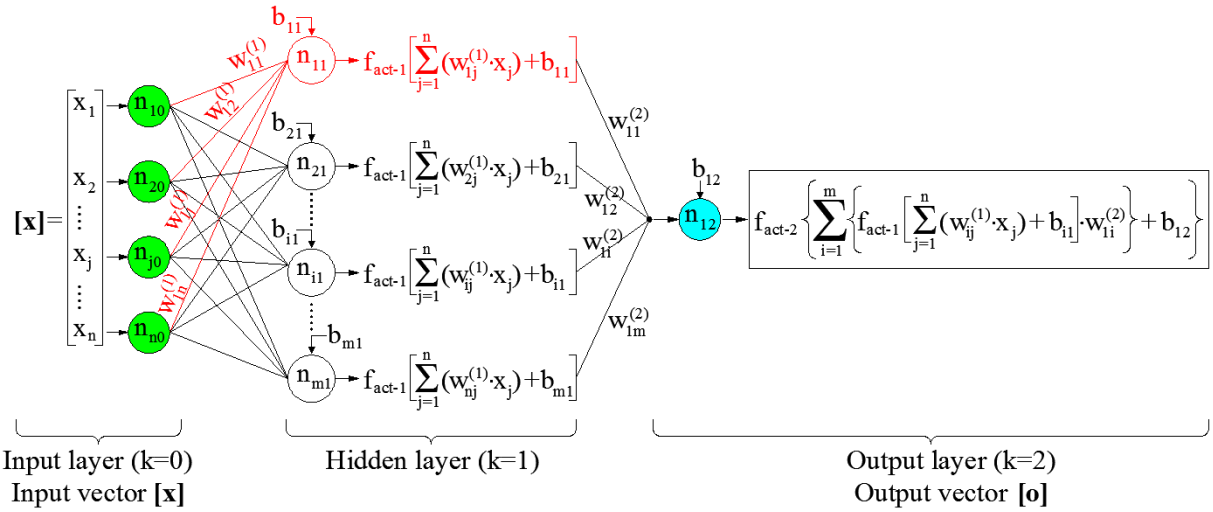

Figure 6: Indicative presentation of the MFPNs' function for the solution of the FA problem

On the basis of the configuration of the MFPN which is presented in Figure 6, the matrix operations for the transformation of the input vector **[x]** to the output vector **[o]** (which is in the present case a scalar parameter and not a vector) can be separated in 3 steps. In the first step the matrix $\mathbf{[A_1]}$ which contains the arguments of the activation functions $f_{act\text{-}1}$ of hidden layer's neurons is calculated. This matrix arises from the multiplication of the input vector **[x]** by the matrix $\mathbf{[W_1]}$ which contains the synaptic weights of synapses that connect the neurons of input layer with neurons of the hidden layer, and the addition of the corresponding product to the vector which contains the biases of hidden layer's neurons:

$$\begin{bmatrix} A_{11} \\ A_{21} \\ ..... \\ A_{i1} \\ ..... \\ A_{m1} \end{bmatrix} = \begin{bmatrix} w_{11}^{(1)} & w_{12}^{(1)} & w_{13}^{(1)} & ... & w_{1j}^{(1)} & ... & w_{1n}^{(1)} \\ w_{21}^{(1)} & w_{22}^{(1)} & w_{23}^{(1)} & ... & w_{2j}^{(1)} & ... & w_{2n}^{(1)} \\ ..... & .... & .... & ... & .... & ... & ..... \\ w_{i1}^{(1)} & w_{i2}^{(1)} & w_{i3}^{(1)} & ... & w_{ij}^{(1)} & ... & w_{in}^{(1)} \\ ..... & .... & ..... & ... & .... & ... & ..... \\ w_{m1}^{(1)} & w_{m2}^{(1)} & w_{m3}^{(1)} & ... & w_{mj}^{(1)} & ... & w_{mn}^{(1)} \end{bmatrix} \cdot \begin{bmatrix} x_1 \\ x_2 \\ .... \\ x_j \\ .... \\ x_n \end{bmatrix} + \begin{bmatrix} b_{11} \\ b_{21} \\ .... \\ b_{i1} \\ .... \\ b_{m1} \end{bmatrix} \tag{4}$$

The Eq. 4 can be written in a symbolic form as follows:

$$\mathbf{[A_1]} = \left[\mathbf{W_1}\right] \cdot \left[\mathbf{x}\right] + \left[\mathbf{B_1}\right] \tag{5}$$

In the framework of the second step the selected activation function of the hidden layer's neurons is applied to all elements of the matrix **[A1]**. Thus, the matrix **[A2]** arises:

$$\begin{bmatrix} A_{12} \\ A_{22} \\ ..... \\ A_{i2} \\ ..... \\ A_{m2} \end{bmatrix} = \begin{bmatrix} f\left(A_{11}\right) \\ f\left(A_{21}\right) \\ ..... \\ f\left(A_{i1}\right) \\ ..... \\ f\left(A_{m1}\right) \end{bmatrix} \tag{6}$$

The Eq. 6 can be written in a symbolic form as follows:

$$\mathbf{[A_2]} = f_{act-1}\mathbf{[A_1]} \tag{7}$$

The third step concerns the manipulation of the matrix **[A2]** by the vector **[W2]** (which contains the synaptic weights of synapses that connect the neurons of the hidden layer with neuron of the output layer), and the addition of the corresponding product to the bias of output layer's neuron. The result of these operations A_3 is the argument of the activation function f_{act-2} of the output layer's neuron:

$$A_3 = \left[w_{11}^{(2)} \;\; w_{12}^{(2)} \;\; .... \;\; w_{1i}^{(2)} \;\; .... \;\; w_{1m}^{(2)} \right] \cdot \begin{bmatrix} A_{12} \\ A_{22} \\ ..... \\ A_{i2} \\ ..... \\ A_{m2} \end{bmatrix} + b_{12} \tag{8}$$

The Eq. 8 can be written in a symbolic form as follows:

$$A_3 = \mathbf{[W_2]} \cdot \mathbf{[A_2]} + b_{12} \tag{9}$$

Thus, the output o of the MFPN is:

$$o = f_{act-2}\left(A_3\right) = f_{act-2}\left(\mathbf{[W_2]} \cdot \mathbf{[A_2]} + b_{12}\right) \tag{10}$$

The combination of Eqs. (5), (7) and (10) leads to an equation which relates the input vector **[x]** with the output o:

$$o = f_{act-2}\left\{[\mathbf{W_2}]\cdot\left[\, f_{act-1}\left\{[\mathbf{W_1}]\cdot[\mathbf{x}]+[\mathbf{B_1}]\right\}\right]+b_{12}\right\} \tag{11}$$

The combined study of Eq. 3 and Eq. 11, leads to the conclusion that the Eq. 11 is a specific expression of the Eq. 3. Thus, we can write the following MFPN-based expression for the seismic Damage Index:

$$DI = f_{act-2}\left\{[\mathbf{W_2}]\cdot\left[\, f_{act-1}\left\{[\mathbf{W_1}]\cdot[StrP\ SeP\ SoP]^T+[\mathbf{B_1}]\right\}\right]+b_{12}\right\} \tag{12}$$

The above described procedure concerns the calculation of MFPNs' output in case of solution of the FA problem in which the outputs are scalar parameters (i.e. the real value of the DI). However, in case of the problem's formulation as a PR problem the MFPNs' outputs are vectors which include the information about the classification of DI to the pre-defined seismic damage classes (Figure 3). In Figure 7 a MFPN with one hidden layer which is used for the solution of the PR problem with three pre-defined seismic damage classes is presented.

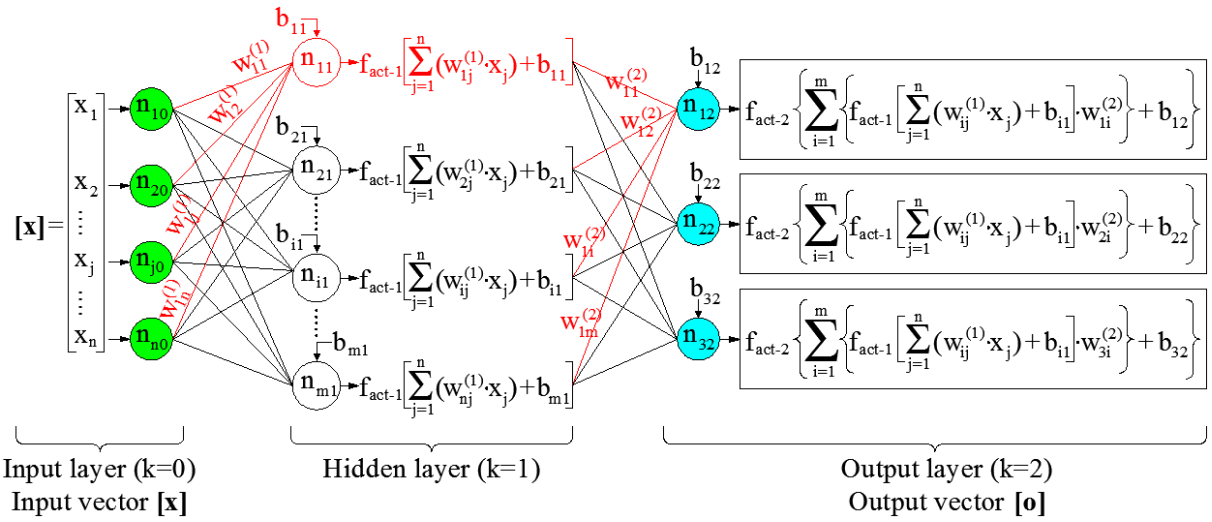

Figure 7: Indicative presentation of the MFPNs' function for the solution of the PR problem (3 damage classes)

Following the procedure which is based on Eqs. (4)-(11) it can be proved that in case of solution of the PR problem using a MFPN with one hidden layer with *m* neurons, *n* input parameters and *p* output parameters (i.e. *p* seismic damage classes), the (*p*x1) output vector (in form which is presented in Figure 3) is:

$$[\mathbf{o}] = \left[f_{act-2}\left\{[\mathbf{W_2}]\cdot\left[\, f_{act-1}\left\{[\mathbf{W_1}]\cdot[StrP\ SeP\ SoP]^T+[\mathbf{B_1}]\right\}\right]+[\mathbf{B_2}]\right\}\right] \tag{13}$$

Where:

$$[\mathbf{B_2}]^T = \left[b_{12}\ \ b_{22}\ \ldots\ b_{t2}\ \ldots\ b_{p2}\right]$$

is the vector of the biases of the output layer's neurons.

Equations similar to Eqs. 12 and 13 arise in case of MFPNs with more than one hidden layer. Certainly, the complexity of these equations is increased as long as the number of hidden layers is also increased. However, even in cases of equations with high complexity the corresponding coding is straightforward provided that the matrices of values of synaptic

weights and biases are available (after the completion of the second stage of the problem's formulation). Thus, no specialized software is required for the performance of the third stage. For this reason, the insertion of a trained MFPN in a system (e.g. [27]) which collects data from earthquakes in near-real time after the event is an easy procedure provided that the stages 1 and 2 have successfully completed at a pro- or a post-seismic period.

Finally, it must be stressed that the dependence of the value of the seismic DI on the values of the synaptic weights and biases of a trained MFPN has as a consequence the dependence of the corresponding equation on the composition of the training data set. For this reason, the form of the MFPN-based equations of DI can be altered if new data for the training of the MFPN are available. This is the case of re-training which gives to MFPN-based equations of DI the versality to improve their prediction ability if new data about the structures' seismic damage are collected.

3 PRACTICAL APPLICATIONS: CLOSED-FORM EQUATIONS FOR THE PREDICTION OF THE SEISMIC DAMAGE OF R/C BUILDINGS

In the current section the procedure that was presented in the section 2.3 for the formulation of closed-form equations which can be used in practice for the seismic vulnerability assessment of R/C buildings is applied. This formulation is based on optimum configured and trained MFPNs which are presented in research works of Morfidis and Kostinakis [8, 15]. More specifically, closed-form expressions which correspond to the solution of the FA and the PR problem will be developed.

3.1 Formulation of closed-form equations for the solution of the FA problem

In case of solution of the FA problem the MFPNs' output is the value of the DI. Thus, the Eq. 12 is valid if MFPNs' with one hidden layer are used. In the reference [15] this type of networks was used for the prediction of R/C buildings' DI, and the parametric investigation which is described in Figure 4 was applied. As DI the Maximum Interstorey Drift Ratio (MIDR) was selected. The utilized input vector [**x**] was comprised of 4 structural parameters [the total height of building H_{tot}, the structural eccentricity e_o, and the ratio of the base shear that is received by r/c walls (if they exist) along two perpendicular directions (axes x and y): n_{vx} and n_{vy}], whereas the number of seismic parameters was mutable. More specifically, the number of the utilized seismic parameters was fluctuated between 1 and 14 in order to detect the optimum configuration of the seismic parameters which led to the most reliable prediction of DI's (MIDR) value. Soil parameters were neglected. A training data-set which was comprised of 1950 samples (extracted by nonlinear time history dynamic analyses of 30 R/C buildings subjected to 65 seismic excitations) was created for the MFPNs' training.

The performance of the parametric investigation (Figure 4) led to the conclusion that the most reliable predictions about the MIDR values for a set of 293 samples (unknown to the trained MFPNs) arise from networks which have as input parameters at least 6 seismic parameters. Furthermore, from the parametric investigation the conclusion that the activation functions logsig and tansig (Figure 5) for the neurons of the hidden layer lead to similar results (i.e. predictions of similar reliability as regards the MIDR values) was extracted. Regarding the activation function of the neuron of the output layer it must be stressed that a linear (lin) function (Figure 5) was used, because this function exports real and not restricted values just as the MIDR values. Thus, the network with the configuration and the input parameters which is presented in Figure 8a is the most efficient between the networks with 6 seismic input parameters (these parameters are: the Housner Intensity (HI), the Peak Ground Acceleration (PGA), the ratio of Peak Ground Velocity to Peak Ground Acceleration (PGV/PGA), the Acceleration Spectrum Intensity (ASI), the Significant Duration (SD) of earthquake and the

Bracketed Duration (BD) of earthquake). This network was selected in the present paper for the presentation of a more specific shape of Eq. 12. Furthermore, for the same reason the network which is presented in Figure 8b with one seismic input parameter (the parameter HI) was selected. This network led to the most reliable predictions of the MIDR value between the networks with one seismic input parameter [15].

Figure 8: Parameters of optimum configured MFPNs which are utilized for the prediction of MIDR values

Introducing the data of networks of Figures 8a and 8b to Eq. 12 the following expressions for the calculation of MIDR values arise respectively:

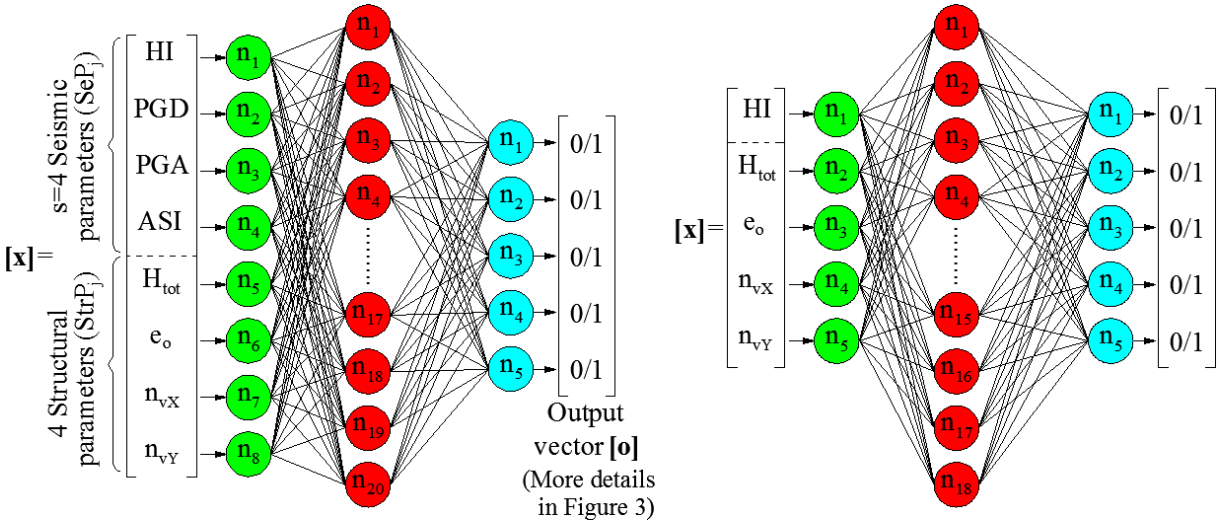
$$MIDR=\sum_{i=1}^{18}\left(\frac{w_{1i}^{(2)}}{1+e^{-\left[\sum_{j=1}^{6}\left(w_{ij}^{(1)}\cdot SeP_j\right)+\sum_{j=7}^{10}\left(w_{ij}^{(1)}\cdot StrP_j\right)+b_{i1}\right]}}\right)+b_{12} \tag{14a}$$

$$MIDR=\sum_{i=1}^{10}\left(\frac{w_{1i}^{(2)}}{1+e^{-\left[w_{i1}^{(1)}\cdot SeP_1+\sum_{j=2}^{5}\left(w_{ij}^{(1)}\cdot StrP_j\right)+b_{i1}\right]}}\right)+b_{12} \tag{14b}$$

For the application of the two above equations, the matrices of the synaptic weights and biases of the neurons of the hidden and the output layer are required. These matrices are extracted from the networks' training procedure. Thus, while the shape of Eqs. 14a and 14b is independent of the utilized training data set, the values of the constants which are introduced to them (i.e. the values of the elements of the matrices of the synaptic weights and biases of the neurons of the hidden and the output layer) are depended on the training data set. In the Appendix A the values of these constants (i.e. the matrices of the synaptic weights and biases of the neurons of the hidden and the output layer) that arise from the parametric investigation which was conducted in the framework of the reference [15] are presented.

3.2 Formulation of closed-form equations for the solution of the PR problem

In case of solution of the PR problem the MFPNs' output is the classification of R/C buildings to pre-defined seismic damage classes on the basis of the selected expression of DI. Thus, in this case the Eq. 13 leads to the problem's solution if MFPNs' with one hidden layer are used. Following the procedure of the parametric investigation which is presented in Figure 4 the optimum configuration of MFPNs with one hidden layer as well as the optimum combination of their seismic input parameters (using also the 4 structural parameters which are referred in subsection 3.1) was extracted by Morfidis and Kostinakis in [8]. In this research work the DI was expressed by means of the MIDR, and five seismic damage classes were predefined. The configuration parameters as well as the optimum combination of the seismic input parameters of the most efficient MFPN are presented in Figure 9a. This network led to the most reliable predictions about the correct classification of 293 samples (unknown to the trained MFPNs) to the five pre-defined seismic damage classes. The network of Figure 9a was selected in the current paper for the presentation of a more specific shape of Eq. 13. Additionally, for the same reason the network which is presented in Figure 9b with one seismic input parameter (the parameter HI) was selected. This network led to the most reliable predictions for the classification of the 293 samples to the correct damage classes, between the networks with one seismic input parameter [8].



(a)

Layer	k=0	k=1	k=2
Neurons	n=8	m=20	p=5
Activation Functions	-	$f_{act\text{-}1}(u)=\frac{1-e^{2u}}{1+e^{2u}}$	$f_{act\text{-}2}(u)=f_{act\text{-}1}(u)$

(b)

Layer	k=0	k=1	k=2
Neurons	n=5	m=18	p=5
Activation Functions	-	$f_{act\text{-}1}(u)=\frac{1-e^{2u}}{1+e^{2u}}$	$f_{act\text{-}2}(u)=f_{act\text{-}1}(u)$

Figure 9: Parameters of optimum configured MFPNs which are used for prediction of the seismic damage class

Introducing the data of MFPNs of Figures 9a, 9b to Eq. 13 the following vectors which give the classification of R/C buildings to 5 damage classes (Figure 3) arise respectively:

$$[\mathbf{o}]^T=\left[o_1 \quad o_2 \quad o_3 \quad o_4 \quad o_5\right]=\left[\frac{e^{2u_1}-1}{e^{2u_1}+1} \quad \cdots\cdots \quad \frac{e^{2u_t}-1}{e^{2u_t}+1} \quad \cdots\cdots \quad \frac{e^{2u_5}-1}{e^{2u_5}+1}\right]$$

$$u_t=b_{t2}+\sum_{i=1}^{20}\left\{\frac{e^{2\cdot\left[b_{i1}+\sum_{j=1}^{4}\left(SeP_j\cdot w_{ij}^{(1)}\right)+\sum_{j=5}^{8}\left(StrP_j\cdot w_{ij}^{(1)}\right)\right]}-1}{e^{2\cdot\left[b_{i1}+\sum_{j=1}^{4}\left(SeP_j\cdot w_{ij}^{(1)}\right)+\sum_{j=5}^{8}\left(StrP_j\cdot w_{ij}^{(1)}\right)\right]}+1}\cdot w_{ti}^{(2)}\right\} \tag{15a}$$

$$[\mathbf{o}]^T = \begin{bmatrix} o_1 & o_2 & o_3 & o_4 & o_5 \end{bmatrix} = \begin{bmatrix} \dfrac{e^{2u_1}-1}{e^{2u_1}+1} & \cdots\cdots & \dfrac{e^{2u_t}-1}{e^{2u_t}+1} & \cdots\cdots & \dfrac{e^{2u_5}-1}{e^{2u_5}+1} \end{bmatrix}$$

$$u_t = b_{t2} + \sum_{i=1}^{18} \left\{ \frac{e^{2\cdot\left[b_{i1}+\left(SeP_1\cdot w_{i1}^{(1)}\right)+\sum_{j=2}^{5}\left(StrP_j\cdot w_{ij}^{(1)}\right)\right]}-1}{e^{2\cdot\left[b_{i1}+\left(SeP_1\cdot w_{i1}^{(1)}\right)+\sum_{j=2}^{5}\left(StrP_j\cdot w_{ij}^{(1)}\right)\right]}+1} \cdot w_{ti}^{(2)} \right\} \tag{15b}$$

For the application of the two above equations, the matrices of the synaptic weights and biases of the neurons of the hidden and the output layer are required. These matrices are extracted from the networks' training procedure. Thus, while the shape of Eqs. 15a and 15b is independent of the utilized training data set, the values of the constants which are introduced to them (i.e. the values of the elements of the matrices of the synaptic weights and biases of the neurons of the hidden and the output layer) are depended on the training data set. In the Appendix B the values of these constants (i.e. the matrices of the synaptic weights and biases of the neurons of the hidden and the output layer) that arise from the parametric investigation which was conducted in the framework of the reference [8] are presented.

4 CONCLUSIONS

In the current paper the procedure of implementation of Artificial Neural Networks (ANN) for the solution of the problem of R/C buildings' seismic vulnerability assessment is presented. For the scope of this presentation Multilayer Feedforward Perceptron Networks (MFPN) were utilized because their ability in the successful approach to solution of the studied problem has been proven in many relevant research studies. More specifically, the present paper is focused on the presentation of the practical point of view of MFPNs' implementation i.e. on the presentation of the procedure for the generation of the required data which are used for their training (pre-training stage) and their function after the training (simulation of MFPNs).

The procedure for R/C buildings' seismic vulnerability assessment using ANNs is comprised of three stages. At the first stage a preliminary selection of the parameters which describe the mathematical formulation of the problem is made. These parameters are the input parameters (i.e. the parameters that affect the R/C buildings' seismic response) and the output parameters (i.e. the parameters which quantitative the R/C buildings' seismic damage). This preliminary selection of the input and output parameters must be made taking into consideration the ANNs' features. Thus, at the first stage the collaboration between a civil engineer (which is expert in earthquake engineering) and an ANN expert can lead to parameters' selection which will ensure against possible malfunctions of ANNs. In the framework of the first stage the data-set for the ANNs' training is also generated. This generation must be compatible to the preliminary selection of the problems' parameters. At the second stage decisions must be made as regards the type of the ANNs and the formulation of the problem in terms compatible to the ANNs' function. The most common selection for the solution of the problem of R/C buildings' seismic vulnerability assessment is the MFPNs, whereas as regards the formulation of the problem the two possible options are the formulation as Function Approximation (FA) problem and the formulation as Pattern Recognition (PR) problem. Finally, at the second stage the training procedure and the parametric investigations for the optimum configuration of the selected ANNs, as well as for the optimum combination of their input parameters, must be performed. The target of these investigations is the optimization of the ANNs' generalization ability (i.e. the ability of ANNs to extract reliable results in case in which the values of the input parameters were no utilized for their training). At the second

stage the ANN expert possesses central role because the deep knowledge of the networks' function aids to the avoidance of problems which are related to low generalization ability (overfitting). The third stage concerns the implementation of the optimum configured and trained networks for the prediction of the seismic damage of R/C buildings in near-real time after a seismic event. This implementation is based on a mathematical procedure which is familiar to the civil engineers since it consists of matrix operations.

In the framework of the current paper the mathematical formulation of the third stage (i.e. the function of the trained MFPNs) is presented in details. This presentation leads to the conclusion that the utilization of the trained networks is based on a procedure which can be separated from their training procedure. Thus, the implementation of MFPNs in the research for the improvement of the R/C buildings' seismic vulnerability assessment methods is a very promising option provided that the civil engineers will gain knowledge about the basic principles of ANNs' function. This knowledge is a kind of a "common language" which can be used by civil engineers in order to efficiently collaborate with ANN experts for the implementation of neural networks in the earthquake engineering research field. In this sense, the present paper attempts to give a description not only of the overall procedure for the solution of the problem of R/C buildings' seismic vulnerability assessment, but also to describe the mathematical framework of the trained MFPNs' function.

Finally, in the present paper was proven that in case of implementation of MFPNs with one hidden layer it is possible to develop closed-form expressions which lead to the problem's solution either it is formulated as FA problem or it is formulated as PR problem. This ability results from the matrix formulation of the trained MFPNs' function. Furthermore, this ability is a proof of the fact that the algorithm which simulates the function of trained MFPNs can be inserted (independently of the procedure which was performed for their training and the computational tools which were used for this procedure) to systems which are dedicated to the recording and processing of data that arise from strong seismic motions in near-real time after the seismic events. Thus, the expansion of the services of these systems in the extraction of data for the seismic damage of a large amount of R/C buildings is possible. The aforementioned conclusion illustrates once again the great importance of understanding of the need for separation of procedure for the solution of the problem of R/C buildings' seismic vulnerability assessment in three stages, since the first two must be integrated in pre- or post-seismic periods (because they are time consuming) while the third can be performed instantly after the seismic event. Another one (but not insignificant) contribution of the present paper is the notation that the simulation of the trained MFPN (and consequently the matrix equations which are used for this purpose) is depended on the utilized training data set. This means that the ability of ANNs to predict reliably the damage state of R/C buildings can be improved if new data are available for their re-training.
